Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

O.5.3 Bay-Delta

O.5.3.1 Delta X2

CalSim 3 modeling indicates that the estimated X2 position under Alternative 2 when compared to the No Action Alternative is similar across all months and water year types. (Table O-198 through Table O-201). Table O-198 through Table O-201 indicate that most landward X2 positions are expected during the summer to fall months in the critically dry years and the most seaward positions are expected during the winter to early spring months in wet years for both alternatives. For the full simulation period, there were either no or small differences in X2 position between all Alternative 2 phases and the No Action Alternative for all months.

O.5.3.2 Delta Exports

CalSim 3 modeling indicates that the total exports of the SWP and CVP under Alternative 2 when compared to the No Action Alternative generally increases in May and decreases in June for all phases and most water year types. For the phases without VAs, exports also increase during April. During the dry and critically dry water years type exports tend to decrease in the winter for all phases. Also during drier years, the phases that included VA agreements tend to have increased exports in the summer whereas for the phases without VA agreements exports tend to decrease during the same season (Table O-202 through Table O-205). For the full simulation period, total exports when compared to the No Action Alternative increase from April and May for the phases without VAs and increase only in May for the phases with VAs. For phases without VAs, exports decrease in June, while for the phases with VAs, exports decrease in March and June.

O.5.3.3 Delta Outflow

CalSim3 modeling indicates that delta outflow under Alternative 2 compared to the No Action Alternative was generally similar except for April or May, depending on the phase (Table O 206 through Table O 209). Some water year types are expected to see flow increases in winter and spring months, as well as June seeing flow increases in certain year types depending on the phase. Flow decreases are expected in some summer and spring months depending on water year type and phase, with May, July, and August having notable decreases in most phases of Alternative 2 during wet, above normal, and below normal water years.

O.5.3.4 Delta OMR

CalSim 3 modeling indicates that average Old and Middle River (OMR) combined flows under Alternative 2 when compared to the No Action Alternative are dissimilar, varying significantly (more than 5% difference) from flow values under the No Action Alternative (Table O 210 through Table O 213) for many months of the year. Values are expected to see increases in all water year types and in all phases for the month of May, as well as for the month of April for phases of Alternative 2 without VA. June is expected to see decreases for almost all water year types across all phases. The period January through June sees the greatest difference between the phases of Alternative 2 and the No Action Alternative. January and February are expected to see decreases in dry and critically dry water years for all phases of Alternative 2. Phases with VA are expected to see flow decreases for most water year types in March.

O.5.3.5 Sacramento River flow at Rio Vista

CalSim 3 modeling indicates that average flows in the Sacramento River at Rio Vista under the four phases of Alternative 2 compared to the No Action Alternative are similar, except in April under Alternative 2 without TUCP with Systemwide VA (Table O-214 through Table O-217). Critically dry water years are expected to see mostly increases from March through July. Under Alternative 2 without TUCP with systemwide VA April is expected to see significant (greater than 5%) flow increases for almost all water year types. Across all four phases of Alternative 2 there are few significant flow decreases scattered across water year types. Average flows across all phases are not significantly different than those under the No Action Alternative, with the exception of April under Alternative 2 without TUCP with Systemwide VA.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

O.5.4 Clear Creek

O.5.4.1 Clear Creek below Whiskeytown Dam

CalSim 3 modeling suggests that average monthly flow below Whiskeytown Dam under the four phases of Alternative 2 compared to the No Action Alternative are expected to generally decrease June through October and February, and generally increase November through January and March through May (Table O-218 through Table O-221). The largest decrease under Alternative 2 compared to the No Action Alternative is expected June through August of all water year types, except critically dry year types when it would be expected in June and September. The largest increases under Alternative 2 compared to the No Action Alternative are expected in December, January, March, and May all water year types, except critically dry year types when it would be expected in January, February, and May.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

O.5.5 Lower American River

O.5.5.1 Folsom Reservoir Storage

CalSim 3 modeling suggests that monthly average volume of Folsom Reservoir storage under the four phases of Alternative 2 compared to the No Action Alternative are expected to be similar to the projections of the No Action Alternative (Table O-222 through Table O-225). During the implementation of Alternative 2 With TUCP Without VA, simulations show there may be an increase in volume March through December of critically dry type years. Under all other phases of Alternative 2, simulations project decreases in volume April through October of critically dry water types and in some phases August and September of dry water year types; all other water year types have the similar projections as the No Action Alternative (less than 5% difference).

O.5.5.2 Lower American River below Nimbus Dam

CalSim 3 modeling suggests that monthly average flow below Nimbus Dam under the four phases of Alternative 2 compared to the No Action Alternative are not expected to be similar (Table O-226 through Table O-229). During implementation of Alternative 2 With TUCP Without VA, simulations show there may be an increase in flows in December and July (up to 31%) while decreases are expected August through November (up to 9%) and Jan through April (up to 13%) of critically dry type years ; other water year types would be similar or the same as the No Action Alternative the majority of the year (less than 5% difference). Under all other phases of Alternative 2, simulations show there may be an increase in flows in March, April, and June while decreases are expected July through February and May of critically dry type years.

O.5.5.3 Lower American River at H Street

CalSim 3 modeling suggests that monthly average flow in the lower American River at H street under the four phases of Alternative 2 compared to the No Action Alternative are expected to be generally the same or similar projections of the No Action Alternative, except under Alternative 2 With TUCP With Systemwide VAs when there is an increase for averaged April projections (Table O-230 through Table O-233). During implementation of Alternative 2 With TUCP Without VA, simulations show there may be an increase in flows in December and July while decreases are expected in June, August through November, and February through April of critically dry type years; all other year types would be similar or the same as the No Action Alternative most months out of the year. Under all other phases of Alternative 2, simulations show there may be an increase in flows in March, April, and June while decreases are expected July through February and May of critically dry type years; all other year types would be similar or the same as the No Action Alternative most months out of the year.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

O.5.6 Stanislaus River

O.5.6.1 Stanislaus River below Goodwin Dam

CalSim 3 modeling suggests monthly average flows (throughout the full simulation period) below Goodwin Dam under all phases of Alternative 2 compared to the No Action Alternative are higher December, February, July, and August and lower in April compared to the No Action Alternative (Table O-234 through Table O-237). The greatest increases under the four phases of Alternative 2 are expected in June through August of critically dry water year types. The greatest decreases under the four phases of Alternative 2 are expected in January of an above normal water year type.

O.5.6.2 Stanislaus River at Mouth

CalSim 3 modeling suggests monthly average flows (throughout the full simulation period) at the mouth of the Stanislaus under the four phases of Alternative 2 compared to the No Action Alternative are higher in August and September, while all other months would be the same or similar to the No Action Alternative (Table O-238 through Table O-241). All phases of Alternative 2 compared to No Action Alternative have the largest projected flow increases in June through September of critically dry water year types. All phases of Alternative 2 compared to No Action Alternative have the largest projected flow decreases in January of above normal water year types and May of below normal water year types.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

O.5.7 San Joaquin River

O.5.7.1 San Joaquin River at Vernalis

CalSim 3 modeling indicates that average flow in the San Joaquin River at Vernalis under the four phases of Alternative 2 compared to No Action Alternative are similar (less than 5% difference) October through May and occasionally increase in critically dry, above normal, and below normal water year types June through September (Table O-242 through Table O-245). The largest increases under the four phases of Alternative 2 compared to the No Action Alternative are expected in July and August of critically dry water year types. There are no anticipated decreases greater than 5% difference under the four phases of Alternative 2 compared to the No Action Alternative. Throughout the full simulation period, average flows are similar (less than 5% difference) under the four phases of Alternative 2 from October through September.

All	1	-2	17	-14	17	-3	-37	-41	-18	13	41	27

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold magenta font indicates a greater than 5% reduction in flow.

O.5.8 Sacramento River Winter-run Chinook Salmon ESU

O.5.8.1 Sacramento River

Spawning and Egg/Alevin Incubation

Winter-run Chinook salmon adults spawn from April through August with peak spawning between May and July (Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). Fry emergence occurs up to 3 months after eggs are spawned, so effects of flow and water temperature on winter-run eggs and alevins may occur from May through November, but primarily occur during June through October.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under the four phases of Alternative 2, differences in mean spawning WUA are increases in wet, above normal, below normal, and dry water year types, and decreases in critically dry water year types when compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between the four phases of Alternative 2 and the No Action Alternative is a 3% increase in dry water years under Alternative 2 Without TUCP Systemwide VA. The largest reduction in estimated spawning habitat is a -0.7% decrease in critically dry water year types under Alternative 2 Without TUCP with Delta VA.

The monthly median values of spawning WUA under the four phases of Alternative 2 are similar to the No Action Alternative in May, June, and August but are slightly higher in July (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are relatively similar in May, June, and August. In July, the median values of spawning WUA are lower across all alternatives when compared to the other months of spawning. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in July than in the other three months (Table O-182 through Table O-185). This results in lower spawning WUA results because the winter-run spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) peak at relatively low flows (approximately 5,000 to 10,000 cfs).

The results of suitable habitat availability analysis using the SIT LCM habitat models indicate that spawning habitat for winter-run Chinook salmon in the upper Sacramento River may not be a limiting factor under both the No Action Alternative and the four phases of Alternative 2 (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The results of the two spawning habitat analyses based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 may have a minor increase (less than 3.1%) and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative, and that spawning habitat may not be a limiting factor for winter-run Chinook salmon in the mainstem upper Sacramento River.

Redd Dewatering Analysis

All phases of Alternative 2 show a general increase in mean redd dewatering potential from wet to dry water year types, but the differences are modest (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). During winter and spring, the principal incubation periods for the other Chinook salmon races and steelhead, redd dewatering is generally higher during wet water years because periodic storms and high runoff, which increase flow fluctuations, tend to be more frequent in such water years. However, winter-run spawning and incubation occur during late spring through early fall, when flows tend to be less variable. The minimum rates of redd dewatering for winter-run during wet years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*) may result from increased stability in project operations related to greater reservoir storage levels. The mean redd dewatering potential for all water year types except critically dry years is lower under the four phases of Alternative 2 than under the No Action Alternative (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). The largest reduction for all water year types is 26.2% under Alternative 2 With TUCP Without VA in critically dry water years. Note that this reduction, which is computed as the relative (percent) difference between the means of 13.9% and 10.3%, corresponds to an absolute difference of 3.6%. For the other phases of Alternative 2, redd dewatering in critically dry water years is higher than that under No Action Alternative, including an increase of 11.8% for Alternative 2 Without TUCP Without VA.

Overall, the results indicate that redd dewatering potential under the four phases of Alternative 2 would be lower than under the No Action Alternative.

SIT Winter-run Chinook Salmon Lifecycle Model: Spawner Abundance

- In the CVPIA Winter-run Chinook Salmon SIT Lifecycle Model, mean winter-run Chinook salmon spawner abundance in **Alternative 2 With TUCP Without VA** is similar to the abundance under the No Action Alternative. The largest abundance increase between Alternative 2 With TUCP Without VA and the No Action Alternative abundance was 1.8% during above normal water years, and the largest decrease was 1.6% during critically dry years. The annual abundance change between all water year types was similar between Alternative 2 With TUCP Without VA and the No Action Alternative.

- In the other three phases of Alternative 2 (**Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VA**), annual abundance is slightly lower (0.1%) than the No Action Alternative, and the total abundance change in these three phases of Alternative 2 was slightly lower (from no change to -2.1%) compared to the No Action Alternative. Of these three phases, the greatest increase in annual spawner abundance was 4.8% between Alternative 2 Without TUCP With Systemwide VA and the No Action Alternative during wet water year types. The largest decrease annual in spawner abundance was 4.8% between Alternative 2 Without TUCP With Systemwide VA and the No Action Alternative during critically dry water year types.

Overall, all phases of Alternative 2 and the No Action Alternative had mean annual decreases in spawner abundance, with annual increases during dry and wet years and decreases during critically dry and above normal water year types.

IOS: Egg Survival

- Under **Alternative 2 With TUCP Without VA**, in critically dry water years, mean predicted winter-run Chinook salmon egg survival is 29.87% higher than when compared to the No Action Alternative (Attachment F.5, *Interactive Object-oriented Simulation Model*). Alternative 2 With TUCP Without VA reflects a change of 0.21 mean proportion predicted to survive when compared to the No Action Alternative. The change in mean predicted winter-run Chinook salmon egg survival in all other water year types less than or equal to 0.000. Alternative 2 With TUCP Without VA provides a substantial benefit to predicted survival of winter-run Chinook salmon eggs during critically dry water years when compared to the No Action Alternative.

- Under **Alternative 2 Without TUCP Without VA**, in critically dry water years, mean predicted winter-run Chinook salmon egg survival is 2.23% lower than when compared to the No Action Alternative. Alternative 2 With TUCP Without VA reflects a change of -0.02 mean proportion predicted to survive when compared to the No Action Alternative. The change in mean predicted winter-run Chinook salmon egg survival in all water year types less than or equal to 0.000.

- Under **Alternative 2 Without TUCP Delta VA**, in critically dry water years, mean predicted winter-run Chinook salmon egg survival is 3.63% lower than when compared to the No Action Alternative. Alternative 2 Without TUCP Delta VA reflects a change of -0.025 mean proportion predicted to survive when compared to the No Action Alternative. The change in mean predicted winter-run Chinook salmon egg survival in all other water year types less than or equal to 0.000.

- Under **Alternative 2 Without TUCP Systemwide VA**, in critically dry water years, mean predicted winter-run Chinook salmon egg survival is 4.94% lower than when compared to the No Action Alternative. However, the change in mean predicted winter-run Chinook salmon egg survival in all water year types less than or equal to 0.000.

OBAN: Spawner Abundance and Probability of Quasi-Extinction

Predicted spawner abundance under all four phases of Alternative 2 was greater under the No Action Alternative (46% greater under Alternative 2 With TUCP Without VA to 80% greater under Alternative 2 Without TUCP With Delta VA), and spawner abundance is greater than one (Table O-30).

Probability of quasi-extinction under all four phases of Alternative 2 was less under the No Action Alternative (0.97 under phases of Alternative 2, Table O-30).

IOS: Female Escapement

- Under **Alternative 2 With TUCP Without VA** in all water year types, mean annual predicted female escapement of winter-run Chinook salmon is 6.3-10.84% higher than when compared to the No Action Alternative. The change in mean annual predicted female escapement of in all water year types ranging from 167 to 398 individuals. Alternative 2 With TUCP Without VA provides a slightly positive impact to mean annual predicted female escapement of winter-run Chinook salmon when compared to the No Action Alternative.

- Under **Alternative 2 Without TUCP Without VA** in all water year types, mean annual predicted female escapement of winter-run Chinook salmon is 2.06-5.41% higher than when compared to the No Action Alternative. The change in mean annual predicted female escapement of in all water year types ranging from 43-197 individuals. Alternative 2 Without TUCP Without VA provides a slightly positive impact to mean annual predicted female escapement of winter-run Chinook salmon when compared to the No Action Alternative.

- Under **Alternative 2 Without TUCP Delta VA** in all water year types except critical and wet, mean annual predicted female escapement of winter-run Chinook salmon is 0.12-1.85% higher than when compared to the No Action Alternative. The change in mean annual predicted female escapement of in all water year types ranging from -57-68 individuals.

- Under **Alternative 2 Without TUCP Systemwide VA** in all water year types except above normal, critical and wet, mean annual predicted female Escapement of winter-run Chinook salmon is 1.44-1.79% higher than when compared to the No Action Alternative. The change in mean annual predicted female escapement of in all water year types ranging from -15-53 individuals.

<u>OBAN: Egg to Fry Survival</u>

Egg to fry survival under all four phases of Alternative 2 was greater under the No Action Alternative (0.016 – 0.027 difference, Addendum to Attachment F.6, Table O-30).

<u>Temperature Dependent Mortality</u>

- Under **Alternative 2 Without TUCP Without VA** for the Anderson model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.096, 0.464, and 0.001 (all less than the No Action, up to 67% less in a above normal water year type). Under **Alternative 2 With TUCP Without VA** for the Anderson model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.073, 0.337, and 0.001 (all less than the No Action Alternative, up to 67% less in a wet water year type).

- Under **Alternative 2 Without TUCP Delta VA** for the Anderson model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.099, 0.472, and 0.001 (all less than the No Action Alternative, up to 67% less in a wet water year type). Under **Alternative 2 Without TUCP Systemwide VA** for the Anderson model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.102, 0.503, and 0.002 (all less than the No Action Alternative, up to 33% less in a wet water year type). Expected proportional TDM values for the Anderson model were less under all four phases of Alternative 2 than No Action Alternative for all water year types except wet.

- Under **Alternative 2 Without TUCP Without VA** for the Martin model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.123, 0.561, and 0.007 (all less

than the No Action Alternative, up to 61% less in a wet water year type). Under **Alternative 2 With TUCP Without VA** for the Martin model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.093, 0.427, and 0.008 (all less than the No Action Alternative, up to 50% less in a wet water year type). Under **Alternative 2 Without TUCP Delta VA** for the Martin model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.124, 0.552, and 0.009 (all less than the No Action Alternative, up to 44% less in a wet water year type).

- Under **Alternative 2 Without TUCP Systemwide VA** for the Martin model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.128, 0.6, and 0.008 (all less than the No Action Alternative, up to 50% less in a wet water year type). Expected proportional TDM values for the Martin model were less under all four phases of Alternative 2 than No Action Alternative for all water year types.

Relative to the Anderson model, expected proportional TDM values were higher for the Martin model for all four phases of Alternative 2 across all water year types except a below normal water year type. For the Anderson and Martin models, greater than 80% of modeled water years resulted in expected proportional TDM values less than 0.125. For critically dry water year types, at least 12.5% of modeled water years resulted in expected proportional TDM values less than 0.5 for all phases except Alt2woTUCPAllVA mixed. For above normal and wet water year types only, expected proportional TDM never exceeded 0.125 (Attachment L.2, *Egg-to-fry Survival and Temperature Dependent Mortality*). A decrease in TDM under all four phases of Alternative 2 compared with the No Action Alternative would generally have a beneficial effect on incubating winter-run Chinook salmon eggs, with some potential for negligible and adverse effects in some water year types.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during January through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 16 for Keswick Dam and Table 18 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during January through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 20 for Keswick Dam and Table 22 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during May through November are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 24 for Keswick Dam and Table 26 for below Clear Creek.

Results for the three analyses are summarized in Table O-31. Table O-31, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 42.1°F to 55°F range for spawning initiation, there were five to nine month-water year type combinations (14.3% to 25.7%) with favorable results, depending on location, and one month-water year type combinations (2.9% of total combinations during the period) with unfavorable results below Keswick Dam (Table O-31). For the 59.9°F adult pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were two to five combinations (5.7% to 14.3%) with favorable results, depending on location, and two to three combinations (5.7% to 8.6%) with unfavorable results. These results suggest that there would be mostly no effect or positive biologically meaningful water temperature-related effects of Alternative 2 With TUCP Without VA on winter-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River, although there were some negligible positive and negative effects on egg incubation and fry emergence.
- Under **Alternative 2 Without TUCP Without VA** for the 42.1°F to 55°F range for spawning initiation, there were five to 10 month-water year type combinations (14.3% to 28.6%) with favorable results, depending on location, one combination (2.9%) with unfavorable effects below Keswick Dam, and no combinations (0% of total combinations during the period) with unfavorable results below Clear Creek (Table O-31). For the 59.9°F adult pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were four to six combinations (11.4% to 17.1%) with favorable results, depending on location, and one to two combinations (2.9% to 5.7%, respectively) with unfavorable results below Keswick Dam and below Clear Creek, respectively. These results suggest that there would be mostly no effect or positive biologically meaningful temperature-related effects of Alternative 2 Without TUCP Without VA on winter-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River, although there were some negligible negative effects on spawning initiation and egg incubation and fry emergence.
- Under **Alternative 2 Without TUCP Delta VA** for the 42.1°F to 55°F range for spawning initiation, there were five to nine month-water year type combinations (14.3% to 25.7%) with favorable results, depending on location, and no combinations (0% of total combinations during the period) with unfavorable results (Table O-31). For the 59.9°F adult pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were two to five combinations (5.7% to 14.3%) with favorable results, depending on location, and two combinations (5.7%) with unfavorable results at both locations. These results suggest that there would be mostly no effect or positive biologically meaningful temperature-related effects of Alternative 2 Without TUCP Delta VA on winter-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River, although there were some negligible negative effects on egg incubation and fry emergence below Clear Creek.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 42.1°F to 55°F range for spawning initiation, there were five to 10 month-water year type combinations (14.3% to 28.6%) with favorable results, depending on location, and no combinations (0% of total combinations during the period) with unfavorable results (Table O-31). For the 59.9°F adult pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were two to five combinations (5.7% to 14.3%) with favorable results, depending on location, and two combinations (5.7%) with unfavorable results below Keswick Dam and below Clear Creek. These results suggest that there would be mostly no effect or positive biologically meaningful temperature-related effects of Alternative 2 Without TUCP Systemwide VAs on winter-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River, although there were some negligible negative effects on egg incubation and fry emergence at both locations.

Overall, the four phases of Alternative 2 would have similar water temperature-related effects to winter-run Chinook salmon spawning and egg/incubation in the Sacramento River relative to the No Action Alternative. All four phases would have mostly no effect or positive effects with some negligible negative effects specific to egg incubation and fry emergence (Table O-31).

Summary

Alternative 2 relative to the No Action Alternative is expected to have possible minor beneficial to minor adverse impacts on spawning and redd dewatering habitat, possible beneficial and adverse impacts on spawner abundance, no impact on female escapement other than a minimal beneficial impact under Alternative 2 With TUCP Without VA, and a beneficial impact on the probability of quasi-extinction due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have possible slight to substantial beneficial impacts using four secondary biological models due to differences in water temperature: IOS, Anderson and Martin (TDM), and OBAN. Alternative 2 and the No Action Alternative using a coarser analysis is expected to have mostly no or beneficial impact on spawning and egg/alevin incubation with negligible adverse impacts specific to egg incubation and fry emergence.

Juvenile Rearing and Emigration

Winter-run Chinook salmon juveniles rear in the Sacramento River primarily from late summer to late winter and emigrate from the river to the Delta beginning in November (see Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). The proportion of juveniles surviving to emigrate to the Delta depends largely on habitat conditions, including flow and water temperature. Inundated floodplain habitat has been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001a, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under the four phases of Alternative 2, mean fry rearing WUA generally decreases in wet, above normal, below normal water year types and fluctuate depending on the phase in dry and critically dry water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between the four phases of Alternative 2 and the No Action Alternative is a 2.2% increase in critically dry water year types under Alternative 2 With TUCP Without VA. The largest reduction in estimated fry rearing habitat is a 0.8% decrease in below normal water year types between Alternative 2 Without TUCP with Systemwide VA and the No Action Alternative.

The monthly median values of fry rearing WUA under the four phases of Alternative 2 are similar to the No Action Alternative throughout the fry rearing period of August through December (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Fry rearing WUA median values for all the modeled alternatives are relatively similar across September through December but slightly lower in August. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in August in comparison to the other fry rearing months, with an average flow of 9,548 to 9,640 cfs under the four phases of Alternative 2 (Table O-182 through Table O-185). Segment 5, which has the highest distribution of winter-run spawning, has decreased WUA values when flows are between 5,000 and 10,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), leading to lower WUA values during higher flows in August. Winter-run Chinook salmon fry rearing WUA starts to increase at flows above 10,000 cfs, and peak at flows around 30,000 cfs. These peak rearing flows are not expected to occur under the No Action Alternative or the four phases of Alternative 2 during the fry rearing period in the Sacramento River below Keswick Dam. Winter-run Chinook salmon is the only Sacramento River salmonid race or species that shows this pattern.

The results of the winter-run Chinook salmon fry rearing habitat analysis suggest that the four phases of Alternative 2 may have a minor (less than 2.5%) increase and/or decrease in estimated fry rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Juvenile Rearing Habitat Analyses

Under the four phases of Alternative 2, mean juvenile rearing WUA increases depending on the phase in critically dry water year types but generally decreases in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated juvenile rearing habitat between Alternative 2 and the No Action Alternative is a 0.7% increase in critically dry water years under Alternative 2 With TUCP Without VA. The largest reduction in estimated juvenile rearing habitat is a 0.5 % decrease in below normal water year types under Alternative 2 Without TUCP Systemwide VA.

The monthly median value of juvenile rearing WUA under the four phases of Alternative 2 are similar to the No Action Alternative October through January (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Juvenile rearing WUA median values for all the modeled alternatives are relatively similar October through January. The CalSim 3 simulated average

flows in the Sacramento River below Keswick Dam are higher in January compared to the other months of juvenile rearing (Table O-182 through Table O-185). Segment 5 has decreased WUA values when flows are between 5,000 and 10,000 cfs but the WUA values do not change as drastically with juvenile rearing in comparison to fry rearing (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Winter-run Chinook salmon juvenile rearing WUA values start increasing at flows above 15,000 cfs, and peak at flows around 30,000 cfs. These peak rearing flows are not expected to occur under the No Action Alternative or the four phases of Alternative 2 during the juvenile rearing period in the Sacramento River below Keswick Dam.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for winter-run Chinook salmon in the upper Sacramento River under the four phases of Alternative 2 have a -0.4% to -2% difference between the months of October through January in comparison to the No Action Alternative (Attachment O.2*, CVPIA SIT LCM Habitat Estimates*). No monthly average increases to habitat are expected October through January under the phases of Alternative 2, and the greatest reductions in estimated habitat are expected in January under Alternative 2 With and without TUCP Without VA compared to the No Action Alternative.

The results of the two winter-run Chinook salmon juvenile rearing habitat analyses suggest that the four phases of Alternative 2 may have a negligible (less than 1%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and potentially no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles who primarily are stronger swimmers. The four phases or Alternative 2 show little difference in stranding of winter-run Chinook salmon juveniles between critically dry and dry water year types or between below normal and above normal water year types, but show much lower stranding for wet water year types (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Winter-run fry rearing occurs primarily during summer through early fall, when flows tend to be less variable. The minimum rates of stranding for winter-run Chinook salmon fry during wet years may result from increased stability in project operations related to greater reservoir storage levels. Median stranding of all alternatives gradually increases from July through October (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). All four phases of Alternative 2 have substantially lower juvenile stranding of winter-run Chinook salmon fry than the No Action Alternative (12% to 15% lower) in below normal water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). All phases of Alternative 2 also have large reductions (8.4% to 9.7%) in critically dry water years, except Alternative 2 Without TUCP Without VA, which has the only notable increase (3.5%) of the four phases and water year types. Overall, winter-run juvenile stranding for fry is generally lower under the four phases of Alternative 2 in comparison to the No Action Alternative, including some substantial reduction. Overall, juvenile stranding for winter-run Chinook salmon fry is lower under the four phases of Alternative 2 than under the No Action Alternative.

Survival and Travel Time: XT and Flow Survival Threshold Models

Del Rosario et al. (2013) found that ≥5% catch at the Knights Landing Rotary Screw Trap (RST) coincided with first day of flow of at least ~14,100 cfs (400 cm) at Wilkins Slough. Acoustically tagged fish released at locations in the upper Sacramento River under varying hydrological conditions are used to estimate survival probabilities and travel times rates. As fish migrate downstream towards the Delta, individuals encounter a range of environmental conditions and transition from reaches with unidirectional flow (upstream) to reaches with bidirectional flow (tidally driven, downstream). Outmigrating juveniles may be exposed to predation and as inflow declines and tidal influence moves upstream, travel time and distance may increase leading to higher exposure to predators. Michel et al. (2021) identified an optimal flow threshold condition favorable for outmigration for juvenile Chinook salmon, 10,712 cfs, which could provide an additional 2.7-fold increase in survival. Travel and survival rates of Chinook salmon in upper Sacramento River reaches are strongly correlated (Notch et al. 2020). Authors hypothesize one mechanism for the threshold is faster outmigration rates due to higher flows decrease exposure to possible predation (Michel et al. 2021).

Differences in daily flows (Upper Sacramento River Daily Operations Model, USRDOM) under all four phases of Alternative 2 compared with the No Action Alternative may have effects on juvenile Chinook salmon's travel time and survival probabilities in the Upper Sacramento River. These possible differences were evaluated using several quantitative models (XT and Flow Survival Threshold) and results from all four phases are presented below by phase.

- **Alternative 2 Without TUCP Without VA**
    - Mean daily Sacramento River flows at Keswick Dam and mean daily Sacramento River flows below Wilkins Slough (March 15th to June 15th) are equal to or greater under Alternative 2 Without TUCP Without VA compared with the No Action Alternative except during May and June at Keswick Dam in critically dry water year types when flows are less under Alternative 2 Without TUCP Without VA compared with the No Action Alternative (Attachment J.4, *XT Model*; Attachment J.5, *Flow Threshold Salmon Survival Model*). These two quantitative models provide results that demonstrate the flows under Alternative 2 Without TUCP Without VA compared with the No Action Alternative could increase survival and decrease travel time for outmigrating juvenile Chinook salmon on the Sacramento River limiting juveniles' exposure to predation and poor environmental conditions.
    - Annual mean survival probability under Alternative 2 Without TUCP Without VA was greater than annual mean survival probability under the No Action Alternative in all water year types (5% to 6% greater in wet and above normal water year types to up to 95% greater in critically dry water year types). This increase, particularly in critically dry water year types of up to 95%, would have a substantial beneficial effect on outmigrating juvenile Chinook salmon. Under both scenarios, average annual mean survival probability was highest during the wet water year types and decreased as the water year type became drier. (Attachment J.5, *Flow Threshold Salmon Survival Model*).

- Mean survival probability for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 2 Without TUCP Without VA was equal to or greater than mean survival probability under the No Action Alternative (equal in wet, above normal, and below normal water year types and to up to 3% greater in dry and critically dry water year types). This increase of up to 3% would have a minimal effect on outmigrating juvenile Chinook salmon. (Attachment J.4, *XT Model*).

- Mean travel time (days) for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 2 Without TUCP Without VA was both greater than and less than mean travel time under the No Action Alternative (up to 2% greater during below normal and above normal water year types to the terminus of both reaches, 5% less during the dry water year type, and up to 10% less under critically dry water year type). This decrease of up to 10% would have a beneficial effect on outmigrating juvenile Chinook salmon, particularly dependent on predator presence and environmental conditions (e.g., water temperature) (Attachment J.4, *XT Model*).

- **Alternative 2 With TUCP Without VA**

  - Mean daily Sacramento River flows at Keswick Dam and mean daily Sacramento River flows below Wilkins Slough (March 15th to June 15th) are equal to or greater under Alternative 2 With TUCP Without VA compared with the No Action Alternative except during May and June at Keswick Dam in critically dry water year types when flows are less under Alternative 2 With TUCP Without VA compared with the No Action Alternative (Attachment J.4, *XT Model*; Attachment J.5, *Flow Threshold Salmon Survival Model*). These two quantitative models provide results that demonstrate the flows under Alternative 2 With TUCP Without VA compared with the No Action Alternative could increase survival and decrease travel time for outmigrating juvenile Chinook salmon on the Sacramento River limiting juveniles' exposure to predation and poor environmental conditions.

  - Annual mean survival probability under Alternative 2 With TUCP Without VA was greater than annual mean survival probability under the No Action Alternative in all water year types (5% to 6% greater in wet and above normal water year types to up to 22% greater in dry and critically dry water year types). This increase, particularly in dry and critically dry water year types of up to 22%, would have a large beneficial effect on outmigrating juvenile Chinook salmon. Under both scenarios, average annual mean survival probability was highest during the wet water year types and decreased as the water year type became drier. (Attachment J.5, *Flow Threshold Salmon Survival Model*).

- Mean survival probability for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 2 With TUCP Without VA was equal to or greater than mean survival probability under the No Action Alternative (equal in wet, above normal, below normal, and critically dry water year types and to up to 1% greater in dry water year types). This increase of up to 1% would have no effect on outmigrating juvenile Chinook salmon. (Attachment J.4, *XT Model*).

- Mean travel time (days) for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 2 With TUCP Without VA was both greater than and less than mean travel time under the No Action Alternative (equal in wet water years to the terminus of both reaches, up to 5% less in dry water year type to the terminus of both reaches, and up to 1% greater to the terminus of both reaches in Critically Dry water years). This decrease of up to 5% may have a beneficial effect on outmigrating juvenile Chinook salmon, particularly dependent on predator presence and environmental conditions (e.g., water temperature) (Attachment J.4, *XT Model*).

- **Alternative 2 Without TUCP Delta VA**

  - Mean daily Sacramento River flows at Keswick Dam and mean daily Sacramento River flows below Wilkins Slough (March 15th to June 15th) are equal to or greater under Alternative 2 Without TUCP Delta VA compared with the No Action Alternative except during May and June at Keswick Dam in critically dry water year types when flows are less under Alternative 2 Without TUCP Delta VA compared with the No Action Alternative (Attachment J.4, *XT Model*; Attachment J.5, *Flow Threshold Salmon Survival Model*). These two quantitative models provide results that demonstrate the flows under Alternative 2 Without TUCP Delta VA compared with the No Action Alternative could increase survival and decrease travel time for outmigrating juvenile Chinook salmon on the Sacramento River limiting juveniles' exposure to predation and poor environmental conditions.

  - Annual mean survival probability under Alternative 2 Without TUCP Delta VA was greater than annual mean survival probability under the No Action Alternative in wet, above normal, and critically dry water year types (4% greater in wet water year types and up to 70% greater in critically dry water year types). Annual mean survival probability under Alternative 2 Without TUCP Delta VA was less than annual mean survival probability under the No Action Alternative in below normal and dry water year types (up to 1.5% in dry water year types). The decrease would have a minimal adverse effect while the increase of up to 70% would have substantial beneficial effect on outmigrating juvenile Chinook salmon. Under both scenarios, average annual mean survival probability was highest during the wet water year types and decreased as the water year type became drier. (Attachment J.5, *Flow Threshold Salmon Survival Model*).

- Mean survival probability for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 2 Without TUCP Delta VA was equal to or greater than mean survival probability under the No Action Alternative (equal in wet, above normal, below normal, and dry water year types and to up to 1% greater in critically dry water year types). This increase of up to 1% would have no effect on outmigrating juvenile Chinook salmon. (Attachment J.4, *XT Model*).

- Mean travel time (days) for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 2 Without TUCP Delta VA was both greater than and less than mean travel time under the No Action Alternative (up to 1% greater under above normal and dry water year types to the terminus of both reaches and 3% less under critically dry water year type to the terminus of both reaches). This decrease of up to 3% may have a minor beneficial effect on outmigrating juvenile winter-run Chinook salmon, particularly dependent on predator presence and environmental conditions (e.g., water temperature) (Attachment J.4, *XT Model*).

- **Alternative 2 Without TUCP Systemwide VA**

  - Mean daily Sacramento River flows at Keswick Dam and mean daily Sacramento River flows below Wilkins Slough (March 15th to June 15th) are equal to or greater under Alternative 2 Without TUCP Systemwide VA compared with the No Action Alternative except during May and June at Keswick Dam in dry and critically dry water year types when flows are less under Alternative 2 Without TUCP Systemwide VA compared with the No Action Alternative (Attachment J.4, *XT Model*; Attachment J.5, *Flow Threshold Salmon Survival Model*). These two quantitative models provide results that demonstrate the flows under Alternative 2 Without TUCP Systemwide VA compared with the No Action Alternative could increase survival and decrease travel time for outmigrating juvenile Chinook salmon on the Sacramento River limiting juveniles' exposure to predation and poor environmental conditions.

  - Annual mean survival probability under Alternative 2 Without TUCP Systemwide VA was greater than annual mean survival probability under the No Action Alternative in all water year types (1% greater in dry water year types and up to 71% greater in critically dry water year types). The increase would have a minimal to substantial beneficial effect, depending on water year type, on outmigrating juvenile Chinook salmon. Under both scenarios, average annual mean survival probability was highest during the wet water year types and decreased as the water year type became drier. (Attachment J.5, *Flow Threshold Salmon Survival Model*).

- Mean survival probability for outmigrating winter-run Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 2 Without TUCP Systemwide VA was equal to or greater than mean survival probability under the No Action Alternative (equal in wet, above normal, and dry water year types and to up to 1% greater in below normal and critically dry water year types). This increase of up to 1% would have no effect on outmigrating juvenile winter-run Chinook salmon. (Attachment J.4, *XT Model*).

- Mean travel time (days) for outmigrating winter-run Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 2 Without TUCP Systemwide VA was both greater than and less than mean travel time under the No Action Alternative (2% greater under dry water year type to the terminus of both reaches and up to 4% less under below normal water year type to the terminus of both reaches). This decrease of 4% may have a beneficial effect on outmigrating juvenile winter-run Chinook salmon, particularly dependent on predator presence and environmental conditions (e.g., water temperature) (Attachment J.4, *XT Model*).

<u>Winter-run Juvenile Production Index (JPI)</u>

- Under **Alternative 2 With TUCP Without VA**, the mean predicted JPI is generally lower than No Action Alternative, ranging from 4.45% higher in 2005 to 29.91% lower in 2014. JPI under Alternative 2 With TUCP Delta VA was lower than the No Action Alternative in all but four years analyzed (2002-2021). These results suggest that in most years the benefits to juvenile winter-run Chinook salmon under Alternative 2 With TUCP Without VA were adverse and in a smaller number of years the effects are not noticeably different when compared to the No Action Alternative. Overall, Alternative 2 With TUCP Without VA is expected to have a negative effect on the number of juveniles produced annually when compared to the No Action Alternative.

- Under **Alternative 2 Without TUCP Without VA**, the mean predicted JPI is generally lower than No Action Alternative, ranging from 10.95% higher in 2015 to 53.08% lower in 2014. JPI under Alternative 2 Without TUCP without Delta VA was lower than the No Action Alternative in all but four years analyzed. These results suggest that in most years the benefits to juvenile winter-run Chinook salmon under Alternative 2 Without TUCP Without VA were adverse and in a smaller number of years the effects are not noticeably different when compared to the No Action Alternative. Overall, Alternative 2 Without TUCP Without VA is expected to have a negative effect on the number of juveniles produced annually when compared to the No Action Alternative.

- Under **Alternative 2 Without TUCP Delta VA**, the mean predicted JPI is generally higher than No Action Alternative, ranging from 272.52% higher in 2014 to 85.00% lower in 2017. JPI under Alternative 2 Without TUCP Delta VA was higher than the No Action Alternative in half of the years analyzed. These results suggest that in half of the years the benefits to juvenile winter-run Chinook salmon under Alternative 2 Without

TUCP Delta VA were adverse and in half the number of years the effects are beneficial when compared to the No Action Alternative due to three years showing very large increases, 272.52% (2014), 100.63% (2020), and 108.00% (2015). Overall, Alternative 2 Without TUCP Delta VA is expected to have a positive effect on the number of juveniles produced annually when compared to the No Action Alternative.

- Under **Alternative 2 Without TUCP Systemwide VA**, the mean predicted JPI is generally lower than No Action Alternative, ranging from 3.60% higher in 2005 to 30.68% lower in 2014. JPI under Alternative 2 Without TUCP Systemwide VA was lower than the No Action Alternative in all but one year analyzed. These results suggest that in most years the impacts to juvenile winter-run Chinook salmon under Alternative 2 Without TUCP Systemwide VA were adverse and in one year the impacts are not noticeably different when compared to the No Action Alternative. Overall, Alternative 2 Without TUCP Systemwide VA is expected to have a negative impact on the number of juveniles produced annually when compared to the No Action Alternative.

<u>IOS: Fry Survival and Juvenile River Migration Survival</u>

- Under **Alternative 2 With TUCP Without VA**, in critically dry water years, mean predicted winter-run Chinook salmon fry survival is 21.92% higher than when compared to the No Action Alternative. Alternative 2 With TUCP Without VA reflects a change of 0.142 mean predicted winter-run Chinook salmon fry survival when compared to the No Action Alternative (0.65 under the No Action Alternative to 0.794 under Alternative 2 With TUCP Without VA). The change in mean predicted winter-run Chinook salmon fry survival in all other water year types was less than or equal to ± 0.002. Alternative 2 With TUCP Without VA provides a substantial benefit to predicted survival of winter-run Chinook salmon fry during critically dry water years when compared to the No Action Alternative.

- Under **Alternative 2 Without TUCP Without VA**, in critically dry water years, mean predicted winter-run Chinook salmon fry survival is 5.89% lower than when compared to the No Action Alternative. However, the change in mean predicted winter-run Chinook salmon fry survival in all water year types was less than or equal to ± 0.00. There is not a substantial difference in predicted survival of winter-run Chinook salmon eggs between Alternative 2 Without TUCP Without VA and the No Action Alternative.

- Under **Alternative 2 Without TUCP Delta VA**, in critically dry water years, mean predicted winter-run Chinook salmon fry survival is 6.47% lower than when compared to the No Action Alternative. However, the change in mean predicted winter-run Chinook salmon fry survival in all water year types less than or equal to ± 0.04. There is not a substantial difference in predicted survival of winter-run Chinook salmon fry between Alternative 2 Without TUCP Delta VA, and the No Action Alternative.

- Under **Alternative 2 Without TUCP Systemwide VA**, in critically dry water years, mean predicted winter-run Chinook salmon fry survival is 9.25% lower than when compared to the No Action Alternative. Alternative 2 Without TUCP Systemwide VA reflects a change of -0.061 mean predicted winter-run Chinook salmon fry survival when compared to the No Action Alternative (0.652 under the No Action Alternative to 0.591 under Alternative 2 Without TUCP Systemwide VA). The change in mean predicted

winter-run Chinook salmon fry survival in all other water year was types less than or equal to ± 0.002. There is a slightly negative effect on survival of winter-run Chinook salmon fry between Alternative 2 Without TUCP Systemwide VA and the No Action Alternative.

- Under **Alternative 2 With TUCP Without VA**, in all water years, mean predicted river migration survival of winter-run Chinook salmon juveniles is higher than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to 0.002. There is not a substantial difference in predicted river migration survival of winter-run Chinook salmon juveniles between Alternative 2 With TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Without VA**, in all water years except Below Normal, mean predicted river migration survival of winter-run Chinook salmon juveniles is higher than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to ± 0.002. There is not a substantial difference in predicted river migration survival of winter-run Chinook salmon juveniles between Alternative 2 Without TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Delta VA**, in all water years except Below Normal, mean predicted river migration survival of winter-run Chinook salmon juveniles is higher than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to ± 0.001. There is not a substantial difference in predicted river migration survival of winter-run Chinook salmon juveniles between Alternative 2 Without TUCP Delta VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Systemwide VA**, in all water years, mean predicted river migration survival of winter-run Chinook salmon juveniles is higher than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to 0.001. There is not a substantial difference in predicted river migration survival of winter-run Chinook salmon juveniles between Alternative 2 Without TUCP Systemwide VA and the No Action Alternative.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 28 for Keswick Dam, Table 30 for Red Bluff Diversion Dam, and Table 32 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 34 for Keswick Dam, Table 36 for Red Bluff Diversion Dam, and Table 38 for Hamilton City.

Results for the two analyses are summarized in Table O-32. Table O-32, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 55.4°F to 68°F optimum temperature range analysis, there were zero to two month-water year type combinations with favorable results (0% to 6.7% of total combinations during the period), depending on location, and zero to two combinations (0% to 6.7%) with unfavorable results (Table O-32). For the 75.2°F upper incipient lethal temperature under Alternative 2 With TUCP Without VA, there would be no favorable or unfavorable results (0%) at any location. These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on water temperature conditions for winter-run Chinook salmon juvenile rearing and emigration in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 55.4°F to 68°F optimum temperature range analysis, there were zero to two month-water year type combinations with favorable results (0% to 6.7% of total combinations during the period), depending on location, and one to two combinations (3.3% to 6.7%) with unfavorable results (Table O-32). For the 75.2°F upper incipient lethal temperature under Alternative 2 Without TUCP Without VA, there would be no favorable or unfavorable results (0%) at any location. These results suggest that there would be negligible positive and negative effects of Alternative 2 Without TUCP Without VA on water temperature conditions for winter-run Chinook salmon juvenile rearing and emigration in the Sacramento River.
- Under **Alternative 2 Without TUCP Delta VA** for the 55.4°F to 68°F optimum temperature range analysis, there were one to four month-water year type combinations with favorable results (3.3% to 13.3% of total combinations during the period), depending on location, and zero to one combinations (0% to 3.3%) with unfavorable results (Table O-32). For the 75.2°F upper incipient lethal temperature Alternative 2 Without TUCP Delta VA, there would be no favorable or unfavorable results (0%) at any location. These results suggest that there would be positive effects of Alternative 2 Without TUCP Delta VA on water temperature conditions for winter-run Chinook salmon juvenile rearing and emigration in the Sacramento River.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 55.4°F to 68°F optimum water temperature range analysis, there were zero to two month-water year type combinations with favorable results (0% to 6.7% of total combinations during the period), depending on location, and zero to three combinations (0% to 10.0%) with unfavorable results (Table O-32). For the 75.2°F upper incipient lethal temperature under Alternative 2 Without TUCP Systemwide VAs, there would be no favorable or unfavorable results (0%) at any location. These results suggest that there would be positive and negative effects of Alternative 2 Without TUCP Systemwide VAs on water temperature conditions for winter-run Chinook salmon juvenile rearing and emigration in the Sacramento River.

Overall, Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP Systemwide VAs would have similar positive and negative water temperature-related effects to winter-run Chinook salmon juvenile rearing and outmigration in the Sacramento River (Table O-32). Alternative 2 Without TUCP Delta VA would have positive water temperature-related effects to winter-run Chinook salmon juvenile rearing and outmigration in the Sacramento River below Keswick Dam.

Summary

Alternative 2 and the No Action Alternative is expected to have possible minor beneficial to minor adverse impacts on fry and juvenile rearing habitat, a beneficial impact on fry stranding, and an adverse impact on the juvenile production index due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have possible little to minor adverse to beneficial impact on fry survival except under Alternative 2 With TUCP Without VA which is expected to have a substantial beneficial impact in critically dry water year type due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have a minimal to substantial beneficial impact, depending on water year type, on individuals' survival and travel time in the upper Sacramento River while Alternative 2 Without TUCP Delta VA could have a possible minimal adverse impact due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have beneficial and adverse water temperature-related impact on juvenile rearing and emigration.

Adult Upstream Migration and Holding

Winter-run Chinook salmon adults enter the Sacramento River from the Delta and make their way to the upper Sacramento River, beginning as early as December through late spring (May/June) (see Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). They hold in the upper River within 10 to 15 miles of Keswick Dam until they are ready to spawn, which may extend through August (Windell et al. 2017). Most of the run passes Red Bluff Diversion Dam from January to May with the peak in mid-March (Hallock and Fisher 1985).

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

CalSim 3 Flows

Releases from Shasta Reservoir during November through early May may be reduced to conserve water for the May through October winter-run Chinook salmon and spring-run Chinook salmon spawning and incubation periods, resulting in reduced flow in the middle Sacramento River. Lower flow in the Sacramento River relative to flow from the lower Yolo and Sutter bypasses and agricultural drains may affect navigation cues and straying of Winter-run adults into canals and behind weirs, increasing their stranding risk. Once the adults have migrated upstream on the Sacramento River, they reach holding habitat in the upper Sacramento River. In the upper Sacramento River, they are more directly affected by Shasta Reservoir and Keswick Dam operations designed to preserve cold water for the winter-run Chinook salmon and spring-run Chinook salmon spawning and incubation periods.

- **Alternative 2 With TUCP Without VA:** During the December through May/June period of adult winter-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 With TUCP Without VA at Sacramento River below Red Bluff Diversion Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative, except in an increase in January of a critically dry water year type (up to 7% greater) and a decrease in May of dry and critically dry water year types (up to 13% less) at all three locations. At Sacramento River below Keswick Dam flows under Alternative 2 With TUCP Without VA would range from less than to greater than flows under the No Action Alternative, depending on month and water year type, generally greater than flows under the No Action Alternative December through February and generally similar to or less than flows under the No Action Alternative in March through June particularly in critically dry water year types. Flows at Hamilton City and Wilkins Slough under Alternative 2 With TUCP Without VA would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 2 With TUCP Without VA would be greater than 5,300 cfs at Wilkins Slough and greater than 7,500 cfs at Hamilton City (Table O-186, Table O-182, Table O-190, Table O-194).
- **Alternative 2 Without TUCP Without VA:** During the December through May/June period of adult winter-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Without VA at Sacramento River below Red Bluff Diversion Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative, except an increase in April (up to 21% in a critical water year type) and a decrease in May and June (up to 6% less in a critically dry critically dry year type). At Sacramento River below Keswick Dam flows under Alternative 2 Without TUCP Without VA would range from less than to greater than flows under the No Action Alternative, depending on month and water year type, generally greater than flows under the No Action Alternative December through April (up to 25% greater in April of a critically dry water year type) and generally similar to or less than flows under the No Action Alternative May and June (up to 10% lower in May of a critically dry water year type). Flows at Hamilton City and Wilkins Slough under Alternative 2 Without TUCP Without VA would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 2 Without TUCP Without VA would be greater than 5,300 cfs at Wilkins Slough and greater than 7,500 cfs at Hamilton City (Table O-187, Table O-183, Table O-191, Table O-195).
- **Alternative 2 Without TUCP Delta VA:** During the December through May/June period of adult winter-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Delta VA at Sacramento River below Red Bluff Diversion Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative, except an increase in April (up to 25% greater in a critically dry water year type) and a decrease in May and June (up to 6% less in dry and critically dry water year types). At Sacramento River below Keswick Dam flows under Alternative 2 Without TUCP Delta VA would range from less than to greater than flows under the No Action Alternative, depending on month and water year type, generally greater than flows under the No Action Alternative December through April (up to 30%

greater in April of a critically dry water year type) and generally similar to or less that flows under the No Action Alternative in May and June (up to 10% less in May of a critically dry water year type). Flows at Hamilton City and Wilkins Slough under Alternative 2 Without TUCP Delta VA would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 2 Without TUCP Delta VA would be greater than 5,300 cfs at Wilkins Slough and greater than 7,550 cfs at Hamilton City (Table O-188, Table O-184, Table O-192, Table O-196.

- **Alternative 2 Without TUCP Systemwide VA:** During the December through May/June period of adult winter-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Delta VA at Sacramento River below Red Bluff Diversion, below Keswick Dam, and at Wilkins Slough would range from less than to greater than flows under Alternative 2 Without TUCP Delta VA, depending on month and water year type, generally greater than flows under the No Action Alternative December through April (up to 23% greater in a critically dry water year type) and generally lower than flows under the No Action Alternative May and June (up to 8% lower in an above normal water year type). At Hamilton City flows under Alternative 2 Without TUCP Delta VA would generally be similar to flows under the No Action Alternative except April of most water year types (up to 29% greater) and June of most water year types (up to 8% less). Flows at Hamilton City and Wilkins Slough under Alternative 2 Without TUCP Systemwide VA would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 2 Without TUCP Systemwide VA would be greater than 5,100 cfs at Wilkins Slough and greater than 7,550 cfs at Hamilton City (Table O-189, Table O-185, Table O-193, Table O-197).

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range for winter-run Chinook salmon adult migration and holding are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 4 for Keswick Dam, Table 6 for Red Bluff Diversion Dam, and Table 8 for Hamilton City.

Results are summarized in Table O-33. Table O-33, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA**, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at all locations (Table O-33). These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on water temperature conditions for winter-run Chinook salmon adult migrants in the Sacramento River.

- Under **Alternative 2 Without TUCP Without VA**, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at all locations (Table O-33). These results suggest that there would be negligible effects of Alternative 2 Without TUCP Without VA on water temperature conditions for winter-run Chinook salmon adult migrants in the Sacramento River.

- Under **Alternative 2 Without TUCP Delta VA**, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at all locations (Table O-33). These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on water temperature conditions for winter-run Chinook salmon adult migrants in the Sacramento River.
- Under **Alternative 2 Without TUCP Systemwide VAs**, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at all locations, except Hamilton City, at which there was one combination (3.3%) with an unfavorable result (Table O-33). These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on water temperature conditions for winter-run Chinook salmon adult migrants in the Sacramento River.

Overall, all four phases would have negligible water temperature-related effects to winter-run Chinook salmon adult upstream migration and holding in the Sacramento River (Table O-33).

Summary

Alternative 2 relative to the No Action Alternative is expected to an adverse to beneficial flow-related impact, depending on location and month, generally a possible beneficial impact early in the season (December and January) and an adverse impact later in the season (May and June) on upstream migrating and holding adult winter-run Chinook salmon, average monthly flows at Hamilton City and Wilkins Slough are high enough to allow upstream passage. Alternative 2 and the No Action Alternative is expected to have a negligible water temperature-related impact on upstream migrating and holding adult winter-run Chinook salmon.

O.5.8.2 Bay-Delta

Juvenile Rearing and Emigration

Rearing winter-run Chinook salmon are present in the Delta from October to May (see Section O.1.9.1.1, *Winter-run Chinook Salmon, Sacramento River ESU*). Key habitat attributes relevant to seasonal operations in the Delta include out-migration cues and entrainment risk. Juveniles enter the Delta primarily during December through April and most emigrate past Chipps Island by the end of April but can potentially exit as late as May (Brandes and McLain 2001; del Rosario et al. 2013). A critical assumption in these analyses is LAD criteria used to identify juveniles (vs genetic ID) are sufficient to represent juveniles' downstream migration patterns.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to adversely affect juvenile Chinook salmon in two distinct ways: (1) "near-field" mortality associated with entrainment to the export facilities: and (2) "far-field" mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team's (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver-linkage-outcome (DLO) framework for specifying how water

project operations (the "driver") can influence juvenile salmonid behavior (the "linkage") and potentially cause changes in survival or routing (the "outcome"). The SST concluded altered "Channel Velocity" and altered "Flow Direction" were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O-13 provides a simplified conceptual model of the DLO defined by the CAMT SST.

Differences in hydrology in the Delta under the four phases of Alternative 2 compared with the No Action Alternative may have effects on flow routing into junctions and the hydrodynamic footprint of the export facilities. These possible differences were evaluated using two quantitative models which estimate the spatial extent of influence of exports under CVP and SWP diversions and estimate the proportion of flow entering a Delta junction: Zone of Influence and Flow into Junctions.

Zone of Influence

For a full description of Zone of Influence model background, see *O.4.8.2 Sacramento River Winter-run Chinook Salmon ESU, Juvenile Rearing and Emigration in the Bay-Delta*. The following section covers discussion of differences in spatial extent of export influence presented as a direction between the four phases of Alternative 2 and the No Action Alternative. For a detailed explanation of methods and analyses, see Attachment I.3, *Delta Export Zone of Influence Analysis*.

The proportional overlap of two phases of Alternative 2 without VA (Alternative 2 With TUCP Without VA and without TUCP Without VA, pumping vs no pumping) was less than the proportional overlap of the No Action Alternative (pumping vs no pumping) at Turner Cut under all OMR bins (Attachment I.3, *Delta Export Zone of Influence Analysis*). The proportional overlap of the two phases of Alternative 2 with VA (Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA, pumping vs no pumping) was less than the proportional overlap of the No Action Alternative (pumping vs no pumping) at Turner Cut under all OMR bins except -3,500. The proportional overlap of all four phases of Alternative 2 (pumping vs no pumping) was less than the proportional overlap of the No Action Alternative (pumping vs no pumping) at Jersey Point under -2,000 and -5,000 OMR groupings; the same under < -5,500; and more under -3,500. The proportion al overlap of all four phases of Alternative 2 (pumping vs no pumping) was more than the proportional overlap of the No Action Alternative (pumping vs no pumping) at Old River at Middle River under all OMR bins except under the most positive OMR bins (-2,000).

With incremental decreases in OMR under all four phases of Alternative 2 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping.

Flow into Junctions

- Under **Alternative 2 With TUCP Without VA** in all OMR bins except -3,500, predicted proportion of flow entering the Central Valley Project (CVP) is less than the No Action Alternative. Changes in predicted proportion of flow entering the CVP when OMR was <-5,500, -5,000, and -3,500 were less than ± 0.03, indicating a negligible difference from the No Action Alternative. However, when OMR was -2,000 the change in predicted

proportion of flow into CVP was -0.069, indicating that slightly less flow will be routed into CVP under Alternative 2 With TUCP Without VA than when compared to the No Action Alternative.

- Under **Alternative 2 Without TUCP Without VA** in all OMR bins except -3,500, predicted proportion of flow entering the CVP is less than the No Action Alternative. Changes in predicted proportion of flow entering the CVP when OMR was <-5,500, -5,000, and -3,500 were less than ± 0.027, indicating a negligible difference from the No Action Alternative. However, when OMR was -2,000 the change in predicted proportion of flow into CVP was -0.0631, indicating that slightly less flow will be routed into CVP under Alternative 2 Without TUCP Without VA than when compared to the No Action Alternative.
- Under **Alternative 2 Without TUCP Delta VA** in all OMR bins except -3,500, predicted proportion of flow entering the CVP is less than the No Action Alternative. However, changes in predicted proportion of flow entering the CVP in all OMR bins was less than ± 0.0467, indicating a negligible difference between Alternative 2 Without TUCP Delta VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Systemwide VA** in all OMR bins except -3,500, predicted proportion of flow entering the CVP is less than the No Action Alternative. However, changes in predicted proportion of flow entering the CVP in all OMR bins was less than ± 0.0425, indicating a negligible difference between Alternative 2 Without TUCP Systemwide VA and the No Action Alternative.
- Under **Alternative 2 With TUCP Without VA** in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the HOR is less than the No Action Alternative. In OMR bins -3,500 and -5,000 predicted proportion of flow into the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.008, indicating a negligible difference between Alternative 2 With TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Without VA** in all OMR bins except <-5,500, predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.007, indicating a negligible difference between Alternative 2 Without TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Delta VA** in all OMR bins except <-5,500, predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.008, indicating a negligible difference between Alternative 2 Without TUCP Delta VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Systemwide VA** in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the HOR is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.008, indicating a negligible

difference between Alternative 2 Without TUCP Systemwide VA and the No Action Alternative.

Summary

Alternative 2 relative to the No Action Alternative is expected to influence flow into the HOR and CVP junctions due to differences in water management. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on flow into the HOR while differences at CVP are best described between phases of Alternative 2 with and without VA due to differences in flow: Alternative 2 With TUCP Without VA and without TUCP Without VA are expected to have slightly less flow into CVP at OMR -2,000 and Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA are expected to have negligible impacts on flow into CVP. Impacts of pumping under Alternative 2 relative to the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Winter-run Chinook Salmon

Differences in monthly flows on the Sacramento River under the four phases of Alternative 2 compared with the No Action Alternative may have effects on entrainment probability of juvenile Chinook salmon. These possible differences were evaluated using three quantitative models: Salvage Density, the Negative Binomial model, Coded Wire Tag Salvage.

Salvage Density and Negative Binomial

- **Alternative 2 With TUCP Without VAs**
    - Predictions from the salvage density model for genetic and LAD winter-run Chinook salmon include mean monthly total exports. Predictions from the negative binomial loss model for LAD winter-run Chinook salmon include mean monthly total exports and mean monthly San Joaquin River flows at Vernalis. Table O-202 shows modeled mean monthly total exports at SWP and CVP and Table O-242 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between the four phases of Alternative 2 and the No Action Alternative.
    - Predicted average monthly loss of genetic winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through May of all water year types. Alternative 2 With TUCP Without VAs was greater than or equal to predicted average monthly loss under the No Action Alternative for all water year types, up to 10% greater in critically dry water year types (Table O-36). Predicted average monthly loss of genetic winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for the wet and above normal water year types, up to 6% greater, for both wet and above normal water year types. Predicted salvage for LAD winter-run Chinook salmon was predicted to be lower for the below normal, dry and critically dry water year types, with up to 8% lower for the critically dry

water year types (Table O-37). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly loss of LAD winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through April of all water year types Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for some water year types, up to 2% greater in a above normal water year type, and up to 23% less for wet water year types compared to the No Action Alternative (Table O-34). Predicted average monthly loss of LAD winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for the wet and above normal water year types, up to 5% greater, for the above normal water year types. Predicted salvage for LAD winter-run Chinook salmon was predicted to be lower for the below normal, dry and critically dry water year types, with up to 7% lower for the critically dry water year types (Table O-35). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of LAD winter-run Chinook salmon at the Delta fish collection facilities for the months of December through April under Alternative 2 With TUCP Without VAs was greater than predicted average monthly salvage under the No Action Alternative for wet, above normal, and below normal water year types with up to 20% greater in a wet water year type. Predicted loss for genetic and LAD winter-run Chinook salmon under Alternative 2 With TUCP Without VAs compared to the No Action Alternative was less for dry and critically dry water year types, with up to an 8% reduction in loss for the critically dry water year types (Table O-38). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.

- **Alternative 2 Without TUCP Without VAs**

  - Mean monthly total exports at SWP and CVP are equal to or greater under Alternative 2 Without TUCP Without VAs compared with the No Action Alternative for the full simulation period and all months December through May. Table O-203 shows modeled mean monthly total exports at SWP and CVP and Table O-243 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between the four phases of Alternative 2 and the No Action Alternative.

  - Predicted average monthly loss of genetic winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through May of all water year types. Alternative 2 Without TUCP Without VAs was less than or equal to predicted average monthly loss under the No Action Alternative for all water year types, except for the above normal water year types with an increase of 1%. Predicted loss from Alternative 2 Without TUCP Without VAs compared to the No Action Alternative was equal or lower for genetic winter-run Chinook salmon

with up to a 12% reduction in predicted loss for critically dry water year types (Table O-36). Predicted average monthly loss of genetic winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for the wet, above normal, and below normal water year types, with up to a 5% increase for above normal water year types. Predicted salvage for LAD winter-run Chinook salmon was predicted to be lower for the dry and critically dry water year types, with up to 8% lower for the critically dry water year types (Table O-37). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly loss of LAD winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through April of all water year types Alternative 2 Without TUCP Without VAs was less than or equal to predicted average monthly loss under the No Action Alternative for all water year types, except for the above normal water year types with an increase of 1%. Predicted loss from Alternative 2 Without TUCP Without VAs compared to the No Action Alternative was equal or lower for LAD winter-run Chinook salmon with up to a 12% reduction in predicted loss for critically dry water year types (Table O-34). Predicted average monthly loss of LAD winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for the wet, above normal, and below normal water year types, with up to a 5% increase for the above normal water year types. Predicted salvage for LAD winter-run Chinook salmon was predicted to be lower for the dry and critically dry water year types, with up to a 8% reduction in predicted loss for the critically dry water year types (Table O-35). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of LAD winter-run Chinook salmon at the Delta fish collection facilities for the months of December through April under Alternative 2 Without TUCP Without VAs was greater than predicted average monthly salvage under the No Action Alternative for wet, above normal, and below normal water year types with up to 20% greater in a wet water year type. Predicted loss for genetic and LAD winter-run Chinook salmon under Alternative 2 Without TUCP Without VA compared to the No Action Alternative was less for dry and critically dry water year types, with up to a 14% reduction in loss for the critically dry water year types (Table O-38). For detailed information on average monthly salvage by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- **Alternative 2 Without TUCP With Delta VAs**

- Mean monthly total exports at SWP and CVP had a wide range under Alternative 2 Without TUCP with Delta VAs compared with the No Action Alternative for the full simulation period and all months December through May. Table O-204 shows modeled mean monthly total exports at SWP and CVP and Table O-244 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between the four phases of Alternative 2 and the No Action Alternative.

- Predicted average monthly loss of genetic winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through May of all water year types. Alternative 2 Without TUCP with Delta VAs was less than predicted average monthly loss under the No Action Alternative for all water year types, except for the wet water year types with an increase of 4%. Predicted loss from Alternative 2 Without TUCP with Delta VAs compared to the No Action Alternative was lower for genetic winter-run Chinook salmon for all other water year types with up to a 23% reduction in predicted loss for below normal water year types (Table O-36). Predicted average monthly loss of genetic winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April for Alternative 2 Without TUCP with Delta VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types except the wet water year type, with up to a 2% increase. Predicted salvage for genetic winter-run Chinook salmon was predicted to be lower for Alternative 2 Without TUCP with Delta VAs for all other water year types, with up to 24% lower for the critically dry water year types (Table O-37). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly loss of LAD winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through April of all water year types. Alternative 2 Without TUCP with Delta VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types. Predicted loss of LAD winter-run Chinook salmon from Alternative 2 Without TUCP with Delta VAs compared to the No Action Alternative had a reduction of up to 16% for dry water year types (Table O-34). Predicted average monthly loss of LAD winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 2 Without TUCP with Delta VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types except for wet water year types, which had a 1% increase. Predicted salvage for LAD winter-run Chinook salmon at Jones under Alternative 2 Without TUCP with Delta VAs compared to the No Action Alternative was predicted to be lower for all other water year types, with up to a 16% reduction in predicted loss for the below normal water year types (Table O-35). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of LAD winter-run Chinook salmon at the Delta fish collection facilities for the months of December through April under Alternative 2 Without TUCP with Delta VAs was lower than predicted average monthly salvage under the No Action Alternative for all water year types except for wet water year types which had an increase of 13%. Predicted loss for genetic and LAD winter-run Chinook salmon under Alternative 2 Without TUCP with Delta VAs compared to the No Action Alternative was less for all other water year types, with up to a 25% reduction in loss for the below normal water year types (Table O-38). For detailed information on average monthly salvage by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- **Alternative 2 Without TUCP Systemwide VAs**

  - Mean monthly total exports at SWP and CVP had a wide range under Alternative 2 Without TUCP Systemwide VAs compared with the No Action Alternative for the full simulation period and all months December through May. Table O-205 shows modeled mean monthly total exports at SWP and CVP and Table O-245 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between the four phases of Alternative 2 and the No Action Alternative.

  - Predicted average monthly loss of genetic winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through May of all water year types. Alternative 2 Without TUCP Systemwide VAs was less than predicted average monthly loss under the No Action Alternative for above normal, below normal, and dry water year types with up to a 21% reduction in predicted loss for below normal water year types. Predicted loss from Alternative 2 Without TUCP Systemwide VAs compared to the No Action Alternative for genetic winter-run Chinook salmon for wet and critically dry water year types increased with up to a 3% increase in predicted loss for wet water year types (Table O-36). Predicted average monthly loss of genetic winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April for Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types except the wet water year type, which had up to a 3% increase. Predicted salvage for genetic winter-run Chinook salmon was predicted to be lower for Alternative 2 Without TUCP Systemwide VAs for all other water year types, with up to 26% lower for the below normal water year types (Table O-37). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

  - Predicted average monthly loss of LAD winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through April of all water year types. Alternative 2 Without TUCP Systemwide VAs was lower or equal to predicted average monthly loss under the No Action Alternative for all water year types. Predicted loss of LAD winter-run Chinook salmon from Alternative 2 Without TUCP Systemwide VAs compared to the No Action Alternative had a reduction of up to 14% for dry water year types (Table O-34). Predicted average

monthly loss of LAD winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types except for wet water year types, which had a 2% increase. Predicted salvage for LAD winter-run Chinook salmon at Jones under Alternative 2 Without TUCP Systemwide VAs compared to the No Action Alternative was predicted to be lower for all other water year types, with up to a 17% reduction in predicted loss for the below normal water year types (Table O-35). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of LAD winter-run Chinook salmon at the Delta fish collection facilities for the months of December through April under Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly salvage under the No Action Alternative for all water year types except for wet water year types which had an increase of 11%. Predicted loss for genetic and LAD winter-run Chinook salmon under Alternative 2 Without TUCP Systemwide VAs compared to the No Action Alternative was less for all other water year types, with up to a 25% reduction in loss for the below normal water year types (Table O-38). For detailed information on average monthly salvage by water year type (Attachment I.2, *Salvage Density Model Loss Simulation*).

<u>Winter-run Chinook Salmon Coded Wire Tag Salvage Model</u>

The Winter-run Chinook Salmon Coded Wire Tag (CWT) Proportional Salvage Model was developed to estimate the fraction of juvenile winter-run Chinook salmon in the Delta predicted to be salvaged based on hydrologic conditions and fish size. To apply this model to hydrologic scenarios outside of those used to construct the model, we had to use a fixed number of winter-run Chinook salmon entering the Delta each month. The raw output of the model is the number of fish salvaged. However, we used the offset variable to convert this number to a proportion. In this way the model predicts the magnitude of salvage independent of the number of fish that may actually be in the Delta during a given month.

Predicted mean of annual and monthly proportion of winter-run Chinook salmon salvaged at CVP and SWP for all months October through May under Alternative 2 With TUCP Without VA in all water year types, is higher than the No Action Alternative (Attachment I.9, *Winter-run Chinook Salmon Coded Wire Tag Salvage Model*). Alternative 2 With TUCP Without VA is predicted to increase the number of fish salvaged when compared to the No Action Alternative, however all predicted proportion salvaged are less than ± 0.01 in all months and years. Overall, there is not a substantial difference in predicted proportion salvaged between Alternative 2 With TUCP Without VA and the No Action Alternative.

Predicted mean of annual and monthly proportion of winter-run Chinook salmon salvaged at CVP and SWP for all months October through May under Alternative 2 Without TUCP Delta VA, Alternative 2 Without TUCP Systemwide VA and Alternative 2 Without TUCP Without VA in all water year types, varied from positive to negative between months when compared to the No Action Alternative. Salvage is predicted to increase in wet years under Alternative 2 Without TUCP Delta VA, Alternative 2 Without TUCP Systemwide VA and Alternative 2 Without TUCP

Without VA when compared to the No Action Alternative, however all predicted proportion salvaged are less than ± 0.01 in all months and years. Overall, there is not a substantial difference in predicted proportion salvaged between Alternative 2 Without TUCP Delta VA, Alternative 2 Without TUCP Systemwide VA and Alternative 2 Without TUCP Without VA and the No Action Alternative.

Summary

Differences in flow between the phases of Alternative 2 relative to the No Action Alternative on entrainment of juvenile winter-run Chinook salmon in the Delta are best explained by grouping the four phases into with VA (Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA) and without VA (Alternative 2 Without TUCP Without VA and with TUCP Without VA). Generally, the Alternative 2 with VA are expected to have an overall beneficial impact compared to the No Action Alternative with the exception of during a wet water year type. Generally, the Alternative 2 without VA could have an adverse to beneficial impact compared to the No Action Alternative depending on water year type and quantitative model, both types of impact could be large. Alternative 2 relative to the No Action Alternative is not expected to have an impact on the salvage proportion of juvenile winter-run Chinook salmon.

Potential Changes to Routing of Winter-run Chinook Salmon

Winter-run Chinook salmon travel through different migratory pathways. Using a conceptual model, a single fish in any location could have arrived at that location via one of several pathways (Figure O-14). For example, a fish observed salvage could have arrived via one of many pathways (e.g., Sacramento Origin via the mainstem Sacramento then below Cache Slough, then South Delta or via the DCC and Central Delta then the South Delta). If a proportion of fish is higher down a migratory pathway documented as a route with higher survival rates for juvenile salmonids, then fish migrating through that route will likely have a better chance of surviving to the ocean than fish migrating through a sub-optimal route (e.g., experiencing potential entrainment into the Central Delta through the DCC or Georgiana Slough).

Empirical estimates of acoustically tagged late fall-run Chinook salmon from Coleman National Fish Hatchery (CNFH) tracked in December 2006, January and December 2007, and January 2008 experienced routing in the mainstem Sacramento from 35.2% to 49.8%, through Georgiana Slough 0% to 31.1%, and through the Sutter and Steamboat sloughs 19.8% to 41.4% (Perry 2010). Results suggest the proportion of fish entering each route generally follows river flow but is not always in agreement with the proportion of discharge entering that route, suggesting another parameter may affect fish routing. Release groups experienced different discharge and export conditions leading to wide ranges in routing probabilities. Other studies also report proportional flow is a strong predictor of route selection (Kemp et al. 2005; Cavallo et al. 2015; Romine et al. 2021). Additionally, variables like DCC gate status (open / closed) will change routing and survival probabilities for fish traveling along the mainstem Sacramento when they get to both Georgiana Slough and the DCC junctions. Newman and Brandes (2010) reported that exports affect routing of fish released in Georgiana Slough more than fish released at Ryde (upstream of Georgiana Slough on the Sacramento River) and the fraction of fish released in Georgiana Slough recovered at the fish collection facilities increased with increased exports.

Differences in monthly flows on the Sacramento River under the four phases of Alternative 2 compared with the No Action Alternative may have effects on juvenile Chinook salmon's routing

and survival probabilities in the Sacramento River. These possible differences were evaluated by phase using two quantitative models: STARS and ECO-PTM.

STARS

Average Sacramento River flows at Freeport December through February are similar under all four phases of Alternative 2 compared with the No Action Alternative. Freeport flows March through May are similar under three phases of Alternative 2 compared with the No Action Alternative, except for Alternative 2 Without TUCP Systemwide VA which has flows slightly greater than the No Action Alternative. The STARS model is responsive to modeled Freeport flows and daily operations of the DCC gates, both obtained from CalSim 3.

- **Alternative 2 With TUCP Without VA:** The STARS model provides predictions of routing and survival probabilities, in this section routing results are discussed. In the "survival" section survival results are discussed. Mean proportion of particles routed to the Interior Delta via either Georgiana Slough or the DCC), averaged across all water year types by month under Alternative 2 With TUCP Without VA was similar to the No Action Alternative (up to 0.5% greater in February to up to 1.7% less in April) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*).
- **Alternative 2 Without TUCP Without VA:** Mean proportion of particles routed to the Interior Delta via either Georgiana Slough or the DCC), averaged across all water year types by month under Alternative 2 Without TUCP Without VA was similar to the No Action Alternative (up to 0.5% greater in January and February and up to 0.4% less in April and December) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*).
- **Alternative 2 Without TUCP Delta VA:** Mean proportion of particles routed to the Interior Delta via either Georgiana Slough or the DCC), averaged across all water year types by month under Alternative 2 Without TUCP Delta VA was similar to the No Action Alternative (up to 0.5% greater in January and February and up to 1.7% less in April) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*.
- **Alternative 2 Without TUCP Systemwide VA:** Mean proportion of particles routed to the Interior Delta via either Georgiana Slough or the DCC), averaged across all water year types by month under Alternative 2 Without TUCP Systemwide VA was similar to or less than the No Action Alternative (up to 0.5% greater in January and February and up to 3.7% less in April) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*).

The minimal range of differences among months in routing of juvenile salmonids into the Interior Delta under three of the four phases of Alternative 2 would have no effect on outmigrating juveniles, and routing under Alternative 2 Without TUCP Systemwide VA may have a minimal beneficial effect, particularly in April.

ECO-PTM

Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under all four phases of Alternative 2 ranged from less than the No Action Alternative (up to 7% less under -5,000 cfs under Alternative 2 Without TUCP Without VA and Alternative 2 with TUCP without VA) to greater than the No Action Alternative (up to 9% greater under -3,500 cfs under Alternative 2 Without TUCP Delta VA) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in the attachment. The decrease in routing to the Interior Delta could have a beneficial effect on outmigrating juveniles while the increase in routing could have an adverse impact on outmigrating juveniles.

Summary

Two flow-based quantitative models suggest depending on considered variables, flows under the four phases of Alternative 2 compared with the No Action Alternative may have minor adverse or minor beneficial impacts for outmigrating juvenile Chinook salmon in the winter and spring, dependent on OMR grouping.

Potential Changes to Through Delta Survival of Winter-run Chinook Salmon

Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. Juvenile Chinook salmon entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010, 2018).

Differences in monthly flows on the Sacramento River under the four phases of Alternative 2 compared with the No Action Alternative may have effects on juvenile Chinook salmon's routing and survival probabilities in the Sacramento River. These possible differences were evaluated by phase using several quantitative models: STARS, ECO-PTM, Delta Passage Model, IOS, and OBAN.

STARS

Average Sacramento River flows at Freeport December through February are similar under all four phases of Alternative 2 compared with the No Action Alternative. Freeport flows March through May are similar under three phases of Alternative 2 compared with the No Action Alternative, excepting Alternative 2 Without TUCP Systemwide VA which has flows slightly greater than the No Action Alternative. The STARS model is responsive to modeled Freeport flows and daily operations of the DCC gates, both obtained from CalSim 3.

- **Alternative 2 With TUCP Without VA:** The STARS model provides predictions of routing and survival probabilities, in this section survival results are discussed. In the "routing" section routing results are discussed. Mean predicted through-Delta survival of particles across all routes, averaged across all water year types by month under Alternative 2 With TUCP Without VA ranged from greater than the No Action Alternative (up to 1% greater in April) to equal to the No Action Alternative (December, January, and February) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*). This minimal change in survival would likely have no effect on outmigrating juveniles.

- **Alternative 2 Without TUCP Without VA:** Mean predicted through-Delta survival of particles across all routes, averaged across all water year types by month under Alternative 2 Without TUCP Without VA was equal to or greater than the No Action Alternative (up to 0.2% greater in December and April) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*). This increase in survival could have a minimal beneficial effect on outmigrating juveniles, particularly in December and April.
- **Alternative 2 Without TUCP Delta VA:** Mean predicted through-Delta survival of particles across all routes, averaged across all water year types by month under Alternative 2 Without TUCP Delta VA ranged from greater than the No Action Alternative (up to 0.8% greater in April) to less than the No Action Alternative (December, January, and February, up to 0.2% less) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*). This increase in survival, particularly in April, could have a minimal beneficial effect on outmigrating juveniles.
- **Alternative 2 Without TUCP Systemwide VA:** Mean predicted through-Delta survival of particles across all routes, averaged across all water year types by month under Alternative 2 Without TUCP Systemwide VA ranged from greater than the No Action Alternative (up to 3% greater in April) to less than the No Action Alternative (up to 0.2% less in December) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*). This increase in survival, particularly in April, could have a beneficial effect on outmigrating juveniles.

The minimal range of differences among months in through-Delta survival of juvenile salmonids under three of the four phases of Alternative 2 would have minimal to no effect on outmigrating juveniles, and through-Delta survival under Alternative 2 Without TUCP Systemwide VA may have a beneficial effect, particularly in April.

<u>ECO-PTM</u>

Particles in ECO-PTM are released at Freeport on the Sacramento River on the first of the month between the months of December and March, to provide routing and survival estimates. ECO-PTM relies on hydrological inputs generated by CalSim 3 combined with swimming behaviors associated with the neutrally buoyant particles in ECO-PTM include upstream or downstream movement, holding behaviors, and swimming velocity. In this section, through-Delta survival estimates are discussed. In the "routing" section routing estimates to the Interior Delta results are discussed. To represent possible conditions in the Delta, results are binned and presented using OMR groupings: < -5,500 cfs; -5,000 cfs; -3,500 cfs; and -2,000 cfs.

Mean through-Delta percent survival December through March under the four phases of Alternative 2 were not as consistent among phases of Alternative 2 as ECO-PTM routing results were. Mean through-Delta survival under the phases with no VA, Alternative 2 Without TUCP Without VA and with TUCP Without VA, ranged from less than the No Action Alternative (up to 4% less under -2,000 cfs) to greater than the No Action Alternative (up to 4% greater under -5,000 cfs) (Attachment I.7, *ECO-PTM*). Mean through-Delta survival under the phases with VA, Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA, ranged from less than the No Action Alternative (up to 5% less under -3,500 cfs) to greater than the No Action Alternative (up to 18% greater under -2,000 cfs) (Attachment I.7, *ECO-PTM*). Survival through Delta-specific routes is discussed further in the attachment. The increase in survival under some

OMR conditions under phases of Alternative 2 with VA could have a large beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have an adverse impact on outmigrating juveniles.

Delta Passage Model

The DPM simulates migration of Chinook salmon smolts entering the Delta from the Sacramento River, Mokelumne River, and San Joaquin River and estimates survival to Chipps Island. For this application, only survival of fish entering the Delta from the Sacramento River are evaluated. The DPM uses available time-series data and values taken from empirical studies or other sources to parameterize model relationships and inform uncertainty, thereby using the greatest amount of data available to dynamically simulate responses of smolt survival to changes in water management. (Attachment I.6, *Delta Passage Model*). The major model functions in the DPM are listed above in Alternative 1 (see *O.4.8.2*).

- Under **Alternative 2 With TUCP Without VA**, in all except critically dry and dry water year types, predicted mean survival of spring-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). However, the change in mean predicted survival to Chipps Island in all water year types less or equal to than ± 0.001. There is not a substantial difference in predicted proportion of spring-run Chinook salmon surviving to Chipps Island between Under Alternative 2 With TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Without VA**, in all except critically dry and dry water year types, predicted mean survival of winter-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative. However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.003. There is not a substantial difference in predicted proportion of winter-run Chinook salmon surviving to Chipps Island between Under Alternative 2 Without TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Delta VA**, in all except critically dry and dry water year types, predicted mean survival of winter-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative. However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.002. There is not a substantial difference in predicted proportion of winter-run Chinook salmon surviving to Chipps Island between Under Alternative 2 Without TUCP Delta VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Systemwide VA**, in all except wet water year types, predicted mean survival of winter-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative. However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.004. There is not a substantial difference in predicted proportion of winter-run Chinook salmon surviving to Chipps Island between Under Alternative 2 Without TUCP Systemwide VA and the No Action Alternative.

IOS: Through-Delta Survival

- Under **Alternative 2 With TUCP Without VA** in critically dry water years only, mean predicted through Delta survival of winter-run Chinook salmon juveniles is lower than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to ± .005. There is not a substantial difference in predicted through Delta survival of winter-run Chinook salmon juveniles between Alternative 2 With TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Without VA** in dry and wet water years only, mean predicted through Delta survival of winter-run Chinook salmon juveniles is higher than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to ± .008. There is not a substantial difference in predicted through Delta survival of winter-run Chinook salmon juveniles between Alternative 2 Without TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Delta VA** in below normal and critical water years only, mean predicted through Delta survival of winter-run Chinook salmon juveniles is lower than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to ± .007. There is not a substantial difference in predicted through Delta survival of winter-run Chinook salmon juveniles between Alternative 2 Without TUCP Delta VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Systemwide VA** in below normal and critically dry water years only, mean predicted through Delta survival of winter-run Chinook salmon juveniles is lower than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to ± .008. There is not a substantial difference in predicted through Delta survival of winter-run Chinook salmon juveniles between Alternative 2 Without TUCP Systemwide VA and the No Action Alternative.

OBAN: Delta Survival

Delta survival for the phases of Alternative 2 are best described as phases of Alternative 2 grouped by Voluntary Agreements (with and without VA). Delta survival for the phases of Alternative 2 without VA (Alternative 2 Without TUCP Without VA and with TUCP Without VA) was less than under the No Action Alternative (1.2% less, Table O-30). This decrease would have a minimal adverse effect on outmigrating juvenile winter-run Chinook salmon. Delta survival for the phases of Alternative 2 with VA (Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA) was greater than under the No Action Alternative (0.5% – 0.8% greater, Table O-30). This increase would have a minimal beneficial effect on outmigrating juvenile winter-run Chinook salmon.

Summary

Alternative 2 relative to the No Action Alternative is expected to have a possible adverse or beneficial impact on survival of outmigrating juvenile winter-run Chinook salmon depending on secondary biological model, phase of Alternative 2, and OMR grouping due to differences in flow. Alternative 2 relative to the No Action Alternative may have no difference on outmigrating juveniles or minimal adverse to minimal beneficial impacts due to flow.

O.5.9 Central Valley Spring-run Chinook Salmon ESU

O.5.9.1 Sacramento River

Spawning and Egg/Alevin Incubation

Spring-run Chinook salmon adults spawn from August through October (Williams 2006) with peak spawning in September (see Section O.1.3.2). Monitoring spring-run spawning in the mainstem Sacramento River is complicated due to lack of spatial/geographic segregation and temporal isolation from Fall-run Chinook salmon. Most Spring-run Chinook salmon spawning occurs between the Keswick Dam and Ball Ferry Bridge (NMFS 2017c). Fry emergence occurs up to three months after eggs are spawned (Moyle 2002), so effects of flow in the upper Sacramento River on incubating Spring-run Chinook salmon eggs and alevins potentially occur from August through January, peaking in December.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under the four phases of Alternative 2, differences in mean spawning WUA vary depending on water year type but are below a 3% difference across all water year types and phases when compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between the four phases of Alternative 2 and the No Action Alternative is a 2.9% increase in critically dry water year types for Alternative 2 With TUCP Without VA. The largest reduction in estimated spawning habitat is a -2.6% decrease in above normal water year types (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

For all three months of the spring-run spawning season, spawning WUA under the four phases of Alternative 2 are similar to that for the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA for all the modeled alternatives are substantially lower in August than in September or October. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in August than in the other two months (Table O-182 through Table O-185). This results in lower spawning WUA results because the fall-run spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), which were used to estimate spring-run spawning WUA, peak at relatively low flows (approximately 3,000 to 6,000 cfs).

The results of suitable habitat availability analysis using the SIT LCM habitat models indicate that spawning habitat for spring-run in the upper Sacramento River may not a limiting factor under both the No Action Alternative and Alternative 2 (See Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The results of the two spawning habitat analyses based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 may have a minor (less than 3%) increase and/or decrease in estimated spawning habitat during above normal water year types when compared to the No Action Alternative, but that spawning habitat may not be a limiting factor for spring-run Chinook salmon in the mainstem upper Sacramento River.

SIT Spring-run Lifecycle Model: Spawner Abundance

In the CVPIA spring-run SIT life cycle model, mean spring-run Chinook salmon spawner abundance in the Central Valley under the four phases of Alternative 2 annual in Chinook salmon spawner abundances are similar to or slightly higher than the No Action Alternative in the Central Valley. The largest increase in abundance between the No Action Alternative and an Alternative 2 phase was 0.7% under Alternative 2 With TUCP Without VA. The results suggest no decreases in abundance under the four phases of Alternative 2. Over the full model run period (1980–1999), abundance under all phases of Alternative 2 was equal to abundance under the No Action Alternative. Overall, the spawner abundance predicted by the CVPIA Spring-run Chinook salmon life cycle model is expected to be similar under all phases of Alternative 2 and the No Action Alternative.

Redd Dewatering Analysis

Under the four phases of Alternative 2, the spring-run Chinook salmon redd dewatering results show a consistent reduction in redd dewatering potential from wet and above normal water year types to drier water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation is expected for spring-run Chinook salmon because their spawning occurs in the fall, with incubation extending into early winter. During wet winters, periodic storms and high runoff increase flow fluctuations, which tends to result in greater redd dewatering. In drier winters, flow fluctuations are reduced and fewer redds are potentially dewatered. Reductions in the estimates of redd dewatering potential from the No Action Alternative are larger and more frequent than increases, with a maximum reduction of 22.0% in critically dry water year types under Alternative 2 Without TUCP With Delta VA. The largest increase is 8.3% in above normal water years for Alternative 2 Without TUCP With Systemwide VA scenario. For individual months, redd dewatering is slightly lower for September spawning under the four phases of Alternative 2 than the No Action Alternative and is about the same for October spawning (Attachment L.4, *Sacramento River Redd Dewatering Analysis*).

Overall, the results indicate that redd dewatering potential under the four phases of Alternative 2 would mostly be smaller than under the No Action Alternative, especially in critically dry water years, but the means would be about 7% higher in above normal water year types.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 48 for Keswick Dam and Table 50 for Red Bluff Diversion Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 54 for Keswick Dam and Table 56 for Red Bluff Diversion Dam. Full results of

the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during September through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 60 for Keswick Dam and Table 62 for Red Bluff Diversion Dam.

Results for the three analyses are summarized in Table O-39. Table O-39, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 42.1°F to 55°F spawning initiation range analysis, there were five and one month-water year type combinations (14.3% and 2.9% of total combinations during the period) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively, and there were two and zero combinations (5.7% and 0%,) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively(Table O-39). For the 59.9°F pathogen virulence threshold, there were zero and 14 combinations (0% and 40.0%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively, and there were no combinations with unfavorable results at either location. For the 42.8°F to 56°F range for egg incubation and fry emergence, there was one combination (2.9%) with favorable results at Red Bluff Diversion Dam and two combinations (5.7%) with unfavorable results below Keswick Dam. These results suggest that there would be positive water temperature-related effects of Alternative 2 With TUCP Without VA on spring-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 42.1°F to 55°F spawning initiation range analysis, there were six and one month-water year type combinations (17.1% and 2.9% of total combinations during the period) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively (Table O-39). There were two and zero combinations (5.7% and 0%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. For the 59.9°F pathogen virulence threshold, there were three and 13 combinations (8.6% and 37.1%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. There were zero combinations (0%) with favorable or unfavorable results below Keswick and at Red Bluff Diversion Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there was one combination (2.9%) with favorable and unfavorable results below Keswick Dam and at Red Bluff Diversion Dam. These results suggest that there would be positive water temperature-related effects of Alternative 2 Without TUCP Without VA on spring-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Delta VA** for the 42.1°F to 55°F spawning initiation range analysis, there were five and zero month-water year type combinations (14.3% and 0% of total combinations during the period) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively (Table O-39). There were three and zero combinations (8.6% and 0%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. For the 59.9°F pathogen virulence threshold, there were zero and 11 combinations (0% and 31.4%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. There were zero

combinations (0%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero and four combinations (0% and 11.4%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. There were three and zero combinations (8.6% and 0%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. These results suggest that there would be positive water temperature-related effects of Alternative 2 Without TUCP Delta VA on spring-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 42.1°F to 55°F spawning initiation range analysis, there were five and one month-water year type combinations (14.3% and 2.9% of total combinations during the period) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively (Table O-39). There were two and zero combinations (5.7% and 0%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. For the 59.9°F pathogen virulence threshold, there were zero and 11 combinations (0% and 31.4%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. There were one and zero combinations (2.9% and 0%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero and two combinations (0% and 5.7%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. There were two and zero combinations (5.7% and 0%, respectively) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. These results suggest that there would be positive water temperature-related effects of Alternative 2 Without TUCP Systemwide VA on spring-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.

Overall, the four phases of Alternative 2 would have similar positive and negative water temperature-related effects to spring-run Chinook salmon spawning and egg/incubation in the Sacramento River (Table O-39).

Summary

Alternative 2 relative to the No Action Alternative is largely expected to have little impact on spring-run Chinook salmon spawning and egg/alevin incubation (mortality) due to flow. There are no expected impacts to spawner abundance under Alternative 2. Flow for spawning habitat is not a limiting factor for spring-run Chinook salmon. Redd dewatering is decreased under Alternative 2 relative to the No Action Alternative, except in above normal water year types where the mean is about 7% higher. Water temperatures for spawning initiation are beneficial and adverse in the Sacramento River. Egg/incubation and fry emergence are similar or more beneficial under Alternative 2 relative to the No Action Alternative. Water temperatures for adult pathogen virulence is beneficial at Red Bluff Diversion Dam under all phases.

Juvenile–Yearling Rearing and Emigration

Spring-run Chinook salmon juveniles rear in the Sacramento River primarily from November through June and most emigrate to the Delta during December and again in March and April (Roberts 2007) (see Section O.1.3.2, Spring-run Chinook Salmon). Migratory cues, such as increased flow and/or turbidity from runoff, may spur emigration of juveniles from the upper Sacramento River basin when they have reached the appropriate stage of maturation (National Marine Fisheries Service 2009a). Inundated floodplain habitats have been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001a, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under the four phases of Alternative 2, mean fry rearing WUA decreases in all water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). There are no expected increases in estimated fry rearing habitat between the four phases of Alternative 2 and the No Action Alternative. The largest reduction in estimated fry rearing habitat is a 2.6% decrease in critically dry water year types under Alternative 2 Without TUCP with Systemwide VA and Alternative 2 Without TUCP with Delta VA in comparison to the No Action Alternative.

There are some differences in fry rearing WUA on a monthly scale between the four phases of Alternative 2 and the No Action Alternative. In April, there may be an 8% reduction in the median value of estimated fry rearing WUA under Alternative 2 Without TUCP with Systemwide VA, and a 7% reduction under Alternative 2 Without TUCP with Delta VA in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The four phases of Alternative 2 and the No Action Alternative are similar during the other fry rearing months. Estimated fry rearing WUA median values for all the modeled alternatives are similar across December, January, and March, which are important months for rearing. The results during these three months show little variation in the third quartile of the WUA distributions. This occurs because the fry rearing WUA curves peak at the lowest flows encountered in the river (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and Keswick Dam flow releases are frequently low during these months in critically dry years when Shasta Reservoir is operated to rebuild storage volume (Table O-182 through Table O-185). The first quartile is much wider because a greater range of flows affect the fry rearing WUA values below the median. November and April have the lowest median WUA values across all alternatives. The occurrence of some higher rearing WUA values for April results from the installation of the ACID dam for that month, which results in higher WUA values in Segment 6 of the river.

The results of the spring-run Chinook salmon fry rearing habitat analysis suggest that the four phases of Alternative 2 may have a minor (less than 3%) decrease in estimated fry rearing habitat across all water year types and the greatest reduction in estimated habitat may occur in April (7-8%) in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Juvenile Rearing Habitat Analyses

Under the four phases of Alternative 2, mean juvenile rearing WUA decreases in all water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). There are no expected increases in estimated juvenile rearing habitat between the four phases of Alternative 2 and the No Action Alternative. The largest reduction in estimated juvenile rearing habitat is between Alternative 2 With TUCP Without VA and the No Action Alternative is a 1.5% decrease in above normal water year types. The median value of estimated juvenile rearing WUA under the four phases of Alternative 2 are similar to the No Action Alternative January through March and in May (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

There are some differences in juvenile rearing WUA on a monthly scale between the four phases of Alternative 2 and the No Action Alternative. In April, there is a 6% reduction in the median value of juvenile rearing WUA under Alternative 2 Without TUCP with Systemwide VA in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The juvenile rearing WUA values under all of the modeled alternatives are similar for January through March, but they are generally lower for April and May. For the January through March period, as described above for spring-run Chinook salmon fry rearing WUA, the third quartiles of the WUA distributions have high values and reduced variation. This occurs because, as described for the fry rearing WUA curves, the juvenile rearing WUA curves peak at the lowest flows encountered in the river and low flows are frequent during January through March in dry and critically dry years when Shasta Reservoir is operated to rebuild storage (Table O-182 through Table O-185).

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for spring-run Chinook salmon in the upper Sacramento River have a 1.3% to –2.7% difference between the months of January and May (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest increase in estimated habitat may occur in the month of May under Alternative 2 Without TUCP without Delta VA and the greatest reduction in estimated habitat may occur in April under Alternative 2 Without TUCP with Systemwide VA in comparison to the No Action Alternative.

The results of the two spring-run Chinook salmon juvenile rearing habitat analyses suggest that the four phases of Alternative 2 may have a minor (less than 2%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and the greatest reduction in estimated habitat may occur in April (6%) in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. The four phases of Alternative 2 differ in how juvenile stranding of spring-fun fry varies with water year type (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Under Alternative 2 Without TUCP Without VA and Alternative 2 Without TUCP Delta VA, juvenile stranding steadily increases from critically dry to wet water years, while for the other two phases of Alternative 2, the rate of stranding falls from critically dry to dry or below normal water years before trending upward (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The four phases of

Alternative 2 show similar patterns of variation across the four principal months of spring-run fry rearing, with highest medians in November, lowest medians in December and January, and intermediate medians in February (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The means of spring-run Chinook salmon fry stranding under the four phases of Alternative 2 differ inconsistently from the means under the No Action Alternative (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The largest difference is a 10.4% reduction for below normal water years under Alternative 2 Without TUCP Systemwide VA and the largest increase is 10.1% for critically dry water years under Alternative 2 With TUCP Without VA. All four phases of Alternative 2 show reductions in stranding relative to the No Action Alternative in wet and above normal water years (ranging from 1.7% to 9.1% lower) and show a mix of increases and reductions for the drier water year types. Large (>5%) reductions outnumber large increases five to one.

Overall, reductions in fry standing are more frequent than increases for all four phases, relative to the No Action Alternative.

Survival and Travel Time: XT and Flow Survival Threshold Models

Differences in daily flows (Upper Sacramento River Daily Operations Model, USRDOM) under all four phases of Alternative 2 compared with the No Action Alternative may have effects on juvenile Chinook salmon's travel time and survival probabilities in the Upper Sacramento River. These possible differences were evaluated using several quantitative models. For a detailed description of how flows under Alternative 2 phases may impact juveniles and yearlings' travel time and survival probabilities in the Upper Sacramento River, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.1).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for juvenile growth, smoltification, and predation vulnerability during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 66 for Keswick Dam, Table 68 for RBDD, and Table 70 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating juveniles during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 74 for Keswick Dam, Table 76 for RBDD, and Table 78 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for yearling growth, smoltification, and predation vulnerability are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 82 for Keswick Dam during April through December, Table 84 for RBDD during April through December, and Table 98 for Hamilton City during October through December (migration only). Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating yearlings are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 88 for Keswick Dam during April through December, Table 90 for RBDD during April through December, and Table 106 for Hamilton City during October through December (migration only).

Results for the four analyses are summarized in Table O-40. Table O-40, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to one month-water year type combinations (0% to 2.5% of total combinations during the period) with favorable results depending on location (Table O-40). There were zero to three combinations (0% to 7.5%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles under Alternative 2 With TUCP Without VA, there would be no combinations with either favorable or unfavorable results at any location. For the 55.4°F to 68°F yearling optimum temperature range under Alternative 2 With TUCP Without VA, there would be zero to two combinations with favorable results (0% to 4.4%) with favorable results depending on location. There would be zero to three combinations (0% to 6.7%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating yearlings under Alternative 2 With TUCP Without VA, there would be no combinations with either favorable or unfavorable results at any location. These results indicate that there would be a mix of minor favorable and unfavorable water temperature-related conditions under Alternative 2 With TUCP Without VA related to optimum temperatures on juveniles and yearlings but no effect of Alternative 2 With TUCP Without VA on lethal temperatures.
- Under **Alternative 2 Without TUCP Without VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to two month-water year type combinations (0% to 6.7% of total combinations during the period) with favorable results depending on location (Table O-40). There were zero to three combinations (0% to 7.5%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles under Alternative 2 Without TUCP Without VA, there would be no combinations with either favorable or unfavorable results at any location. For the 55.4°F to 68°F yearling optimum temperature range under Alternative 2 Without TUCP Without VA, there would be zero to two combinations with favorable results (0% to 4.4%) with favorable results depending on location. There would be zero to five combinations (0% to 11.1%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating yearlings under Alternative 2 Without TUCP Without VA, there would be no combinations with either favorable or unfavorable results at any location. These results indicate that there would be a mix of minor favorable and unfavorable water temperature-related conditions under Alternative 2 Without TUCP Without VA related to optimum temperatures on juveniles and yearlings but no effect of Alternative 2 Without TUCP Without VA on lethal water temperatures.
- Under **Alternative 2 Without TUCP Delta VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were one to two month-water year type combinations (3.3% to 5.0% of total combinations during the period) with favorable results depending on location (Table O-40). There were one to three combinations (2.5% to 7.5%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles under Alternative 2 Without TUCP Delta VA, there would be no combinations

with either favorable or unfavorable results at any location. For the 55.4°F to 68°F yearling optimum temperature range under Alternative 2 Without TUCP Delta VA, there would be one to four combinations with favorable results (2.2% to 8.9%) with favorable results depending on location. There would be zero to three combinations (0% to 6.7%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating yearlings under Alternative 2 Without TUCP Delta VA, there would be no combinations with either favorable or unfavorable results at any location. These results indicate that there would be a mix of minor favorable and unfavorable water temperature-related conditions under Alternative 2 Without TUCP Delta VA related to optimum temperatures on juveniles and yearlings but no effect of Alternative 2 Without TUCP Delta VA on lethal water temperatures.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to one month-water year type combinations (0% to 3.3% of total combinations during the period) with favorable results depending on location (Table O-40). There were one to three combinations (3.3% to 7.5%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles under Alternative 2 Without TUCP Systemwide VAs, there would be no combinations with either favorable or unfavorable results at any location. For the 55.4°F to 68°F yearling optimum temperature range under Alternative 2 Without TUCP Systemwide VAs, there would be zero to two combinations with favorable results (0% to 4.4%) with favorable results depending on location. There would be zero to three combinations (0% to 6.7%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating yearlings under Alternative 2 Without TUCP Systemwide VAs, there would be no combinations with either favorable or unfavorable results at any location. These results indicate that there would be a mix of minor favorable and unfavorable water temperature-related conditions under Alternative 2 Without TUCP Systemwide VAs related to optimum temperatures on juveniles and yearlings but no effect of Alternative 2 Without TUCP Systemwide VAs on lethal temperatures.

Overall, the four phases of Alternative 2 would have similar water temperature-related effects to spring-run Chinook salmon juvenile and yearling rearing and outmigration in the Sacramento River (Table O-40). All four phases would have mostly small positive and negative effects related to the optimum temperature range for juvenile and yearling growth, smoltification, and predation vulnerability and no effects related to the UILT for juveniles and yearlings.

<u>Summary</u>

Alternative 2 relative to the No Action Alternative is largely expected to have negligible impacts on spring-run Chinook salmon fry and juvenile rearing habitat due to differences in flow. However, Alternative 2 relative to the No Action Alternative is expected to have an adverse impact on juvenile stranding in drier water year types. Mean annual survival and mean survival is increased and travel time decreased, which could have a beneficial impact on juvenile and yearling spring-run Chinook salmon. Alternative 2 relative to the No Action Alternative is expected to have an adverse water temperature-related impacts below Keswick Dam on juvenile growth, smoltification, and predation vulnerability, and a negligible impact at Red Bluff Diversion Dam and Hamilton City. Yearling growth, smoltification, and predation vulnerability

would be minorly adversely impacted below Keswick Dam and Red Bluff Diversion Dam under all phases, and minorly beneficially impacted below Keswick Dam and Hamilton City. Water temperatures above the incipient lethal limit for juveniles and yearlings are not expected to change in frequency under Alternative 2 relative to the No Action Alternative.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon enter the San Francisco Estuary from the Pacific Ocean to begin their upstream spawning migration in late January and early February (California Department of Fish and Game 1998). Spring-run Chinook salmon generally enter rivers as sexually immature fish and must hold in freshwater for up to several months before spawning (Moyle 2002). While maturing, adults hold in deep pools with cold water. Documentation of holding locations in the Sacramento River was not identified.

Spring-run Chinook salmon adults enter the Sacramento River from March to September, primarily in May and June (Moyle 2002; Yoshiyama et al. 1998). In the upper Sacramento River, migration extends from mid-March through July with peak migration in late May and early June (California Department of Fish and Wildlife 1998).

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

<u>CalSim 3 Flows</u>

- **Alternative 2 With TUCP Without VA:** During the January through June/July period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 With TUCP Without VA at Sacramento River below Red Bluff Diversion Dam, Keswick Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative, except for an increase in January of critically dry water year types (up to 7% greater) and a decrease in May to July in critically dry water year types (up to 13% less at Keswick Dam) at all four locations. At Sacramento River below Keswick Dam, flows under Alternative 2 With TUCP Without VA would range from less than to greater than flows under the No Action Alternative, depending on month and water year type. Flows are generally greater than flows under the No Action Alternative in January and February and generally similar to or less than flows under the No Action Alternative in May through July, except lower in critically dry water year types. Flows at Hamilton City and Wilkins Slough under Alternative 2 With TUCP Without VA would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 2 With TUCP Without VA would be greater than 5,300 cfs at Wilkins Slough and greater than 7,500 cfs at Hamilton City (Table O-186, Table O-182, Table O-190, Table O-194).
- **Alternative 2 Without TUCP Without VA:** During the January through June/July period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Without VA at Sacramento River below Red Bluff Diversion Dam, Keswick Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative, except an increase in April (up to 21% in a critically dry water year type) and a decrease in May and June (up to 6% less in a critically dry water year type). At Sacramento River below Keswick Dam flows under Alternative 2 Without TUCP Without VA would range from less than to greater than

flows under the No Action Alternative, depending on month and water year type. Flows are generally greater than flows under the No Action Alternative January through April (up to 25% greater in April of a critically dry water year type) and generally similar to or less than flows under the No Action Alternative May and June (up to 10% lower in May of a critically dry water year type). Flows at Hamilton City and Wilkins Slough under Alternative 2 Without TUCP Without VA would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 2 Without TUCP Without VA would be greater than 5,300 cfs at Wilkins Slough and greater than 7,550 cfs at Hamilton City (Table O-187, Table O-183, Table O-191, Table O-195).

- **Alternative 2 Without TUCP Delta VA:** During the January through June/July period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Delta VA at Sacramento River below Red Bluff Diversion Dam, Keswick Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative, except an increase in April (up to 25% greater in a critically dry water year type) and a decrease in May and June (up to 6% less in dry and critically dry water year types). At Sacramento River below Keswick Dam flows under Alternative 2 Without TUCP Delta VA would range from less than to greater than flows under the No Action Alternative, depending on month and water year type. Flows are generally greater than flows under the No Action Alternative in January and February and in April (up to 30% greater in April of a critically dry water year type) and generally similar to or less that flows under the No Action Alternative in May and June (up to 10% less in May of a critically dry water year type). Flows at Hamilton City and Wilkins Slough under Alternative 2 Without TUCP Delta VA would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 2 Without TUCP Delta VA would be greater than 5,300 cfs at Wilkins Slough and greater than 7,550 cfs at Hamilton City (Table O-188, Table O-184, Table O-192, Table O-196).

- **Alternative 2 Without TUCP Systemwide VA:** During the January through June/July period of adult winter-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Systemwide VA at Sacramento River below Red Bluff Diversion, below Keswick Dam, Hamilton City and at Wilkins Slough would range from less than to greater than flows, depending on month and water year type. Flows are generally greater than flows under the No Action Alternative January through April (up to 28% greater in a critically dry water year type) and generally lower than flows under the No Action Alternative May through July (up to 7% lower in a critically dry water year type). At Hamilton City flows under Alternative 2 Without TUCP Systemwide VA would generally be similar to flows under the No Action Alternative except April in a critically dry year type (up to 29% greater) and June of most water year types (up to 8% less). Flows at Hamilton City and Wilkins Slough under Alternative 2 Without TUCP Systemwide VA would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 2 Without TUCP Systemwide VA would be greater than 5,100 cfs at Wilkins Slough and greater than 7,550 cfs at Hamilton City from January to July (Table O-189, Table O-185, Table O-193, Table O-197).

Overall, the four phases of Alternative 2 would have similar flows compared to the No Action Alternative. However, for all of the phases, flows are greater in January and February and decreased from May to July (up to 9%) during critically dry water years. Flows at Hamilton City and Wilkins Slough are sufficient to allow passage and holding for all four phases during all water year types.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during March through September are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 40 for Keswick Dam, Table 42 for RBDD, and Table 44 for Hamilton City.

Results for the analysis are summarized in Table O-41. Table O-41, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under all four phases of Alternative 2, there were zero to one month-water year type combinations (0% to 2.9% of total combinations during the period) with favorable results and zero to two combinations (0% to 5.7%) with unfavorable results, depending on location (Table O-41). These results suggest that there would be mostly negligible water temperature-related effects of all four phases of Alternative 2 on spring-run Chinook salmon migration and holding in the Sacramento River.

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts, depending on location and month, on upstream migrating and holding adult spring-run Chinook salmon due to differences in flow. Average monthly flows at Hamilton City and Wilkins Slough are high enough to allow upstream passage. Alternative 2 relative to the No Action Alternative is expected to have negligible water temperature-related impacts on upstream migrating and holding adult spring-run Chinook salmon.

O.5.9.2 Clear Creek

Spawning and Egg Incubation

Spawning occurs in gravel substrate in relatively fast-moving, moderately shallow riffles or along banks with relatively high water velocities to promote higher oxygen levels. Spawning in Clear Creek normally occurs between mid-August and early October, peaking in September (Moyle 2002).

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under the four phases of Alternative 2, mean spawning WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean spawning WUA under the four phases of Alternative 2 in comparison to the No Action Alternative. The largest reduction in estimated

spawning habitat is an 18.7% decrease in critically dry water year types under Alternative 2 Without TUCP with Systemwide VA. On average across all water year types, there is a 10.8-13.6% reduction in estimated spawning habitat under the four phases of Alternative 2.

The mean values of spawning WUA by month are lower under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). October is expected to have the highest spawning WUA values under the four phases of Alternative 2.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that spawning habitat for spring-run in Clear Creek may be a limiting factor under all of the modeled alternatives and that spawning habitat may decrease 9.5-11.1% in September and October for the four phases of Alternative 2 in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The two spawning habitat analyses suggest that the four phases of Alternative 2 may have an adverse impact (up to 18.7% decrease) in spring-run Chinook salmon spawning habitat in Clear Creek across water year types when compared to the No Action Alternative, and that spawning habitat may be a limiting factor for spring-run Chinook salmon in Clear Creek.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 52 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 58 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during September through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 6 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-42. Table O-42, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 42.1°F to 55°F spawning initiation range analysis, there were zero month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results below Whiskeytown Dam (Table O-42). For the 59.9°F pathogen virulence threshold, there were zero combinations (0%) with favorable and unfavorable results below Whiskeytown Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero (0%) combinations with favorable and unfavorable results below Whiskeytown Dam. These results suggest that there would be no effect of Alternative 2 With TUCP Without VA on spring-run Chinook salmon spawning in Clear Creek.

- Results for **Alternative 2 Without TUCP Without VA** were identical to those for Alternative 2 With TUCP Without VA (Table O-42).
- Results for **Alternative 2 Without TUCP Delta VA** were identical to those for Alternative 2 With TUCP Without VA (Table O-42).
- Results for **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-42).

Overall, the four phases of Alternative 2 would have no effect on water temperature conditions for spring-run Chinook salmon spawning in Clear Creek (Table O-42).

Summary

Alternative 2 relative to the No Action Alternative is expected to include a decrease in flows and have moderate to adverse impacts on spawning habitat area that is anticipated to have adverse impacts on spawning spring-run Chinook salmon, although changes in flows did not cause water temperature-related effects.

Juvenile–Yearling Rearing and Emigration

While the majority of juvenile spring-run Chinook salmon outmigrate as fry, a proportion rears in Clear Creek through the spring and summer and emigrates as subyearlings with the first rainstorms in the fall or winter following their birth (NMFS 2014a). Spring-run Chinook salmon outmigration from Clear Creek occurs during late October through late April with peak emigration of juveniles occurring in November, and few fish exiting through the end of May.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under the four phases of Alternative 2, mean fry rearing WUA increases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The greatest increase in estimated fry rearing habitat is a 7.8% increase in dry water year types under all four phases of Alternative 2. There are no anticipated reductions in mean fry rearing WUA under the four phases of Alternative 2 in comparison to the No Action Alternative.

The mean values of fry rearing WUA by month are generally higher under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the five fry rearing months, January and February are expected to have the highest fry rearing WUA values under the four phases of Alternative 2.

The results of the spring-run Chinook salmon fry rearing habitat analysis suggest that the four phases of Alternative 2 may have a minor (5.8-7.8%) increase in estimated spring-run Chinook salmon fry rearing habitat across all water year types in comparison to the No Action Alternative in Clear Creek.

Juvenile Rearing Habitat Analyses

Under the four phases of Alternative 2, mean juvenile rearing WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under

the four phases of Alternative 2 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between Alternative 2 and the No Action Alternative is a 6.5% decrease in critically dry water year types. On average across all water year types, there is a 5.1-5.3% reduction in estimated juvenile rearing habitat under the four phases of Alternative 2.

The mean values of juvenile rearing WUA by month are lower June through August and higher in April and May under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the five months, May and June are expected to have the highest juvenile rearing WUA values.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for spring-run in Clear Creek may decrease 12-15 during the summer months (June through August) but may increase 4.2-12.6% in the spring months April and May under the four phases of Alternative 2 compared to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest decrease in estimated juvenile rearing habitat may occur in June and the greatest increase in estimated juvenile rearing habitat may occur in May.

The results of the two spring-run Chinook salmon juvenile rearing habitat analyses suggest that the four phases of Alternative 2 may have a minor adverse effect, as rearing habitat may decrease up to 5.3% across all water year types in comparison to the No Action Alternative, and that there may be increases to habitat in the spring and reductions in habitat in the summer in Clear Creek.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for juvenile growth, smoltification, and predation vulnerability during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 72 below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating juveniles during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 80 below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for yearling growth, smoltification, and predation vulnerability are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 86 below Whiskeytown Dam April through December. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating yearlings are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 92 below Whiskeytown Dam for April through December.

Results for the four analyses are summarized in Table O-43. Table O-43, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- For the 55.4°F to 68°F juvenile optimum temperature range under **Alternative 2 With TUCP Without VA**, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-43). For the 75.2°F UILT for rearing and migrating juveniles, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam. For the 55.4°F to 68°F yearling optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam. For the 75.2°F UILT for rearing and migrating yearlings, there were no combinations (0%) with favorable results and two combinations (4.4%) with unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on spring-run Chinook salmon juvenile and yearling rearing and emigration in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA** were identical to those for Alternative 2 With TUCP Without VA.
- Results for **Alternative 2 Without TUCP Delta VA** were identical to those for Alternative 2 Without TUCP With VA (Table O-43).
- Results for **Alternative 2 Without TUCP Systemwide VA** were identical to those for Alternative 2 Without TUCP With VA (Table O-43).

Overall, all 4 phases of Alternative 2 would have similar negligible effects on water temperature conditions for spring-run Chinook salmon juvenile and yearling rearing and emigration in Clear Creek (Table O-43).

Summary

Alternative 2 relative to the No Action Alternative is largely expected to have minor impacts on spring-run Chinook salmon fry and juvenile rearing habitat due to differences in flow. Fry rearing habitat is expected to increase, while juvenile rearing habitat may decrease up to 5.2% under Alternative 2 compared to the No Action Alternative. Increases in habitat in the spring and reductions in the summer are expected. Alternative 2 relative to the No Action Alternative is expected to be negligible water-temperature related impacts on juvenile and yearling rearing and emigration. There are some adverse water temperature impacts related to the critical upper temperature limit for yearlings under all 4 phases of Alternative 2.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon migrate into Clear Creek from April to August, and peak passage occurs in May and June (Clear Creek Technical Team 2018; Giovannetti et al 2013). Adults distribute throughout Clear Creek and hold in deep pools throughout the summer from Whiskeytown Dam (river mile 18.3) as far downstream as river mile 4.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

CalSim 3 Flows

- **Alternative 2 With TUCP Without VA**
    - During the April through August period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 With TUCP Without VA at Clear Creek below Whiskeytown Dam would generally be higher or lower compared to the No Action Alternative. Flows are much higher from March to May, ranging from an increase of 14% to 54% in May of a critically dry year. From June to August flows are much lower, ranging from -3% in July of a critically dry year to -36% in June of a critically dry year. Flows are greater than flows under the No Action Alternative March through May and less than flows under the No Action Alternative in June through August in almost all water year types. The average monthly flows across all water year types under Alternative 2 With TUCP Without VA range from 119 cfs in August to 261 cfs in May (Table O-218).
    - Flows during the spring-run immigration and holding will be less than the No Action Alternative during the main passage and holding months. This reduction could have a negative effect on adult spring-run Chinook salmon.
- **Alternative 2 Without TUCP Without VA**
    - During the April through August period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Without VA at Clear Creek below Whiskeytown Dam would generally be higher or lower compared to the No Action Alternative. Flows are much higher from March to May, ranging from 14% to 54% in May of a critically dry year. From June to August flows are much lower, ranging from -3% in July of a critically dry year to -33% in June of a critically dry year. Flows are greater than flows under the No Action Alternative March through May and less than flows under the No Action Alternative in June through August in almost all water year types. The average monthly flows across all water year types under Alternative 2 Without TUCP Without VA range from 113 cfs in July to 261 cfs in May (Table O-219).
    - Flows during the spring-run Chinook salmon immigration and holding will be less than the No Action Alternative during the main passage and holding months. This reduction could have a negative effect on adult Spring-run Chinook salmon.
- **Alternative 2 Without TUCP Delta VA**
    - During the April through August period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Delta VA at Clear Creek below Whiskeytown Dam would be higher or lower compared to the No Action Alternative. Flows are much higher from March to May, ranging from 14% to 54% in May of a critically dry year. From June to August flows are much lower, ranging from -7% in August of a critically dry year

to -33% in June of a critically dry year. Flows are greater than flows under the No Action Alternative March through May and less than flows under the No Action Alternative in June through August in almost all water year types. The average monthly flows across all water year types under Alternative 2 Without TUCP Delta VA range from a low of 112 cfs in July to a high of 261 cfs in May (Table O-220).

- Flows during the spring-run Chinook salmon immigration and holding will be less than the No Action Alternative during the main passage and holding months. This reduction could have a negative effect on adult spring-run Chinook salmon.

- **Alternative 2 Without TUCP Systemwide VA**
    - During the April through August period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 2 Without TUCP Systemwide VA at Clear Creek below Whiskeytown Dam would be higher or lower compared to the No Action Alternative. Flows are much higher from March to May, ranging from 14% to 54% in May of a critically dry year. From June to August flows are much lower, ranging from -7% in August of a critically dry year to -33% in June of a critically dry year. Flows are greater than flows under the No Action Alternative March through May and less than flows under the No Action Alternative in June through August in almost all water year types. The average monthly flows across all water year types under Alternative 2 Without TUCP Systemwide VA range from a low of 112 cfs in July to a high of 261 cfs in May (Table O-221).
    - Flows during the spring-run Chinook salmon immigration and holding will be less than the No Action Alternative during the main passage and holding months. This reduction could have a negative effect on adult spring-run Chinook salmon.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during March through September are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 46 below Whiskeytown Dam.

Results for the analysis are summarized in Table O-44. Table O-44, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP With VA** for the 37.9°F to 68°F successful adult migration range, there were zero month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results below Whiskeytown Dam (Table O-44). These results suggest that there would be no effect of Alternative 2 With TUCP with VA on spring-run Chinook salmon adult upstream migration and holding in Clear Creek.

- Results for **Alternative 2 Without TUCP With VA**, **Alternative 2 Without TUCP Delta VA** and **Alternative 2 With TUCP With VA** were identical to those for Alternative 2 With TUCP With VA (Table O-44).

Overall, all 4 phases of Alternative 2 would have no effect on water temperature conditions for spring-run Chinook salmon adult upstream migration and holding in Clear Creek (Table O-44).

Summary

Alternative 2 relative to the No Action Alternative is expected to have an adverse impact on adult spring-run Chinook salmon migration and holding habitat due to differences in flow. Alternative 2 relative to the No Action Alternative could have no water temperature-related impacts on adult migration and holding.

O.5.9.3 Bay-Delta

Juvenile–Yearling Rearing and Emigration

Juvenile spring-run Chinook salmon show two distinct out-migration patterns in the Central Valley: out-migrating to the Delta and ocean during their first year of life as YOY or holding over in their natal streams and out-migrating the following fall/winter as yearlings. YOY spring-run Chinook salmon presence in the Delta peaks during April and May, as suggested by the recoveries of Chinook salmon in the CVP and SWP salvage operations and the Chipps Island trawls of a size consistent with the predicted size of spring-run fish at that time of year.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Zone of Influence

Differences in hydrology under the four phases of Alternative 2 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions.

With incremental decreases in OMR under all four phases of Alternative 2 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under the four phases of Alternative 2 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2, *Zone of Influence*).

Flow into Junctions

Alternative 2 relative with the No Action Alternative is expected to have effects on the flow into the Head of Old River and CVP junctions due to differences in flow routing. For a detailed description of how flows under the four phases of Alternative 2 may impact the flow at Head of Old River and CVP, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2, *Flow into Junctions*).

Under all four phases of Alternative 2 and for most OMR bins except -3,500, the predicted proportion of flow entering the CVP is less than the No Action Alternative, although the predicted difference was negligible (up to ± 0.0467 for Alternative 2 Without TUCP Delta VA). Exceptions include the -2,000 OMR bin, with slightly greater change in predicted proportion of flow into CVP for Alternative 2 With TUCP Without VA (-0.069) or Alternative 2 Without TUCP Without VA (-0.0631) indicating that slightly less flow will be routed into CVP under these conditions compared to the No Action Alternative.

Under all four phases of Alternative 2 and for all OMR bins, the predicted differences in proportion of flow entering the HOR compared to the No Action Alternative are negligible (either positive or negative, but always lower than ± 0.008),

Summary

Alternative 2 With TUCP Without VA and without TUCP Without VA are expected to have slightly less flow into CVP at OMR -2,000 and Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA are expected to have negligible impacts on flow into CVP. Impacts of pumping under all four phases of Alternative 2 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Spring-run Chinook Salmon from Entrainment

Salvage Density and Negative Binomial

- **Alternative 2 With TUCP Without VAs**
    - Predictions from the salvage density and the negative binomial model for LAD spring-run Chinook salmon include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP and Table O-242 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between the four phases of Alternative 2 and the No Action Alternative.
    - Predicted average monthly loss of LAD spring-run Chinook salmon at SWP Banks Pumping Plant for all the months January through June, of all water year types Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative, up to 116% greater in above normal water year types (Table O-45). Predicted average monthly loss of LAD spring-run Chinook salmon under Alternative 2 at CVP Jones Pumping Plant, for all the months December through June of all water year types, was greater or equal to predicted average monthly loss under the No Action Alternative, up to a maximum of 4% greater in below normal water year types. The predicted loss of LAD spring-run Chinook salmon at Jones for Alternative 2 With TUCP Without VAs compared to the No Action Alternative was lower for the dry water year types, with 1% reduction in predicted loss (Table O-46). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of LAD spring-run Chinook salmon at the Delta fish collection facilities for the months of March through June under Alternative 2 With TUCP Without VAs was greater than predicted loss under the No Action Alternative for all water year types, with loss up to 95% greater for above normal water year types (Table O-47). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.

- **Alternative 2 Without TUCP Without VAs**

  - Predictions from the salvage density and negative binomial model for genetic and LAD spring-run Chinook salmon include mean monthly total exports. Predictions from the negative binomial loss model for LAD spring-run Chinook salmon include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP and Table O-243 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between the four phases of Alternative 2 and the No Action Alternative.

  - Predicted average monthly loss of LAD spring-run Chinook salmon at SWP Banks Pumping Plant for all the months January through June, of all water year types, under Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative, with loss up to 116% greater in above normal water year types (Table O-45). Predicted average monthly loss of LAD spring-run Chinook salmon at CVP Jones Pumping Plant for all the months December through June under Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for all water year types except for the dry water year types, which had a reduction of 1% in predicted loss. For all other water year types, the predicted loss of LAD spring-run Chinook salmon increased under Alternative 2 Without TUCP Without VAs as compared to the No Action Alternative, with loss up to 5% greater in critically dry water year types (Table O-46). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

  - Predicted average monthly salvage of LAD spring-run Chinook salmon at the Delta fish collection facilities for the months of March through June under Alternative 2 Without TUCP Without VAs was greater than predicted loss under the No Action Alternative for all water year types, with loss up to 94% greater for above normal water year types. (Table O-47). For detailed information on average monthly salvage by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- **Alternative 2 Without TUCP With Delta VAs**

  - Predictions from the salvage density and the negative binomial model for LAD spring-run Chinook salmon include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP and Table O-244 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer

to the tables for differences between the four phases of Alternative 2 and the No Action Alternative.

- Predicted average monthly loss of LAD spring-run Chinook salmon at SWP Banks Pumping Plant, for all the months January through June of all water year types, under Alternative 2 Without TUCP with Delta VAs was greater than predicted average monthly loss under the No Action Alternative, with loss up to 69% greater in above normal water year types (Table O-45). Predicted average monthly loss of LAD spring-run Chinook salmon at CVP Jones Pumping Plant for all the months December through June for Alternative 2 Without TUCP with Delta VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types except for the critically dry water year types, which had an increase of 3% in predicted loss. For all other water year types, the predicted loss of LAD spring-run Chinook salmon decreased under Alternative 2 Without TUCP with Delta VAs as compared to the No Action Alternative, with up to a 13% reduction in predicted loss for the dry water year types (Table O-46). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of LAD spring-run Chinook salmon at the Delta fish collection facilities for the months of March through June under Alternative 2 Without TUCP with Delta VAs was greater than predicted loss under the No Action Alternative for all water year types, with up to 25% greater for below normal water year types. (Table O-47). For detailed information on average monthly salvage by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- **Alternative 2 Without TUCP Systemwide VAs**

  - Predictions from the salvage density and the negative binomial model for LAD spring-run Chinook salmon include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP and Table O-245 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between the four phases of Alternative 2 and the No Action Alternative.

  - Predicted average monthly loss of LAD spring-run Chinook salmon at SWP Banks Pumping Plant, for all the months January through June of all water year types, under Alternative 2 Without TUCP Systemwide VAs was greater than predicted average monthly loss under the No Action Alternative, with loss up to 67% greater in above normal water year types (Table O-45). Predicted average monthly loss of LAD spring-run Chinook salmon at CVP Jones Pumping Plant for all the months December through June for Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types except for the critically dry water year types, which had an increase of 2% in predicted loss. For all other water year types, the predicted loss of LAD spring-run Chinook salmon decreased under Alternative 2 Without TUCP Systemwide VAs as compared to the No Action

Alternative, with up to a 13% reduction in predicted loss for the dry water year types (Table O-46). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of LAD spring-run Chinook salmon at the Delta fish collection facilities for the months of March through June under Alternative 2 Without TUCP Systemwide VAs was greater than predicted loss under the No Action Alternative for all water year types, with up to 26% greater for below normal water year types (Table O-47). For detailed information on average monthly salvage by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Summary

Alternative 2 relative to the No Action Alternative is expected to have effects on entrainment of juvenile spring-run Chinook salmon in the Delta are generally the same due to similar flows. Alternative 2 relative to the No Action Alternative is expected to have an increase in average monthly loss at SWP and a decrease of loss at CVP. Salvage is expected to increase under Alternative 2 relative to the No Action Alternative regardless of water year type. Alternative 2 relative to the No Action Alternative is expected to have an adverse impact at SWP due to differences in flow.

Potential Changes to Routing of Spring-run Chinook Salmon

ECO-PTM

Alternative 2 relative to the No Action Alternative is expected to have effects on juvenile Chinook salmon's routing to Interior Delta via Georgiana Slough in the Delta. For a detailed description of how flows under the phases of Alternative 2 may impact spring-run Chinook salmon routing, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2).

Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under Alternative 2 ranged from less than the No Action Alternative (up to 7% less under -5,000 cfs under Alternative 2 Without TUCP Without VA and Alternative 2 With TUCP Without VA) to greater than the No Action Alternative (up to 9% greater under -3,500 cfs under Alternative 2 Without TUCP Delta VA) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in the attachment. The decrease in routing to the Interior Delta could have a beneficial effect on outmigrating juveniles while the increase in routing could have an adverse impact on outmigrating juveniles.

Summary

The quantitative model suggests that depending on considered variables, flows under the four phases of Alternative 2 compared with the No Action Alternative may have minor adverse or minor beneficial impacts for outmigrating juvenile Chinook salmon in the winter and spring, dependent on OMR grouping.

Potential Changes to Through Delta Survival of Spring-run Chinook Salmon

ECO-PTM

Differences in flows under all four phases of Alternative 2 compared with the No Action Alternative may have effects on juvenile Chinook salmon's through-Delta survival. For a detailed description of how flows under the phases of Alternative 2 may impact spring-run Chinook salmon through-Delta survival, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2).

Mean through-Delta percent survival December through March under the four phases of Alternative 2 were not as consistent among phases of Alternative 2 as ECO-PTM routing results were. Mean through-Delta survival under the phases with no VA, Alternative 2 Without TUCP Without VA and with TUCP Without VA, ranged from less than the No Action Alternative (up to 4% less under -2,000 cfs) to greater than the No Action Alternative (up to 4% greater under -5,000 cfs) (Attachment I.7, *ECO-PTM*). Mean through-Delta survival under the phases with VA, Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA, ranged from less than the No Action Alternative (up to 5% less under -3,500 cfs) to greater than the No Action Alternative (up to 18% greater under -2,000 cfs) (Attachment I.7, *ECO-PTM*). Survival through Delta-specific routes is discussed further in the *attachment*. The increase in survival under some OMR conditions under phases of Alternative 2 with VA could have a large beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have an adverse impact on outmigrating juveniles.

Delta Passage Model

- Under **Alternative 2 With TUCP Without VA**, in all except critically dry water year types, predicted mean survival of spring-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). However, the change in mean predicted survival to Chipps Island in all water year types is less than or equal to ± 0.002. There is not a substantial difference in predicted proportion of spring-run Chinook salmon surviving to Chipps Island between Under Alternative 2 With TUCP Without VA and the No Action Alternative.
- Under **Alternative 2 Without TUCP Without VA**, in all except critically dry water year types, predicted mean survival of spring-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative. The change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.007.
- Under **Alternative 2 Without TUCP Delta VA**, in all except critically dry and dry water year types, predicted mean survival of spring-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative. The change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.006.
- Under **Alternative 2 Without TUCP Systemwide VA**, in all except wet water year types, predicted mean survival of spring-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative. The change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.009.

Summary

Alternative 2 relative to the No Action Alternative is expected to have a possible adverse or beneficial impact on survival of outmigrating juvenile spring-run Chinook salmon depending on OMR grouping due to differences in flow.

O.5.10 California Central Valley Steelhead DPS

O.5.10.1 Sacramento River

Spawning and Egg Incubation

Steelhead primarily use the Sacramento River as a migratory corridor for reaching other tributaries to spawn. Data on steelhead spawning in the mainstem Sacramento River is limited and likely restricted to the area upstream of Red Bluff (National Marine Fisheries Service 2009a). No steelhead specific spawner surveys occur in the upper Sacramento River. Data from recent surveys for the four runs of Chinook salmon have found carcasses of *O. mykiss* but the majority are thought to be resident trout adults (Killam 2022). Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional two to four weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In the Sacramento River, estimated incubation timing based on spawning is December through June.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

Under the four phases of Alternative 2, differences in mean spawning WUA vary depending on water year type but are below a 1.5% difference across all water year types and phases when compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between the four phases of Alternative 2 and the No Action Alternative is a 1.25% increase in above normal water years under Alternative 2 Without TUCP Without VA. The largest reduction in estimated spawning habitat is a -1.0% decrease in below normal water year types under Alternative 2 Without TUCP Systemwide VA.

The monthly median values of spawning WUA under the four phases of Alternative 2 are similar to the No Action Alternative in May, June, and August but are slightly higher in July (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are relatively similar in January through March. In April, the median values of spawning WUA are higher across all alternatives when compared to the other spawning months. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently lowest in April when compared to other spawning months (Table O-182 through Table O-185). This results in lower spawning WUA results because the steelhead spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 4,000 to 7,000 cfs).

The results of suitable habitat analysis using the SIT LCM habitat models indicate that spawning habitat for steelhead in the upper Sacramento River may increase in April under all alternatives compared to the other spawning months (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

Lack of consistent spawner estimates for steelhead prevented Reclamation staff from calculating spawner limitation ratios for this species.

The results of the two spawning habitat analyses based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 are expected to have a negligible (less than 2%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. Out of the four months of steelhead spawning, April has the highest estimated spawning WUA across all alternatives.

Redd Dewatering Analysis

All phases of Alternative 2 show a consistent and large reduction in mean potential from wetter to drier water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation reflects flow conditions for the winter and early spring months, when steelhead spawning and incubation occurs. During wet winters and springs, periodic storms and high runoff increase flow fluctuations, which tends to result in greater redd dewatering. In drier years, flow fluctuations are reduced and fewer redds are dewatered. Most differences in mean redd dewatering potential between Alternative 2 and the No Action Alternative are reductions, ranging from 0.2% in wet water years under Alternative 2 With TUCP Without VA and Alternative 2 Without TUCP With Delta VA to 30.3% for Alternative 2 Without TUCP With Delta VA in critically dry water years. A 7.7% increase for Alternative 2 Without TUCP With Systemwide VA is the only increase greater than 1%. Note that, on an absolute scale, the largest differences for all water year types between the Alternative 2 scenarios and the No Action Alternative is a reduction of 2.1% for Alternative 2 Without TUCP With Systemwide VA in above normal years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*).

Overall, the results indicate that redd dewatering potential under the four phases of Alternative 2 would mostly be lower than under the No Action Alternative, but the reductions on an absolute difference scale are small.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis* Table 134 for Keswick Dam and Table 136 for RBDD. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 140 for Keswick Dam and Table 142 for RBDD. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 170 for Keswick Dam and Table 172 for RBDD.

Results for the three analyses are summarized in Table O-48. Table O-48, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 45.5°F to 55°F successful spawning range analysis, there were five and one month-water year type combinations (16.7% and 3.3% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-48). There were one and zero combinations (3.3% and 0%, respectively) with unfavorable results at both Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there were zero and five combinations (0% and 16.7%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. For the 45°F to 52°F range for optimal egg incubation, there were eight and zero combinations (22.9% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were four and zero combinations (11.4% and 0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be frequent positive water temperature-related effects and some negative effects of Alternative 2 With TUCP Without VA on steelhead spawning and egg incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 45.5°F to 55°F successful spawning range analysis, there were six and zero month-water year type combinations (20.0% and 0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-48). There were one and zero combinations (3.3% and 0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there were zero and five combinations (0% and 16.7%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. For the 45°F to 52°F range for optimal egg incubation, there were eight and zero combinations (22.9% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were five and zero combinations (14.3% and 0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be frequent positive water temperature-related effects and some negative effects of Alternative 2 Without TUCP Without VA on steelhead spawning and egg incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Delta VA** for the 45.5°F to 55°F successful spawning range analysis, there were five and one month-water year type combinations (16.7% and 3.3% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-48). There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. For the 59.9°F pathogen virulence threshold, there were zero and five combinations (0% and 16.7%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. For the 45°F to 52°F range for optimal egg incubation, there were seven and zero combinations (20.0% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were three and zero combinations (8.6% and 0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be frequent positive water temperature-related effects and some negative effects of Alternative 2 Without TUCP Delta VA on steelhead spawning and egg incubation in the Sacramento River.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 45.5°F to 55°F successful spawning range analysis, there were five and one month-water year type combinations (16.7% and 3.3% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-48). There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. For the 59.9°F pathogen virulence threshold, there were zero and five combinations (0% and 16.7%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. For the 45°F to 52°F range for optimal egg incubation, there were seven and zero combinations (20.0% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were three and zero combinations (8.6% and 0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be frequent positive effects and some negative effects of Alternative 2 Without TUCP Systemwide VAs on steelhead spawning and egg incubation in the Sacramento River.

Overall, the four phases of Alternative 2 would have positive and negative water temperature-related effects to steelhead spawning and egg incubation in the Sacramento River (Table O-48).

Sacramento River Pulse Flows

To increase outmigration survival of Chinook salmon, Reclamation would release up to 150 TAF in pulse flow(s) each water year, typically in the spring, to benefit Chinook salmon in the Sacramento River watershed when the pulse does not interfere with the ability to meet temperature objectives or other anticipated operations of the reservoir. Reclamation will schedule this pulse after coordination through the Sacramento River Group and Shasta Operations Team and may include coordinating timing with natural flow events, potential storage management operations and/or pulse flows in tributaries. There may be unintentional adverse impacts of spring pulse flows on steelhead spawning behavior and redd dewatering from sudden drops in flow. Redd surveys are occurring during the pulse flow period and redd dewatering has not been observed.

Summary

There are expected minor adverse and beneficial impacts of seasonal operations on steelhead spawning and egg incubation based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under the four phases of Alternative 2, changes in flows are expected to have a minor increase and/or decrease on spawning habitat area and redd dewatering potential would generally be smaller. There may be adverse impacts to spawning behavior from spring pulse flows. There may be redd dewatering following spring pulse flow events, though this has not been observed during redd surveys. There would be similar beneficial and adverse water temperature-related effects of the four phases of Alternative 2 on steelhead spawning and egg incubation.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in the Sacramento River. The timing of juvenile outmigration depends on the watershed and water year. The RST monitoring station at Knight's Landing indicate outmigration into the Delta, with median passage starting in January and ending in May from 2006-2024 (Columbia Basin Research, University of Washington 2024).

Potential Changes to Steelhead from Seasonal Operations

Fry Rearing Habitat Analysis

Under the four phases of Alternative 2, mean fry rearing WUA increases in critically dry water year types and reductions in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). WUA curves were not developed for steelhead, so the late fall-run Chinook salmon curves were used to quantify steelhead habitat. The largest increase in estimated fry rearing habitat is under Alternative 2 With TUCP Without VA and the No Action Alternative, with a 5.8% increase in critically dry water year types. The largest reduction in estimated fry rearing habitat is under Alternative 2 Without TUCP with Systemwide VA, with a 1.1% decrease in below normal water year types.

There are some differences in fry rearing WUA on a monthly scale between the four phases of Alternative 2 and the No Action Alternative. In April, there is a 11% reduction in the median value of estimated fry rearing WUA under Alternative 2 Without TUCP with Systemwide VA and an 8% reduction under Alternative 2 Without TUCP with Delta VA in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). In September, there is a 6-7% reduction in the median value of estimated fry rearing WUA under Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP with Systemwide VA. In October, there is a 5% reduction in Alternative 2 Without TUCP with Delta VA. The four phases of Alternative 2 and the No Action Alternative are similar during the other fry rearing months. The estimated fry rearing WUA values under the modeled alternatives are highly variable across the months, April through October, but are generally highest in April and October. WUA values of the fry rearing WUA curve are lowest in the range of approximately 7,000 cfs to 13,000 cfs in Segment 5 and flows in this range are more frequent during May through August (Table O-182 through Table O-185).

The results of the steelhead fry rearing habitat analysis based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 compared to the No Action Alternative are expected to have a minor increase (up to 5.8%) and a minor decrease (less than 1.5%) in estimated fry rearing habitat across all water year types and the greatest reduction in estimated habitat may occur in April (8-11%) in the mainstem upper Sacramento River.

Juvenile Rearing Habitat Analyses

Under the four phases of Alternative 2, mean juvenile rearing WUA decreases compared to the No Action Alternative across all water year types (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The upper and lower limits of the range in WUA values are determined by the ranges of the juvenile rearing WUA curves for late fall-run Chinook salmon since there

were no reliable WUA curves for steelhead. The analysis includes all months because steelhead juveniles may reside in freshwater for a year or more before emigrating to the ocean. There are no expected increases in estimated juvenile rearing habitat between the four phases of Alternative 2 and the No Action Alternative. The largest reduction in estimated juvenile rearing habitat is under Alternative 2 Without TUCP with Delta VA and the No Action Alternative, with a 1.4% decrease in above normal water year types.

The monthly median values of juvenile rearing WUA under the four phases of Alternative 2 are similar (less than 5% difference) to the No Action Alternative throughout the year (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The juvenile rearing WUA values under the modeled alternatives are similar December through March, and gradually decrease until the lowest estimated values in July. As discussed previously for spring-run rearing WUA and steelhead spawning WUA, the high WUA values with low variability in the third quartile for December through March result from the peaking of the WUA curve at the lowest flows and frequent low Keswick Dam flow releases during these months to build Shasta Reservoir storage (Table O-182 through Table O-185). The wide range of values in the first quartile of these months reflects the high frequency and variability of higher flows in these wet months. The low juvenile rearing WUA values June through August result from releases in the summer months above 10,000 cfs and estimated peak juvenile rearing at flows below 5,000 cfs.

The results of suitable habitat analysis using the SIT LCM habitat models suggest that juvenile rearing instream habitat for steelhead in the upper Sacramento River may have a 6.5% to -2.7% difference from January through December (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest increase in estimated habitat may occur in June under Alternative 2 Without TUCP with Systemwide VA and the greatest reduction in estimated habitat may occur in April under Alternative 2 Without TUCP With Systemwide VA in comparison to the No Action Alternative.

The results of the two steelhead juvenile rearing habitat analyses suggest that the four phases of Alternative 2 in comparison to the No Action Alternative may have a minor (less than 2%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and the greatest increase in estimated habitat may occur in June (6.7%) in the mainstem upper Sacramento River.

<u>Fry Stranding Analysis</u>

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. The four phases of Alternative 2 show a similar pattern of variation in how juvenile stranding of steelhead fry varies with water year type (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). All four phases have the highest mean steelhead fry stranding in wet water years and relatively small differences among the other four water year types. Steelhead fry rearing occurs primarily during late winter and spring. All four phases of Alternative 2 show the highest stranding in February, with the median levels trending down over the next three months (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The higher mean stranding levels for steelhead fry during February and wet water year types likely results from periodic storms and high runoff that produce increased variability of flow. Differences in juvenile stranding of steelhead fry between the four phases of Alternative 2 and the No Action Alternative vary greatly, but except for

critically dry water years they all constitute reductions in stranding (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The largest reductions occur under Alternative 2 Without TUCP Systemwide VA, including 30.0% lower in below normal water year types and 19.8% lower in above normal water years. Reductions are large in dry water years under all four phases of Alternative 2, ranging from 9.6% lower under Alternative 2 Without TUCP Systemwide VA to 19.7% lower under Alternative 2 With TUCP Without VA. The only increases in mean stranding are 8.0% and 8.8% for Alternative 2 Without TUCP Delta VA and Alternative 2 Without TUCP Systemwide VA, respectively, in critically dry water years.

Overall, steelhead juvenile stranding for fry is lower under the four phases of Alternative 2 than under the No Action Alternative, but the magnitude of the differences varies greatly. Moderate increases in stranding occur in critically dry years for two phases of Alternative 2.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperature range year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 182 for Keswick Dam and Table 184 for RBDD. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 188 for Keswick Dam, Table 190 for Red Bluff Diversion Dam, and Table 192 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 55°F upper limit of successful smoltification during January through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 196 for Keswick Dam, Table 198 for Red Bluff Diversion Dam, and Table 200 for Hamilton City.

Results for the three analyses are summarized in Table O-49. Table O-49, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 66.2°F upper limit of optimum temperature range, there were zero month-water year type combinations (0%) with favorable or unfavorable results at Keswick Dam and RBDD (Table O-49). For the 59.9°F juvenile pathogen virulence threshold, there were zero to 14 combinations (0% and 23.3%, respectively) with favorable results depending on location. There were zero to one combination (0% to 1.7%) with unfavorable results depending on location. For the 55°F upper limit of successful smoltification, there were zero to five combinations (0% to 20.0%) with favorable results depending on location. There were zero to one combinations (0% to 4.0%) with unfavorable results depending on location. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 2 With TUCP Without VA on steelhead juvenile rearing and emigration.
- Under **Alternative 2 Without TUCP Without VA** for the 66.2°F upper limit of optimum temperature range, there were zero and one month-water year type combinations (0% and 1.7%, respectively) with favorable results at Keswick Dam and RBDD, respectively

(Table O-49). For the 59.9°F juvenile pathogen virulence threshold, there was one to 15 combinations (1.7% to 25.0%) with favorable results depending on location. There were no combinations (0%)with unfavorable results at any of the locations. For the 55°F upper limit of successful smoltification, there were 0 to 5 combinations (0% to 20.0%) with favorable results depending on location. There were zero to one combinations (0% to 4.0%) with unfavorable results depending on location. These results suggest that there would be positive effects and negligible negative effects of Alternative 2 Without TUCP Without VA on steelhead juvenile rearing and emigration.

- Under **Alternative 2 Without TUCP Delta VA** for the 66.2°F upper limit of optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period, respectively) with favorable or unfavorable results at both Keswick Dam and RBDD (Table O-49). For the 59.9°F juvenile pathogen virulence threshold, there were zero to 11 combinations (0% to 18.3%) with favorable results depending on location. There were zero combinations (0%) with unfavorable results at any location. For the 55°F upper limit of successful smoltification, there were zero to five combinations (0% to 20.0%) with favorable results depending on location. There were no combinations (0%) with unfavorable results at any location. These results suggest that there would be positive effects and negligible negative effects of Alternative 2 Without TUCP Delta VA on steelhead juvenile rearing and emigration.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 66.2°F upper limit of optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period, respectively) with favorable results at both Keswick Dam and RBDD, and one combination (1.7%) with unfavorable results at RBDD (Table O-49). For the 59.9°F juvenile pathogen virulence threshold, there were zero to 11 combinations (0% to 18.3%) with favorable results depending on location. There were zero to one combinations (0% to 1.7%) with unfavorable results depending on location. For the 55°F upper limit of successful smoltification, there were zero to five combinations (0% to 20.0%) with favorable results depending on location. There were no combinations (0%) with unfavorable results at any location. These results suggest that there would be positive effects and negligible negative effects of Alternative 2 With TUCP systemwide VAs on steelhead juvenile rearing and emigration.

Overall, the four phases of Alternative 2 would have positive effects and negligible negative effects on water temperature conditions for steelhead juvenile rearing and emigration in the Sacramento River (Table O-49).

Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

Summary

There are expected adverse and beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under the four phases

of Alternative 2, changes in flows may have a minor increase and/or decrease on fry and juvenile rearing habitat area. Changes in flows are expected to generally decrease fry stranding during but fry stranding may moderately increase during two of the phases of Alternative 2 in critically dry water year types. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. There would be beneficial and negligible adverse water temperature-related effects of the four phases of Alternative 2 on steelhead juvenile rearing and emigration.

Adult Upstream Migration and Holding

Adult steelhead enter the San Francisco Estuary from the Pacific Ocean and will either spawn within a few months of entering freshwater or stage in pools for more extended periods until the first high flows (Moyle 2002; Williams 2006). Historical data at the Fremont Weir have shown that adult steelhead migrate upstream in the Sacramento River during most months of the year, beginning in July, peaking in September, and continuing through March (Hallock 1989; McEwan 2001; Hallock et al. 1957).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During peak steelhead adult upstream migration, flows at Wilkins Slough in the Sacramento River may be increased on average in October and decreased on average in September under Alternative 2 compared to the No Action Alternative, but none of the differences are large (Table O-182 through Table O-185). CalSim 3 Sacramento River mean monthly flows at Wilkins Slough are below the minimum flow in September and October of critically dry water years under the No Action Alternative. Under the four phases of Alternative 2, flows in the Sacramento River at Wilkins Slough range from about 3,002 cfs in September of critically dry water years to about 19,920 cfs in February of wet water year types during the adult migration period. Flows in the Sacramento River at RBDD range from about 4,793 cfs in October of critically dry water years to about 37,110 cfs in February of wet water years during the adult migration period (Table O-186 through Table O-189). Under Alternative 2, Reclamation will operate minimum instream flows at 2,300 cfs in March, July, and August, and 3,250 cfs from September through February but the schedule may change in critically dry water years (WRO Order 90-5).

These results suggest that there are likely minor adverse and beneficial effects of the four phases of Alternative 2 compared to the No Action Alternative on steelhead adult migration and holding in the Sacramento River, as flows increase (6-14%) above the threshold and decrease (2-10%) below the threshold during peak migration in the lower sections of the river in critically dry water year types.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range for minimal migration impairment during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 110 for Keswick Dam, Table 112 for Red Bluff Diversion Dam, and Table 114 for Hamilton City. Results for the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment L.1, *Sacramento River Water Temperature*

Analysis, Table 118 for Keswick Dam, Table 120 for Red Bluff Diversion Dam, and Table 122 for Hamilton City. Results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for adult migration and holding during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 126 at Keswick Dam, Table 128 for Red Bluff Diversion Dam, and Table 130 for Hamilton City.

Results for the three analyses are summarized in Table O-50. Table O-50, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 41°F to 66.2°F range for minimal migration impairment, there were zero to one month-water year type combinations (0% to 2.2% of total combinations during the period) with favorable results depending on location (Table O-50). There were zero combinations (0%) with unfavorable results depending on location. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at any location. There were no combinations (0%) with unfavorable results depending on location. For the 59.9°F adult migration pathogen virulence threshold, there were zero to four combinations (0% to 8.9%) with favorable results depending on location. There were zero combinations (0%) with unfavorable results depending on location. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 2 With TUCP Without VA on steelhead adult upstream migration and holding.
- Under **Alternative 2 Without TUCP Without VA** for the 41°F to 66.2°F range for minimal migration impairment, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at any location (Table O-50). There were zero combinations (0%) with unfavorable results depending on location. For the 69.8°F upper lethal limit to adult migrants, there were zero to one combination (0% to 2.2%) with favorable results depending on location. There were zero combinations (0%) with unfavorable results depending on location. For the 59.9°F adult migration pathogen virulence threshold, there were one to four combinations (2.2% to 8.9%) with favorable results depending on location. There were zero combinations (0%) with unfavorable results depending on location. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 2 Without TUCP Without VA on steelhead adult upstream migration and holding.
- Under **Alternative 2 Without TUCP Delta VA** for the 41°F to 66.2°F range for minimal migration impairment, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at any location (Table O-50). There were also zero combinations (0%) with unfavorable results depending on location. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at any location. There were zero to one combinations (0% to 2.2%) with unfavorable results depending on location. For the 59.9°F adult migration pathogen virulence threshold, there were zero to four combinations (0% to 8.9%) with favorable results depending on location. There were zero to one combinations (0% to 2.2%) with unfavorable results depending on location. These results suggest that there would be

positive water temperature-related effects and negligible negative effects of Alternative 2 Without TUCP Delta VA on steelhead adult upstream migration and holding.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 41°F to 66.2°F range for minimal migration impairment, there were zero month-water year type combinations (0% of total combinations during the period) with favorable results depending on location (Table O-50). There were zero to one combinations (0% to 2.2%) with unfavorable results depending on location. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at any location. There were zero to one combinations (0% to 2.2%) with unfavorable results depending on location. For the 59.9°F adult migration pathogen virulence threshold, there were zero to four combinations (0% to 8.9%) with favorable results depending on location. There were zero to one combination (0% to 2.2%) with unfavorable results depending on location. These results suggest that there would be negligible water temperature-related effects of Alternative 2 Without TUCP Systemwide VAs on steelhead adult upstream migration and holding.

Overall, the four phases of Alternative 2 would have positive effects and negligible negative effects on water temperature conditions for steelhead juvenile rearing and emigration in the Sacramento River (Table O-50).

Sacramento River Pulse Flows

There may be beneficial impacts of spring pulse flows on adult migration through decreased travel time.

Summary

There are expected minor beneficial and minor adverse impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison with the No Action Alternative. Under the four phases of Alternative 2 compared to the No Action Alternative, changes in flows are expected to have negligible impacts in the upper river and minor beneficial and minor adverse impact in the lower river for migrating adult steelhead. Spring pulse flow events may decrease travel time for adult migrants. Alternative 2 would have beneficial and negligible adverse effects on steelhead adult upstream migration and holding in the Sacramento River.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Similar to the adult migration section above, a flow threshold of 3,250 cfs has been used to evaluate the potential for adverse effects on steelhead kelts (Bureau of Reclamation 2019). Flows in the Sacramento River rarely drop below this level, and adults have not been observed to experience passage delays, crowding, or other adverse effects at this flow. Therefore, it represents a reasonable threshold for evaluating the potential for adverse effects on kelt emigration in the Sacramento River.

During the steelhead kelt emigration period, CalSim 3 modeled Sacramento River mean monthly flows do not go below the threshold of 3,250 cfs at Keswick Dam, RBDD, Wilkins Slough or Hamilton City under the four phases of Alternative 2 and the No Action Alternative (Table O-182 through Table O-197). These results suggest flows are adequate for kelt emigration in the Sacramento River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F migration impairment limit during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 146 for Keswick Dam, Table 148 for Red Bluff Diversion Dam, and Table 150 for Hamilton City. Full results for the percent of months with water temperature above the 69.8°F lethal limit to kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 154 for Keswick Dam, Table 156 for Red Bluff Diversion Dam, and Table 158 for Hamilton City. Full results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 162 for Keswick Dam, Table 164 for Red Bluff Diversion Dam, Table 166 for Hamilton City.

Results for the three analyses are summarized in Table O-51. Table O-51, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 66.2°F migration impairment limit, there were zero to one month-water year type combinations (0% to 4.0% of total combinations during the period) with favorable results depending on location (Table O-51). There were no combinations (0%) with unfavorable results at all locations. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at all locations. There were also no combinations (0%) with unfavorable results depending at all locations. For the 59.9°F adult migration pathogen virulence threshold, there were zero to ten combinations (0% to 40.0%) with favorable results depending on location. There were no combinations (0%) with unfavorable results at all locations. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 2 With TUCP Without VA on steelhead kelt emigration.

- Under **Alternative 2 Without TUCP Without VA** for the 66.2°F migration impairment limit, there were zero to two month-water year type combinations (0% to 8.0% of total combinations during the period) with favorable results depending on location (Table O-51). There were no combinations (0%) with unfavorable results at all locations. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at all locations. There were also no combinations (0%) with unfavorable results depending at all locations. For the 59.9°F adult migration pathogen virulence threshold, there were zero to 10 combinations (0% to 40.0%) with favorable results depending on location. There were no combinations (0%) with unfavorable results at all locations. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 2 Without TUCP Without VA on steelhead kelt emigration.
- Under **Alternative 2 Without TUCP Delta VA** for the 66.2°F migration impairment limit, there were zero to two month-water year type combinations (0% to 8.0% of total combinations during the period) with favorable results depending on location (Table O-51). There were no combinations (0%) with unfavorable results at all locations. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at all locations. There were no combinations (0%) with unfavorable results depending at all locations. For the 59.9°F adult migration pathogen virulence threshold, there were 0 to seven combinations (0% to 28.0%) with favorable results depending on location. There were no combinations (0%) with unfavorable results at all locations. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 2 Without TUCP Delta VA on steelhead kelt emigration.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 66.2°F migration impairment limit, there were zero to two month-water year type combinations (0% to 8.0% of total combinations during the period) with favorable results depending on location (Table O-51). There were no combinations (0%) with unfavorable results at all locations. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at all locations. There were no combinations (0%) with unfavorable results depending at all locations. For the 59.9°F adult migration pathogen virulence threshold, there were one to seven combinations (4% to 28.0%) with favorable results depending on location. There were no combinations (0%) with unfavorable results at all locations. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 2 Without TUCP Systemwide VAs on steelhead kelt emigration.

Overall, the four phases of Alternative 2 would have positive effects on water temperature conditions for steelhead juvenile rearing and emigration in the Sacramento River, although positive effects are muted under Alternative 2 Without TUCP Systemwide VAs relative to the other phases of Alternative 2 (Table O-51).

<u>Sacramento River Pulse Flows</u>

There may be beneficial impacts of spring pulse flows on kelt emigration through decreased travel time.

Summary

There are expected beneficial impacts of seasonal operations on steelhead kelts based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under the four phases of Alternative 2, changes in flows are expected to be above the minimum flow to avoid crowding and passage delays from Keswick Dam to Hamilton City in the Sacramento River. Spring pulse flow events may decrease travel time for kelt emigration. Alternative 2 would cause beneficial effects to steelhead kelt migration in the Sacramento River.

O.5.10.2 Clear Creek

Spawning and Egg Incubation

In Clear Creek, the temporal distribution of redd count data shows spawning December through April, with peak spawning January (Schaefer et al. 2019; Provins and Chamberlain 2019a, 2019b, 2020). Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional 2-4 weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In Clear Creek, estimated incubation timing based on spawning is late-December through late-May.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

Under the four phases of Alternative 2, mean spawning WUA increases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The greatest increase in estimated spawning habitat is an 7.3% increase in dry water year types under all four phases of Alternative 2. There are no anticipated reductions in mean spawning WUA under the four phases of Alternative 2 in comparison to the No Action Alternative.

The mean values of spawning WUA by month are higher under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The four months of spawning are expected to have similar spawning WUA values.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that steelhead spawning habitat in Clear Creek may have a minor decrease (0.5-1%) in January and March, and a minor increase (4.2%) in February for the four phases of Alternative 2 in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The two spawning habitat analyses based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 may have a beneficial effect (up to 7.3% increase) in steelhead spawning habitat in Clear Creek across all water year types when compared to the No Action Alternative, and that spawning habitat will likely decrease in January/March and increase in February on a monthly scale in Clear Creek.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis* Table 138 for Clear Creek at Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 144 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 174 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-52. Table O-52, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 45°F to 55°F range for successful spawning, there was one month-water year type combination (3.3% of total combinations during the period) with both favorable and unfavorable results below Whiskeytown Dam (Table O-52). For the 59.9°F adult pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 45°F to 52°F range for optimal egg incubation, there was one combination (2.9%) with both favorable and unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA steelhead spawning and egg incubation in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA** were identical to those for Alternative 2 With TUCP Without VA (Table O-52).
- Results for **Alternative 2 Without TUCP Delta VA** were identical to those for Alternative 2 With TUCP Without VA (Table O-52).
- Under **Alternative 2 With TUCP Systemwide VA** for the 45°F to 55°F range for successful spawning, there was one month-water year type combination (3.3% of total combinations during the period) with both favorable and unfavorable results below Whiskeytown Dam (Table O-52). For the 59.9°F adult pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 45°F to 52°F range for optimal egg incubation, there was one combination (2.9%) with favorable results and two combinations (5.7%) with unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP systemwide VAs on steelhead spawning and egg incubation in Clear Creek.

Overall, the four phases of Alternative 2 would have similar negligible effects on water temperature conditions for steelhead spawning in Clear Creek (Table O-52).

Summary

There are expected minor to moderate beneficial impacts of seasonal operations on steelhead spawning and egg incubation based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under the four phases of Alternative 2, changes in flows may have a beneficial impact on spawning habitat (up to 7.3% increase) across all water year types. Water temperatures outside of the successful spawning range and optimal egg incubation range will have similar negligible impacts in Clear Creek below Whiskeytown Dam.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in Clear Creek. The timing of juvenile outmigration depends on the watershed and water year. The RST monitoring station in lower Clear Creek indicates outmigration into the Sacramento River with median passage starting in November and ending in June, with peak passage between April and June (Schraml and Chamberlain 2019a, 2019b, 2020, 2021).

Potential Changes to Steelhead from Seasonal Operations

Fry Rearing Habitat Analysis

Under the four phases of Alternative 2, mean fry rearing WUA increases in dry water year types and decreases in all other water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The greatest increase in estimated fry rearing habitat is a 0.7% increase in dry water year types under all four phases of Alternative 2. The greatest reduction in estimated fry rearing habitat is a 0.65% decrease in critically dry water year types under Alternative 2 With TUCP Without VA in comparison to the No Action Alternative.

The mean values of fry rearing WUA by month are slightly higher March through May and slightly lower February and June under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The five fry rearing months are expected to have similar fry rearing WUA values.

The results of the fry rearing habitat analysis suggest that the four phases of Alternative 2 may have a negligible (less than 1%) increase and/or decrease in steelhead estimated fry rearing habitat across all water year types in comparison to the No Action Alternative in Clear Creek.

Juvenile Rearing Habitat Analyses

Under the four phases of Alternative 2, mean juvenile rearing WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under the four phases of Alternative 2 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between the four phases Alternative 2 and the No Action Alternative is a 5.7% decrease in below normal water year types under Alternative 2 Without TUCP Without VA. On average across all water year types and phases of Alternative 2, there is a 3.6-4.4% reduction in estimated juvenile rearing habitat.

The mean values of juvenile rearing WUA by month are lower July through October and higher in November and December under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the six months, December is expected to have the highest juvenile rearing WUA values under Alternative 2.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for steelhead in Clear Creek may decrease 1.2-15% in February and June through October and may increase 5.2-12.6% November through January and March through May under the four phases of Alternative 2 in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest decrease in estimated juvenile rearing habitat may occur in June and the greatest increase in juvenile rearing habitat may occur in May.

The results of the two steelhead juvenile rearing habitat analyses based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 may have a negative effect, as rearing habitat may decrease up to 5.7% depending on the water year type and phase in comparison to the No Action Alternative, and may increase and decrease throughout the year on a monthly scale. The steelhead juvenile rearing WUA analysis in Attachment O.1, *Clear Creek Weighted Usable Area Analysis*, analyzed the period between July and December, but some juveniles may rear year-round in Clear Creek, up to four years before emigration to the ocean. The greatest decrease in estimated juvenile rearing habitat may occur in July and the greatest increase in juvenile rearing habitat may occur in May.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperature range year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 186 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 194 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 55°F upper limit of successful smoltification during January through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 202 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-53. Table O-53, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 66.2°F upper limit of optimum temperature range for juvenile steelhead growth, there were no month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results below Whiskeytown Dam (Table O-53). For the 59.9°F juvenile pathogen virulence threshold, there were no combinations (0%) with favorable and unfavorable results results below Whiskeytown Dam. For the 55°F upper limit of successful smoltification, there were no combinations (0%) with either favorable or

unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on juvenile steelhead rearing and emigration in Clear Creek.

- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-53).

Overall, the four phases of Alternative 2 would have no anticipated effects on water temperature conditions for juvenile steelhead rearing and emigration in Clear Creek (Table O-53).

Summary

There are expected adverse impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under the four phases of Alternative 2, changes in flows are expected to have a negligible impact on fry rearing habitat and a minor to moderate adverse impact on juvenile rearing habitat. However, there would be no water temperature-related effects.

Adult Upstream Migration and Holding

Adult steelhead enter the San Francisco Estuary from the Pacific Ocean and will either spawn within a few months of entering freshwater or stage in pools for more extended periods until the first high flows (Moyle 2002; Williams 2006). In Clear Creek, *O. mykiss* greater than 16 inches have been seen migrating upstream through video monitoring as early as August and throughout February (Killam 2022).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During the period of adult steelhead migration and holding in Clear Creek, the mean monthly flows under the four phases of Alternative 2 will generally be reduced August through October and increased November through February compared to the No Action Alternative (Table O-218 through Table O-221). Throughout the full simulation period, flows on average will range from 10-21% reduction. Flows are above 100 cfs in Clear Creek throughout this period under Alternative 2. These results suggest there are negligible effects of flow to steelhead kelt emigration under the four phases of Alternative 2.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range for minimal migration impairment during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 116 for below Whiskeytown Dam. Results for the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 124 for below Whiskeytown Dam. Results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for adult migration and holding during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 32 for below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-54. Table O-54, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 41°F to 66.2°F range for minimal migration impairment, there were no month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results below Whiskeytown Dam (Table O-54). For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable and unfavorable results below Whiskeytown Dam. For the 59.9°F pathogen virulence threshold for adults, there were no combinations (0%) with favorable and unfavorable results below Whiskeytown Dam. These results suggest that there would be no effect of Alternative 2 With TUCP Without VA on steelhead adult upstream migration and holding in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-54).

Overall, the four phases of Alternative 2 would have no effect on water temperature conditions for steelhead adult upstream migration and holding in Clear Creek (Table O-54).

Summary

There are anticipated minor adverse impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison with the No Action Alternative. Under Alternative 2 compared to the No Action Alternative, Clear Creek flows are likely adequate for migrating adults. However, there would be no water temperature-related effects.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During the period of steelhead kelt emigration in Clear Creek, the mean monthly flows under the four phases of Alternative 2 compared to the No Action Alternative will be reduced towards the tail ends of emigration and increased during peak emigration (Table O-218 through Table O-221). Throughout the full simulation period, flows on average will have a 10% reduction in February and a 31% reduction in June under Alternative 2. Throughout the full simulation

period, flows on average will have a 15-36% increase March through May under Alternative 2. Flows are above 100 cfs in Clear Creek from February through March under Alternative 2, which are likely adequate for emigrating kelts.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F migration impairment limit during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 152 for below Whiskeytown Dam. Full results for the percent of months with water temperature above the 69.8°F lethal limit to kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 160 for below Whiskeytown Dam. Full results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 168 for below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-55. Table O-55, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 66.2°F kelt migration impairment limit, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-55). For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F pathogen virulence threshold for adult migration, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be no effects of Alternative 2 With TUCP Without VA on steelhead kelt migration in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-55).

Overall, the four phases of Alternative 2 would have similar no effects on water temperature conditions for steelhead kelt migration in Clear Creek (Table O-55).

Summary

There are expected negligible impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison with the No Action Alternative. Under the four phases of Alternative 2 compared to the No Action Alternative, flows are likely adequate for the small proportion of the population that emigrate as kelts in Clear Creek. Water temperatures above the three temperature criteria for kelts are not anticipated to change in frequency in Clear Creek below Whiskeytown Dam under the four phases of Alternative 2 in comparison to the No Action Alternative.

O.5.10.3 Lower American River

Spawning and Egg Incubation

In the lower American River, redd surveys have reported spawning January through mid-April, with peak spawning in February (Sweeney et al. 2021). The median months of spawning from 2002-2021 were from January through March. Redd surveys on the lower American River do not occur until the first week of January, and there are reports from the Sacramento Water Forum (2015) that indicate spawning starts in late December. Therefore, the timing window of spawning on the lower American River was analyzed from late December until March.

Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional 2-4 weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). On the lower American River, egg incubation starts in late December and ends in late May, with peak incubation between February and April (Hannon pers. comm. 2023; Sacramento Water Forum 2015).

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

Under the four phases of Alternative 2, lower American River steelhead mean spawning WUA is highest in critically dry water years and steadily falls with wetter year types (Attachment M.3, *American River Weighted Usable Area Analysis*). This pattern of variation occurs because streamflows during the January through March spawning season of steelhead under the four phases of Alternative 2 rise from dry to wetter water year types (Table O-226 through Table O-229). The lower American River steelhead spawning WUA curve peaks at about 2,000 cfs (Attachment M.3, *American River Weighted Usable Area Analysis*) and flows under the four phases of Alternative 2 are consistently well above this level in the wetter water years. February flows are especially high in all but critically dry water years and consequently February shows the lowest spawning WUAs (Attachment M.3, *American River Weighted Usable Area Analysis*). Mean spawning WUA is consistently lower under the four phases of Alternative 2 than under the No Action Alternative, but the differences are small, ranging from 0.3% lower under Alternative 2 Without TUCP Systemwide VA in wet water years to 4.4% lower under the same phase of Alternative 2 in critically dry water years (Attachment M.3, *American River Weighted Usable Area Analysis*).

The results of the SIT LCM habitat model for the four phases of Alternative 2 are generally the same as those described above, showing small decreases (1.1- 2.7%) in spawning habitat in comparison to the results for the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

Overall, the results indicate that mean spawning WUA for steelhead under the four phases of Alternative 2 is lower than under the No Action Alternative, but all reductions are small.

Redd Dewatering Analysis

The results of the analysis for redd dewatering potential for lower American River steelhead indicate that redd dewatering is much greater in wetter water years than in drier water years for

the four phases of Alternative 2 (Attachment M.1, *American River Redd Dewatering Analysis*). This difference reflects the greater frequency of larger flow fluctuations in wetter years. Redd dewatering potential is consistently similar or higher under the four phases of Alternative 2 than under the No Action Alternative, except for a 15.3% reduction for Alternative 2 Without TUCP Systemwide VA, and the percent difference increases from wet to dry or critically dry water years (Attachment M.1, *American River Redd Dewatering Analysis*). The differences range from essentially no differences in wet years for all four phases to a 40.0% increase for Alternative 2 Without TUCP Without VA in critically dry water years. This increase, although large in relative terms, corresponds to an absolute change of only 1.8%. For the individual months of steelhead spawning in the lower American River, redd dewatering potential is highest and most variable in February for both the No Action Alternative and the four phases of Alternative 2 (Attachment M.1, *American River Redd Dewatering Analysis*). This occurs because flows during the two-month incubation period following February spawning exhibit greater declines Table O-226Table O-229).

Overall, the results indicate that the four phases of Alternative 2 increase in redd dewatering potential of steelhead relative to the No Action Alternative. The increases are especially large for dry and critically dry years, although on an absolute difference scale the largest difference is 31.8%.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 20 for Hazel Avenue and Table 22 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold for spawning adults during December through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 24 for Hazel Avenue and Table 26 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 40 for Hazel Avenue and Table 42 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold during December through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 44 for Hazel Avenue and Table 46 for Watt Avenue.

Results for the four analyses are summarized in Table O-56. Table O-56, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.13.3.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 45°F to 55°F range for successful spawning there were there were no month-water year type combinations (0%) with favorable or unfavorable results at both Hazel Avenue and Watt Avenue (Table O-56). For the 59.9°F spawning pathogen virulence threshold, there were no month-water year type combinations (0%) with favorable or unfavorable results at both Hazel Avenue and Watt

Avenue. For the 45°F to 52°F range for optimal egg incubation there were one and two month-water year type combinations (3.3% and 6.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were no month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 59.9°F fry pathogen virulence threshold there were zero and one month-water year type combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and zero month-water year type combinations (3.3% and 0%, respectively) unfavorable results at Hazel Avenue and Watt Avenue, respectively.

- Under **Alternative 2 Without TUCP Without VA** for the 45°F to 55°F range for successful spawning there were there were zero month-water year type combinations (0%) with favorable or unfavorable results at both Hazel Avenue and Watt Avenue (Table O-56). For the 59.9°F spawning pathogen virulence threshold, there were zero month-water year type combinations (0%) with favorable or unfavorable results at both Hazel Avenue and Watt Avenue. For the 45°F to 52°F range for optimal egg incubation there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue. There were zero and one month-water year type combinations (0% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold there were zero month-water year type combinations (0%) with both favorable and unfavorable results at Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Delta VA** for the 45°F to 55°F range for successful spawning there were zero month-water year type combinations (0%) with both favorable and unfavorable results at Hazel Avenue and Watt Avenue (Table O-56). There were zero and one month-water year type combinations (0% and 5%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F spawning pathogen virulence threshold, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue. For the 45°F to 52°F range for optimal egg incubation there was one and zero month-water year type combinations (3.3% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and zero month-water year type combinations (3.3% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold there were zero and one month-water year type combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water year type combinations (6.7% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 45°F to 55°F range for successful spawning there were zero month-water year type combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-56). There were zero and one month-water year type combinations (0% and 5%, respectively), with unfavorable results at both Hazel Avenue and Watt Avenue, respectively. For the 59.9°F spawning pathogen virulence threshold, there were zero month-water year type combinations (0%) with favorable or unfavorable results at both Hazel Avenue and Watt Avenue. For the 45°F to 52°F range for optimal egg incubation there was one month-

water year type combination (3.3%) with favorable results at both Hazel Avenue and Watt Avenue,. There were one and zero month-water year type combinations (3.3% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold there were zero and one month-water year type combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water year type combinations (6.7% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, the four phases of Alternative 2 would have similar positive (3.3% - 6.7% favorable) and negative (3.3% - 6.7% unfavorable) water temperature-related effects to steelhead spawning and egg incubation in the lower American River.

Summary

There are expected minor adverse and minor beneficial impacts of seasonal operations on steelhead spawning and egg incubation in the lower American River based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are expected to have a minor decrease on spawning habitat area and a minor increase of redd dewatering potential. Water temperatures above the four spawning and egg incubation criteria have similar increases and decreases in frequency in the lower American River.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Yearling rearing is year-round in the lower American River. Young of the year fry rearing is from February through May (Sacramento Water Forum 2015). The timing of juvenile outmigration depends on the watershed and water year. The RST monitoring station in the lower American River indicates outmigration into the Sacramento River with median passage starting in January and ending in May, with peak passage between March and May (Day 2022a).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During steelhead rearing in the lower American River, the mean monthly flows under the four phases of Alternative 2 compared to the No Action Alternative are reduced in the late summer and fall, and increased some months in the spring under critically dry water year types, which may alter their rearing habitat (Table O-230 through Table O-233; Table O-226 through Table O-229). Reductions under Alternative 2 are anticipated in September through November of critically dry years when flows are below 1,000 cfs. The greatest increase in flows under Alternative 2 occur in April of a critically dry water year type (up to 1321% in the lower American River at H St) which may benefit young of the year steelhead fry rearing, but flows are expected to decrease in February and May (10-30%) under the same water year type. The greatest reduction occurs in May of a critically dry water year type (27% in the lower American River at H St).

The CalSim 3 simulated flow results suggest that changes in flow in the lower American River under the four phases of Alternative 2 compared to the No Action Alternative may have a minor adverse and a minor beneficial effect on both juvenile and fry rearing habitat during critically dry water year types. There are no reliable estimates for steelhead juvenile rearing habitat using weighted usable area analyses. USFWS 1985 derives spawning and rearing weighted usable area on fall-run Chinook salmon, but this study did not assess steelhead and has not been peer reviewed.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 48 for Hazel Avenue and Table 50 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F rearing and outmigration pathogen virulence threshold year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 52 for Hazel Avenue and Table 54 for Watt Avenue. Full results of the analysis assessing water temperatures above the percent of months with water temperature above the 55°F limit of successful smoltification during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 56 for Hazel Avenue and Table 58 for Watt Avenue.

Results for the three analyses are summarized in Table O-57. Table O-57, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.13.3.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels, there were two and one month-water year type combinations (3.3% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-57). There were one and two month-water year type combinations (1.7% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F juvenile rearing and outmigration pathogen virulence threshold, there were zero and one month-water year type combinations (0% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There was one and zero month-water year type combinations (1.7% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 55°F limit of successful smoltification, there were one and zero month-water year type combinations (4% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Without VA** for the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels, there were four and one month-water year type combinations (6.7% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-57). There

were one month-water year type combinations (1.7%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 59.9°F juvenile rearing and outmigration pathogen virulence threshold, there was zero and one month-water year type combinations (0% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue. There were zero month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 55°F limit of successful smoltification, there were zero month-water year type combinations (0%) with favorable and unfavorable results at Hazel Avenue and Watt Avenue.

- Under **Alternative 2 Without TUCP Delta VA** for the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels, there were three and two month-water year type combinations (5% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-57). There were three and zero month-water year type combinations (5% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F juvenile rearing and outmigration pathogen virulence threshold, there was zero and one month-water year type combinations (0% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water year type combinations (3.3% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 55°F limit of successful smoltification, there were zero and one month-water year type combinations (0% and 4%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels, there was one month-water year type combination (1.7%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-57). There were three and zero month-water year type combinations (5.0% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F juvenile rearing and outmigration pathogen virulence threshold, there were zero and two month-water year type combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water year type combinations (3.3% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 55°F limit of successful smoltification, there were one and zero month-water year type combinations (4.0% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue.

Overall, the four phases of Alternative 2 would have similar positive (1.7% - 6.7% favorable) and negative (1.7% - 5% unfavorable) water temperature-related effects to steelhead juvenile rearing and emigration in the lower American River.

Summary

There are expected adverse and beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration in the lower American River based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under Alternative 2 in critically dry water year types, reductions in flows may decrease rearing habitat area (February, May, October through December) and increases in flows may increase rearing habitat area (March, April, and June). Water temperatures above the three juvenile rearing and emigration criteria have similar increases and decreases in frequency in the lower American River.

Adult Upstream Migration and Holding

Adult steelhead enter the San Francisco Estuary from the Pacific Ocean and will either spawn within a few months of entering freshwater or stage in pools for more extended periods until the first high flows (Moyle 2002; Williams 2006). In the lower American River, adult steelhead migration may occur as early as July and through early April, with peak abundance in January and February (Sacramento Water Forum 2015; Hallock 1989; Hallock et al. 1957).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Flows in the lower American River below Nimbus Dam will be lower under the four phases of Alternative 2 compared to the No Action Alternative during the initial months of steelhead adult migration and holding, but are expected to be similar during peak migration (Table O-226 through Table O-233). Peak steelhead adult migration in the lower American River occurs between January and February (Sacramento Water Forum 2015), when flows are expected to be less than a 18% increase or decrease under the four phases of Alternative 2 across all water year types. The largest reductions in flow under the four phases of Alternative 2 for peak adult migration occur in January of critically dry water year types, but flows are expected to be above 1,000 cfs during this period. Throughout the adult migration period, November has the greatest reductions in flow under Alternative 2, with an up to 21% reduction in critically dry water year types. Flows in October (and December in some phases) of critically dry water year types are expected to be below 1,000 cfs under Alternative 2 but are likely still adequate for adult migration. These results of the CalSim 3 simulated flows suggest that there may be a negligible impact of the four phases of Alternative 2 compared to the No Action Alternative on steelhead adult migration and holding in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range of minimal migration impairment for adult steelhead during July through April are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 8 for Hazel Avenue and Table 10 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through April are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 12 for Hazel Avenue and Table 14 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult upstream migration and holding pathogen virulence threshold during July through April are presented in Attachment M.2,

American River Water Temperature Analysis, Table 16 for Hazel Avenue and Table 18 for Watt Avenue.

Results for the three analyses are summarized in Table O-58. Table O-58, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.13.3.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead there were two and one month-water year type combinations (4.0% and 2.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-58). There were zero and one month-water year type combinations (0.0% and 2.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F upper lethal limit to adult migrants, there were two and zero month-water year type combinations (4.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero and three month-water year type combinations (0.0% and 6.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F adult upstream migration and holding pathogen virulence threshold, there were zero and one month-water year type combinations (0% and 2.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Without VA** for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead there were four and one month-water year type combinations (8.0% and 2.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-58). There was one month-water year type combination (2.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 69.8°F upper lethal limit to adult migrants, there were one and zero month-water year type combinations (2.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and two month-water year type combinations (2.0% and 4.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F adult upstream migration and holding pathogen virulence threshold, there were zero and one month-water year type combinations (0.0% and 2.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Delta VA** for the for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead there were three and two month-water year type combinations (6.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-58). There were one and zero month-water year type combinations (2.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F upper lethal limit to adult migrants, there were one and zero month-water year type combinations (2.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There

were zero and three month-water year type combinations (0.0% and 6.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F adult upstream migration and holding pathogen virulence threshold, there were zero and one month-water year type combinations (0.0% and 2.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead there was one month-water year type combination (2.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-58). There were two and zero month-water year type combinations (4.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F upper lethal limit to adult migrants, there were two and one month-water year type combinations (4.0% and 2.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero and four month-water year type combinations (0.0% and 8.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F adult upstream migration and holding pathogen virulence threshold, there were zero and two month-water year type combinations (0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at Hazel Avenue and Watt Avenue.

Overall, the four phases of Alternative 2 would have similar positive (2% - 8% favorable) and negative (2% - 8% unfavorable) water temperature-related effects to steelhead adult upstream migration and holding in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There are expected minor adverse and minor beneficial impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison with the No Action Alternative. Under Alternative 2 compared to the No Action Alternative, reductions in lower American River flows in dry and critically dry water year types may cause crowding and delays for adult migrants in October and November, but there are likely adequate flows during peak adult migration and holding. Water temperatures above all three temperature criteria both increase in frequency and decrease in frequency (2-8%) in the lower American River under the four phases of Alternative 2 in comparison to the No Action Alternative, depending on the location (Hazel Ave or Watt Ave).

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Flows in the lower American River below Nimbus Dam will be similar to or higher on average under the four phases of Alternative 2 compared to the No Action Alternative during steelhead kelt emigration period (Table O-226 through Table O-233). Peak kelt emigration is likely March through May when flows are expected to be adequate for emigration under Alternative 2. The largest changes between Alternative 2 and the No Action Alternative occur in critically dry water year types, with reductions in May (up to 24%) and increases in flow in March and April (up to 113%). These results of the CalSim 3 simulated flows suggest that there may be minor beneficial and minor adverse effects of Alternative 2 compared to the No Action Alternative to kelt emigration, but flows are likely adequate for kelt emigration.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F limit of migration impairment for steelhead kelt emigration during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 28 for Hazel Avenue and Table 30 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F lethal limit for steelhead kelt emigration during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 32 for Hazel Avenue and Table 34 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F kelt emigration pathogen virulence threshold during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 36 for Hazel Avenue and Table 38 for Watt Avenue.

Results for the three analyses are summarized in Table O-59. Table O-59, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.10.3.4, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without V**A for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-59). There was one month-water year type combination (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 69.8°F upper lethal limit to adult migrants, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue. For the 59.9°F kelt emigration pathogen virulence threshold, there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and zero month-water year type combinations (4.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Without VA** for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead, there were 0 month-water year type

combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue (Table O-59). For the 69.8°F upper lethal limit to adult migrants, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue. For the 59.9°F kelt emigration pathogen virulence threshold, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue, respectively.

- Under **Alternative 2 Without TUCP Delta VA** for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead, there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-59). There were two and zero month-water year type combinations (8.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F upper lethal limit to adult migrants, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F kelt emigration pathogen virulence threshold, there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water year type combinations (8.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead, there were zero month-water year type combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-59). There were one and zero month-water year type combinations (4.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F upper lethal limit to adult migrants, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue. For the 59.9°F kelt emigration pathogen virulence threshold, there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water year type combinations (8.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, the four phases of Alternative 2 would have positive (4% favorable) and negative (4% - 8% unfavorable) water temperature-related effects to steelhead kelt emigration in the lower American River at Hazel Avenue and Watt Avenue.

<u>Summary</u>

There are expected minor adverse and beneficial impacts of seasonal operations on steelhead kelts based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison with the No Action Alternative. Under Alternative 2 compared to the No Action Alternative, flows are likely adequate for kelt emigration. In the lower American River at Watt Ave and Hazel Ave, there are adverse and beneficial water temperature impacts (less than 8% favorable/unfavorable).

O.5.10.4 Bay-Delta

Juvenile Rearing and Emigration

While juvenile steelhead can be found in all waterways of the Delta, they are seen more frequently in the main channels to their natal river systems (National Marine Fisheries Service 2009a). The San Francisco Estuary is used as a short-term outmigration corridor for juvenile steelhead but the propensity of rearing in the Delta is currently unknown (Hayes and Kocik 2014, Chapman et al. 2015, Buchanan et al. 2021). The USFWS monitoring programs (Sacramento beach seines, Sacramento trawl, and Knight's Landing RST) indicate outmigration timing from the Sacramento River with first median passage in January and last median passage in May (Columbia Basin Research, University of Washington 2024). Outmigration from the San Joaquin River is monitored through the Mossdale Trawl, and median passage is April through May (Columbia Basin Research, University of Washington 2024).

Potential Changes to Steelhead from Seasonal Operations

Zone of Influence

Differences in hydrology under the four phases of Alternative 2 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions.

With incremental decreases in OMR under all four phases of Alternative 2 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under the four phases of Alternative 2 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2, *Zone of Influence*).

Flow into Junctions

For a detailed description of how flows under the four phases of Alternative 2 may impact the flow at Head of Old River and CVP, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2, *Flow into Junctions*).

Under all four phases of Alternative 2 and for most OMR bins except -3,500, the predicted proportion of flow entering the CVP is less than the No Action Alternative, although the predicted difference was negligible (up to ± 0.0467 for Alternative 2 Without TUCP Delta VA). Exceptions include the -2,000 OMR bin, with slightly greater change in predicted proportion of flow into CVP for Alternative 2 With TUCP Without VA (-0.069) or Alternative 2 Without TUCP Without VA (-0.0631) indicating that slightly less flow will be routed into CVP under these conditions compared to the No Action Alternative.

Under all four phases of Alternative 2 and for all OMR bins, the predicted differences in proportion of flow entering the HOR compared to the No Action Alternative are negligible (either positive or negative, but always lower than ± 0.008),

Summary

Alternative 2 relative to the No Action Alternative is expected to influence flow into the HOR and CVP junctions due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impact on flow into HOR while differences at CVP are best described between phases of Alternative 2 with and without VA due to differences in flow: Alternative 2 With TUCP Without VA and without TUCP Without VA are expected to have slightly less flow into CVP at OMR -2,000 and Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA are expected to have negligible impacts on flow into CVP. Impacts of pumping under Alternative 2 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Steelhead

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on juvenile steelhead entrainment at the Delta Fish Collection Facilities.

Salvage Density and Negative Binomial

- **Alternative 2 With TUCP Without VAs**
    - Predictions from the salvage density and the negative binomial model for steelhead include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of steelhead at SWP Banks Pumping Plant for all the months December through April of all water year types Alternative 2 With TUCP Without VAs was lower or equal to predicted average monthly loss under the No Action Alternative, except for critically dry water year types with an increase in predicted loss of 2%. Predicted average monthly loss of steelhead at Banks was lower for the wet, above normal, and below normal water year types with up to a 3% reduction in predicted loss for the below normal water year types. (Table O-60). Predicted average monthly loss of steelhead at CVP Jones Pumping Plant for all the months October through April for Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for the above normal and dry water year types, with up to a 6% increase in predicted loss for the above normal water year types. For wet, above normal, and the critically dry water year type Alternative 2 With TUCP Without VAs had a lower predicted loss for steelhead at Jones compared to the No Action Alternative with up to a 5% reduction in predicted loss for the critically dry water year types (Table O-61). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.
    - Predicted average monthly salvage of juvenile steelhead at the Delta fish collection facilities for the months of December through June under Alternative 2 With TUCP Without VAs was greater than predicted loss under the No Action Alternative for most water year types, with up to 41% increase for the above

normal water year types. For the critically dry water year types, predicted loss of steelhead at Jones had a reduction of 4% for Alternative 2 With TUCP Without VAs as compared to the No Action Alternative (Table O-62). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.

- **Alternative 2 Without TUCP Without VAs**
    - Predictions from the salvage density model for steelhead include mean monthly total exports. Predictions from the negative binomial loss model for steelhead include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of steelhead at SWP Banks Pumping Plant for all the months December through April and all water year types Alternative 2 Without TUCP Without VAs was lower or equal to predicted average monthly loss under the No Action Alternative, with up to a 5% decrease in predicted loss for the critically dry water year types (Table O-60). Predicted average monthly loss of steelhead at CVP Jones Pumping Plant for all the months October through April for Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for the above normal and critically dry water year types, with up to a 6% increase in predicted loss for the above normal water year types. For wet, below normal, and dry water year type Alternative 2 Without TUCP Without VAs had a lower or equal predicted loss for steelhead at Jones compared to the No Action Alternative with up to a 3% reduction in predicted loss for the below normal water year types (Table O-61). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.
    - Predicted average monthly salvage of juvenile steelhead at the Delta fish collection facilities for the months of December through June under Alternative 2 Without TUCP Without VAs was greater than predicted loss under the No Action Alternative for most water year types, with up to 36% increase for wet water year types. For the critically dry water year types, predicted loss of steelhead at Jones had a reduction of 11% for Alternative 2 Without TUCP Without VAs as compared to the No Action Alternative (Table O-62). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.
- **Alternative 2 Without TUCP With Delta VAs**
    - Predictions from the salvage density and the negative binomial model for steelhead include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.

- Predicted average monthly loss of steelhead at SWP Banks Pumping Plant for all the months December through April and all water year types Alternative 2 Without TUCP with Delta VAs was lower than predicted average monthly loss under the No Action Alternative, with up to a 8% decrease in predicted loss for the critically dry water year types (Table O-60). Predicted average monthly loss of steelhead at CVP Jones Pumping Plant for all the months October through April for Alternative 2 Without TUCP with Delta VAs was lower than predicted average monthly loss under the No Action Alternative for the wet, below normal and dry water year types, with up to a 4% decrease in predicted loss for the below normal water year types. For above normal, and critically dry water year type Alternative 2 Without TUCP with Delta VAs had a increase in predicted loss for steelhead at Jones compared to the No Action Alternative with up to a 7% increase in predicted loss for the above normal water year types (Table O-61). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of juvenile steelhead at the Delta fish collection facilities for the months of December through June under Alternative 2 Without TUCP with Delta VAs was greater than predicted loss under the No Action Alternative for wet and above normal water year types, with up to a 25% increase for wet water year types. For the below normal, dry, and critically dry water year types, predicted loss of steelhead at Jones was lower, with a reduction of up to 18% for dry water year types for Alternative 2 Without TUCP with Delta VAs as compared to the No Action Alternative (Table O-62). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.

- **Alternative 2 Without TUCP Systemwide VAs**

  - Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.

  - Predicted average monthly loss of steelhead at SWP Banks Pumping Plant for all the months December through April and all water year types Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly loss under the No Action Alternative, with up to a 8% decrease in predicted loss for the critically dry water year types (Table O-60). Predicted average monthly loss of steelhead at CVP Jones Pumping Plant for all the months October through April for Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly loss under the No Action Alternative for the wet, below normal and dry water year types, with up to a 4% decrease in predicted loss for the below normal water year types. For above normal, and critically dry water year type Alternative 2 Without TUCP Systemwide VAs had a increase in predicted loss for steelhead at CVP Jones Pumping Plant compared to the No Action Alternative with up to a 7% increase in predicted loss for the above normal water year types (Table O-61). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- Predicted average monthly salvage of juvenile steelhead at the Delta fish collection facilities for the months of December through June under Alternative 2 Without TUCP Systemwide VAs was greater than predicted loss under the No Action Alternative for wet water year types, with up to a 22% increase in predicted loss. For the above normal, below normal, dry, and critically dry water year types, predicted loss of steelhead at Jones was lower, with a reduction of up to 18% for dry water year types for Alternative 2 Without TUCP Systemwide VAs as compared to the No Action Alternative (Table O-62). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.

Summary

The results of the two entrainment models suggest adverse and beneficial impacts of exports under the four phases of Alternative 2 compared to the No Action Alternative, with increases and decreases in entrainment (depending on water year type), and the magnitude of the impacts varying between the two models. Differences in exports between the four phases of Alternative 2 and the No Action Alternative are expected to have moderate to substantial increases in steelhead loss in wetter water year types (22-36%) and moderate decreases in steelhead loss during drier water year types (12-18%) in the Delta at both fish facilities under the Negative Binomial model. Differences in exports between the four phases of Alternative 2 and the No Action Alternative are expected to have adverse and beneficial impacts (-8% to 7% difference) without a consistent trend with water year type on the entrainment of steelhead in the Delta at both fish facilities.

Potential Changes to Routing and Through Delta Survival of Steelhead

ECO PTM

For a detailed description of how flows under the phases of Alternative 2 may impact steelhead routing, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2).

Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under all four phases of Alternative 2 ranged from less than the No Action Alternative (up to 7% less under -5,000 cfs under Alternative 2 Without TUCP without VA and Alternative 2 With TUCP Without VA) to greater than the No Action Alternative (up to 9% greater under -3,500 cfs under Alternative 2 Without TUCP Delta VA) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in Attachment I.7, *ECO-PTM.* The decrease in routing to the Interior Delta could have a beneficial effect on outmigrating juveniles while the increase in routing could have an adverse impact on outmigrating juveniles.

Mean through-Delta percent survival December through March under the four phases of Alternative 2 were not as consistent among phases of Alternative 2 as ECO-PTM routing results were. Mean through-Delta survival under the phases with no VA, Alternative 2 Without TUCP Without VA and with TUCP Without VA, ranged from less than the No Action Alternative (up to 4% less under -2,000 cfs) to greater than the No Action Alternative (up to 4% greater under -5,000 cfs) (Attachment I.7, *ECO-PTM*). Mean through-Delta survival under the phases with VA, Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA, ranged from less than the No Action Alternative (up to 5% less under -3,500 cfs) to greater than the No Action Alternative (up to 18% greater under -2,000 cfs) (Attachment I.7, *ECO-PTM*). Survival through

Delta-specific routes is discussed further in the attachment. The increase in survival under some OMR conditions under phases of Alternative 2 with VA could have a large beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have an adverse impact on outmigrating juveniles.

Summary

The quantitative model suggests depending on considered variables, flows under Alternative 2 compared with the No Action Alternative may have minor adverse or minor beneficial impacts for outmigrating juvenile steelhead in the winter and spring, dependent on OMR grouping. Alternative 2 relative to the No Action Alternative is expected to have a possible adverse or beneficial impact on survival of outmigrating juvenile steelhead depending on OMR grouping due to differences in flow.

O.5.10.5 San Joaquin River

Juvenile Emigration

The San Joaquin River is primarily documented as an outmigration corridor for juvenile steelhead (Buchanan et al. 2021). Outmigration from the San Joaquin River into the Delta is monitored through the Mossdale Trawl, and median passage is April through May (Columbia Basin Research, University of Washington 2024). RSTs in the lower Stanislaus River, a tributary to the San Joaquin River, suggests juvenile emigration into the San Joan Joaquin River starts in January and ends in June (Day 2022b).

Potential Changes to Steelhead from Seasonal Operations

Changes in flows from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative may have a negligible effect on juvenile steelhead in the San Joaquin River. During the evaluated months in the juvenile emigration period, CalSim 3 estimates of mean monthly flows at Vernalis would generally be similar or increase under Alternative 2 compared to the No Action Alternative across all water year types (Table O-242 through Table O-245). Throughout the full simulation period, average flows will range from 3,472 to 6,459 cfs under Alternative 2 during juvenile emigration.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible effect on juvenile steelhead in the San Joaquin River. Under Alternative 2, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile emigration period (Figure O-15).

Summary

The results of these two simulation models indicate there are expected negligible impacts of seasonal operations on juvenile steelhead in the San Joaquin River under the four phases of Alternative 2 in comparison with the No Action Alternative.

Adult Upstream Migration and Holding

Steelhead/rainbow trout of anadromous parentage occur at low numbers in all three major San Joaquin River tributaries. These tributaries have a higher percentage of resident rainbow trout compared to the Sacramento River and its tributaries (Zimmerman et al. 2009). Estimates of

migrating adults in the San Joaquin River are made from the CDFW angler report cards and suggest that migration starts in July, peaks in December and January, and ends in March (California Department of Fish and Wildlife 2007).

Potential Changes to Steelhead from Seasonal Operations

Changes in flows from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative may have a minor beneficial effect on adult steelhead migration and holding in the San Joaquin River in critically dry water year types. During the evaluated months in the adult migration period, CalSim 3 estimates of mean monthly flows at Vernalis would increase from June through September of critically dry water year types under Alternative 2 compared to the No Action Alternative (Table O-242 through Table O-245). Throughout the full simulation period, average flows will range from about 1,400 to 6,500 cfs under the four phases of Alternative 2.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible effect on adult steelhead migration and holding in the San Joaquin River. Under Alternative 2, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the adult migration period (Figure O-15).

Summary

There are likely negligible to minor beneficial impacts of seasonal operations on adult steelhead migration and holding in the San Joaquin River based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison with the No Action Alternative.

O.5.10.6 Stanislaus River

Spawning and Egg Incubation

Data on steelhead spawning in the Stanislaus River is limited, but adults appear to spawn primarily from January to April. In 2021, as part of the reasonable and prudent measure to accelerate steelhead monitoring and research in the NMFS (2019) Biological Opinion, CDFW initiated the Stanislaus River Life Cycle Monitoring Program. Based on the initial redd survey report, which had a late start due to COVID-19 restrictions, spawning appears to start in February and last until April (Kok and Keller 2023). Although few steelhead spawning surveys have been conducted in the Stanislaus River, spawning *O. mykiss* has been documented upstream of the Highway 120 Bridge in Oakdale, between Goodwin Dam and the Oakdale Recreation Area.

Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional two to four weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In the Stanislaus River, timing can only be estimated and would be January through late May.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

The results for the four phases of Alternative 2 show consistent trends of reduction in mean spawning WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the shape of the steelhead spawning WUA curves (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which show reduced WUA with increased flow, except at the lowest and highest flows (less than about 200 cfs and greater than about 500 cfs, respectively). CalSim 3 mean monthly flows below Goodwin Dam, which is immediately upstream of the WUA study reach, are 200 cfs or above in all water year types, with flow consistently increasing from critically dry to wet water years during all months of the December through April steelhead spawning period, except December (Table O-234 through Table O-237). The mean spawning WUA estimates for all four phases of Alternative 2 are below those for the No Action Alternative in all water year types, ranging from 1.2% lower under Alternative 2 Without TUCP Without VA in wet water years to 6.6% lower for Alternative 2 With TUCP Without VA in below normal water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). The differences are generally small (<5%), which is expected because differences in the mean flow between the Phases of Alternative 2 and the No Action Alternative are relatively small (Table O-234 through Table O-237). For the individual months of the spawning period, spawning WUA is lower under the four phases of Alternative 2 than under the No Action Alternative during December through March, but is higher in April (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

The results of the SIT LCM model for four phases of Alternative 2 are somewhat different from those described above for the WUA analysis, showing increases in spawning habitat acreage for February through April and slight decreases in January (3.5-4.4) in comparison to the results for the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The increases for April are large (12.4%). The differences between these results and those of the spawning WUA analysis described above may be related to differences in how the results of the spawning WUA from the different spawning reaches were combined (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

Overall, the results indicate that mean spawning WUA for steelhead under the four phases of Alternative 2 is similar to or lower than that under the No Action Alternative, but most reductions are small, while results for the SIT spawning habitat analysis show little change except for large increases in April.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 16 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold for spawning adults during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 18 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis s*, Table 32

for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 54°F index value for egg incubation during December through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis,* Table 34 Full results of the analysis assessing the percent of months with water temperature above the 59.9°F fry pathogen virulence threshold during December through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 36 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-63. Table O-63, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.10.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 45°F to 55°F range for successful spawning, there were zero month-water year type combinations (0.0%) with favorable results and one month-water year type combination (3.3%) with unfavorable results at Orange Blossom Bridge (Table O-63). For the 59.9°F spawning pathogen virulence threshold, there were zero month-water year type combinations (0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 45°F to 52°F range for optimal egg incubation analysis, there was one month-water year type combination (2.5%) with favorable results and two month-water year type combinations (5.0%) with unfavorable results at Orange Blossom Bridge. For the 59.9°F fry pathogen virulence threshold analysis, there were zero month-water year type combinations (0.0%) with favorable and one month-water year type combination (2.5%) with unfavorable results at Orange Blossom Bridge.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-63).

Overall, the four phases of Alternative 2 would have similar negligible water temperature-related effects to steelhead spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

<u>Summary</u>

There are expected minor adverse and minor beneficial impacts of seasonal operations on steelhead spawning and egg incubation in the Stanislaus River based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are expected to have a minor increase and/or decrease in spawning habitat area. Water temperatures outside the spawning and egg incubation criteria are expected to have negligible increases in frequency the Stanislaus River at Orange Blossom Bridge.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in the Stanislaus River. The timing of juvenile outmigration depends on the watershed and water year. RST in the lower Stanislaus River suggests juvenile emigration into the San Joan Joaquin River starts in January and ends in June (Day 2022b).

Potential Changes to Steelhead from Seasonal Operations

Rearing Habitat—WUA Analyses

The results fry rearing WUA under the four phases of Alternative 2 generally show similar mean WUA for critically dry and dry water year types and small reductions for wetter years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the steelhead fry WUA curves (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which show moderately reduced WUA with increased flow, especially in the two longest river segments, Orange Blossom Bridge and Riverbank. Mean fry rearing WUA under the four phases of Alternative 2 is similar to that for the No Action Alternative in all water year types, ranging from 1.3% lower for critically dry water years in three of the four phases of Alternative 2 to 3.2% higher for dry water years under all four phases of Alternative 2 (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For all four months of the fry rearing period, median rearing WUA is roughly similar or moderately higher under the four phases of Alternative 2 relative to the No Action Alternative (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

The results for juvenile rearing WUA under the four phases of Alternative 2 show minor increases in mean rearing WUA from critically dry to wet water year types, except for very small reductions from below normal to above normal water year types for all four phases of Alternative 2 (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Mean juvenile rearing WUA under the four phases of Alternative 2 is higher than that under the No Action Alternative in all water year types, but the differences are small, ranging from 0.2% for wet water years under Alternative 2 Without TUCP Without VA to 2.1% or 2.2% for critically dry water years under all four phases of Alternative 2. Juveniles rear year-round and juvenile rearing WUA is highest for all four phases of Alternative 2 in February, April, and May (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in median rearing WUA between the four phases of Alternative 2 and the No Action Alternative are small in most months, but the medians are lower for all phases of Alternative 2 in January and are much higher in February.

The SIT LCM habitat model provides rearing habitat results for all juveniles, not separating out the fry stage from older juveniles. The instream juvenile rearing habitat results for the four phases of Alternative 2 are similar to those described above for juvenile rearing WUA. The SIT LCM habitat model results for the four phases of Alternative 2 show minor reductions and increases, depending on the month, in rearing habitat acreages from the No Action Alternative, ranging from 0.6% lower for Alternative 2 With TUCP With Systemwide VA in June to 5.4-5.6% higher for all four phases of Alternative 2 in February (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The differences in the results from the different analyses may be related to differences in how the habitat results from the different juvenile rearing reaches were combined in the analyses.

Overall, the results indicate that mean fry and juvenile rearing WUA for steelhead is largely similar under the four phases of Alternative 2 to the means under the No Action Alternative. The results from the SIT habitat model provide similar results, showing small differences in rearing habitat between the four phases of Alternative 2 and the No Action Alternative.

Rearing Habitat—ASH Analyses

The Area of Suitable Habitat (ASH) estimates for fry and juvenile rearing varied consistently with water year type for both fry and juvenile steelhead, increasing from critically dry to wet years. This pattern of variation reflects the overall relationship between flow and ASH for both life stages determined from modeling and field studies (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in both fry and juvenile rearing ASH between the four phases of Alternative 2 and the No Action Alternative are small, which is largely consistent with the results of the rearing WUA analyses. For fry rearing, the differences in mean ASH range from 2.6% lower for dry water years under all four phases of Alternative 2 to 1.8% higher for critically dry water years under all phases of Alternative 2 except Alternative 2 With TUCP Without VA. For juvenile rearing, all differences in mean ASH are less than 0.4%, except for 2.0% to 2.4% increases in mean juvenile rearing ASH for critically dry water years under the four phases of Alternative 2 (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the rearing periods, the medians for fry rearing ASH are lower under the four phases of Alternative 2 than under the No Action Alternative in April, and there is little difference for the other months, while for juvenile rearing ASH, the medians are lower in January and April and higher in February and roughly the same in the other months (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

Overall, the results indicate that mean fry and juvenile rearing ASH for steelhead is largely similar under the four phases of Alternative 2 to the means under the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimal growth without food limitation year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 38 for Orange Blossom Bridge and Table 40 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 42 for Orange Blossom Bridge and Table 44 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperatures above the 55°F limit of successful smoltification during January through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 48 for Orange Blossom Bridge and Table 50 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-64. Table O-64, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.10.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 66.2°F upper limit of optimal growth without food limitation, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-64). There were zero and two month-water year type combinations (0.0% and 3.3%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 59.9°F juvenile pathogen virulence threshold, there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River. There were one and three month-water year type combinations (1.7% and 5.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 55°F limit of successful smoltification, there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. There were one and zero month-water year type combinations (4.0% and 0.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-64).

Overall, the four phases of Alternative 2 would have similar negligible water temperature-related effects to steelhead spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge and above the confluence of the San Joaquin River.

Summary

There are expected adverse and beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under the four phases of Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are expected to have minor increases and decreases in fry and juvenile rearing habitat area across all water year types in the analyses in Attachment N.1, *Stanislaus River Habitat Availability Analysis* and increases and decreases in juvenile rearing habitat area depending on the month in the analyses in Attachment O.2, *CVPIA SIT LCM Habitat Estimates*. Water temperatures above the three juvenile rearing and emigration criteria are expected to have negligible increases in frequency in the Stanislaus River under the four phases of Alternative 2.

Adult Upstream Migration and Holding

In the Stanislaus River, *O. mykiss* greater than 16 inches have been seen migrating upstream through video monitoring as early as September and throughout March and can be recovered in the RST in Oakdale from November through April (Hellmair 2022; Eschenroeder et al. 2022).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Average flows in the Stanislaus River below Goodwin Dam are expected to be similar or increased during September through March under the four phases of Alternative 2 compared to the No Action Alternative (Table O-234 through Table O-241). The largest reduction in flow under Alternative 2 is a 33% decrease in January of an above normal water year type (Alternative 2 without TUCP Delta VA). The largest increase in flow under Alternative 2 is a 46% increase in February of a dry water year type (Alternative 2 without TUCP Delta VA). Average flows are expected to be lowest in September and November under the No Action Alternative and Alternative 2 during the adult migration and holding period. The major differences between the No Action Alternative and Alternative 2 in these two months are a 17% increase in below normal water year types and a 42% increase critically dry water year types in September under Alternative 2 at the mouth of the Stanislaus River.

These results of the CalSim 3 simulated flows suggest that there may be a minor beneficial effect of Alternative 2 compared to the No Action Alternative on steelhead adult migration and holding in the Stanislaus River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range of minimal migration impairment for adult steelhead during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 4 for Orange Blossom Bridge and Table 6 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 8 for Orange Blossom Bridge and Table 10 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult upstream migration and holding pathogen virulence threshold during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 12 for Orange Blossom Bridge and Table 14 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-65. Table O-65, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.10.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead, there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River (Table O-65). There were also zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River. For the 69.8°F upper lethal limit to adult migrants there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San

Joaquin River. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River. For the 59.9°F adult upstream migration and holding pathogen virulence threshold there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River.

- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-65).

Overall, the four phases of Alternative 2 would have similar negligible water temperature-related effects to steelhead adult upstream migration and holding in the Stanislaus River at Orange Blossom Bridge and above the confluence of the San Joaquin River.

Summary

There are expected minor beneficial impacts of seasonal operations in the Stanislaus River on adult steelhead based on analyses of simulated flows and water temperature under the four phases of Alternative 2 compared to the No Action Alternative. Under Alternative 2 compared to the No Action Alternative, there are potential minor beneficial impacts of increased flow in the fall for adult migration and holding for drier water year types. Water temperatures outside the range or above the adult migration and holding criteria are not anticipated to increase or decrease in frequency under Alternative 2 compared to the No Action Alternative.

Kelt Emigration

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Average flows in the Stanislaus River below Goodwin Dam are expected to be similar during kelt emigration under the four phases of Alternative 2 compared to the No Action Alternative, with a minor increase in February and a minor decrease in April (Table O-234 through Table O-241). The largest reduction in flow is a 21% decrease under Alternative 2 in April of a below normal water year type. The largest increase in flow is a 46% increase under Alternative 2 in February of a dry water year type. Flows are expected to be lowest in February and March of drier water year types under the No Action Alternative and Alternative 2. The largest differences in these two months are 43-46% increases in February of dry and critically dry water year types under Alternative 2.

These results of the CalSim 3 simulated flows suggest that there are anticipated minor beneficial effects of the four phases of Alternative 2 compared to the No Action Alternative on steelhead kelt emigration in the Stanislaus River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F limit of migration impairment for steelhead kelt emigration during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 20 for Orange Blossom Bridge and Table 22 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F lethal limit for steelhead kelt emigration during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 24 for Orange Blossom Bridge and Table 26 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F kelt emigration pathogen virulence threshold during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 28 for Orange Blossom Bridge and Table 30 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-66. Table O-66, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.10.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 66.2°F limit of migration impairment for steelhead kelt emigration, there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-66). There were zero and two month-water year type combinations (0.0% and 8.0%, respectively) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 69.8°F lethal limit for steelhead kelt emigration there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River. For the 59.9°F kelt emigration pathogen virulence threshold there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River. There were one and three month-water year type combinations (4.0% and 12.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-66).

Overall, the four phases of Alternative 2 would have negative water temperature-related effects on California central valley steelhead kelt emigration in the Stanislaus River.

Summary

There are expected minor to moderate adverse and minor beneficial impacts of seasonal operations in the Stanislaus River on steelhead kelts based on analyses of simulated flows and water temperature under the four phases of Alternative 2 compared to the No Action Alternative. Under Alternative 2 compared to the No Action Alternative, there are potential minor beneficial impacts of flow for kelt emigration. Water temperatures above the limit of migration impairment and pathogens and disease threshold are expected to increase in frequency under Alternative 2 compared to the No Action Alternative.

O.5.11 Southern DPS Green Sturgeon

O.5.11.1 Sacramento River

Spawning and Egg Incubation

Southern DPS green sturgeon adults spawn primarily from April through July, although they periodically spawn in late summer and fall (as late as October). Northern DPS green sturgeon eggs hatch about a week after fertilization (at 60ºF), and incubation time of Southern DPS green sturgeon eggs is assumed to be similar (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). Because the incubation time for green sturgeon is so short, the effects analysis period for incubating eggs is considered to be the same as the spawning period, April through July, occasionally extending to October.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

CalSim 3 Flows

During the April through July green sturgeon spawning period, CalSim 3 estimates of mean monthly flows at RBDD under all four phases of Alternative 2 range from about 5,000 cfs for April of critically dry water years to about 15,098 cfs for April of wet water years (Table O-186 through Table O-189). Mean flows during most of this period are moderate (~8,900 cfs to ~12,300 cfs) under all four phases of Alternative 2. Alternative 2 relative to the No Action Alternative is expected to have small negative effects most months (up to 10%), but flows are moderately higher for Alternative 2 Without TUCP Without VA, with Delta VA, and with Systemwide VA for April of critically dry water years (up to 25%) and for April of above normal and below normal water years under Alternative 2 Without TUCP with Systemwide VA (8%). Flows are moderately lower in June of critically dry water under all four phases of Alternative 2 (up to 8%), May of critically dry water years under all phases except Alternative 2 Without TUCP with Systemwide VA (up to 9%), and July of critically dry water years under Alternative 2 With TUCP Without VA (10%). Flows are also moderately lower under Alternative 2 Without TUCP with Systemwide VA in June of above normal, below normal, dry, and critical water years (Table O-186 through Table O-189). During the August through October period, when green sturgeon spawning occurs in occasional years, the flows under both alternatives and all phases tend to be lower than those in April through July, but the mean flows would be close to or above 6,500 cfs under all phases for all water year types in all three 3 months. Moderate reductions in mean flows from the No Action Alternative to Alternative 2 under all four phases are predicted for August and September of critically dry water years (up to 11%); however, a moderate increase in mean flows is predicted under Alternative 2 With TUCP Without VA in October of

critically dry years (8%) (Table O-186 through Table O-189). Flow levels during all spawning months under all four phases are likely to be suitable for green sturgeon spawning and egg incubation; no adverse effects are expected to result; effects may be beneficial in April of critically dry water years under three of the four phases of Alternative 2.

CalSim 3 simulations at Hamilton City predict minor reductions in mean flow under all phases of Alternative 2 during June and July of all water years. Generally, mean flows during the April through July spawning and egg incubation period are lower at Hamilton City than at RBDD but remain similar to the No Action Alternative (~7,500 cfs to ~17,600 cfs) (Table O-194 through Table O-197). Flows are predicted to moderately to substantially increase in April of critically dry water years (up to 26%) under all four phases of Alternative 2. During the August through October spawning period, the flows under both alternatives and all four phases tend to be lower than those in April through July. The mean flows for all water years in all three months under all phases are between ~6,200 cfs to ~7,400 cfs. Generally, flows during the August to October spawning period will remain similar under all four phases of Alternative 2 compared to the No Action Alternative (Table O-194 through Table O-197). If flows are not suitable for green sturgeon spawning at Hamilton City, they would likely move upstream until they find suitable flows, so effects of reduced flows under the four phases of Alternative 2 at Hamilton City are likely to be minor.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 49.3°F to 63.7°F range for spawning initiation during April through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 208 for Bend Bridge and Table 210 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 52.3°F to 60.8°F range supporting egg incubation during April through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 216 for Bend Bridge and Table 218 for Hamilton City.

Results for the three analyses are summarized in Table O-67. Table O-67, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP with VA** for the 49.3°F to 63.7°F spawning initiation range, there were zero and four month-water year type combinations (0% and 20.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-67). There were no combinations (0%) with unfavorable results below Bend Bridge and one combination (5%) with unfavorable results at Hamilton City. For the 52.3°F to 60.8°F range for egg incubation, there were no combinations (0%) with favorable or unfavorable results at both locations. These results suggest that there would be positive water temperature-related effects or negligible negative effects of Alternative 2 With TUCP with VA on green sturgeon spawning and egg incubation.

- Under **Alternative 2 Without TUCP Without VA** for the 49.3°F to 63.7°F spawning initiation range, there were zero and three month-water year type combinations (0% and 15.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-67). There were zero and one combinations (0% and 5.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. For the 52.3°F to 60.8°F range for egg incubation, there were zero combinations (0%) with favorable and unfavorable results at Bend Bridge and Hamilton City. These results suggest that there would be positive water temperature-related effects or negligible negative effects of Alternative 2 Without TUCP Without VA on green sturgeon spawning and egg incubation.
- Under **Alternative 2 Without TUCP Delta VA** for the 49.3°F to 63.7°F spawning initiation range, there were zero and five month-water year type combinations (0% and 25.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-67). There were zero and one combinations (0% and 5.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. For the 52.3°F to 60.8°F range for egg incubation, there were zero and one combinations (0% and 5.0%, respectively) with favorable results at Bend Bridge and Hamilton City, respectively. There were also zero and one combinations (0% and 5.0%, respectively) with unfavorable results Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive water temperature-related effects or negligible negative effects of Alternative 2 Without TUCP Delta VA on green sturgeon spawning and egg incubation.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 49.3°F to 63.7°F spawning initiation range, there were zero and four month-water year type combinations (0% and 20.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-67). There were zero and one combination (0% and 5%, respectively) with unfavorable results below Bend Bridge and Hamilton City, respectively. For the 52.3°F to 60.8°F range for egg incubation, there were zero and one combinations (0% and 5.0%, respectively) with favorable results at Bend Bridge and Hamilton City, respectively. There were zero combinations (0%) with unfavorable results at Bend Bridge and Hamilton City. These results suggest that there would be positive water temperature-related effects or negligible negative effects of Alternative 2 Without TUCP Systemwide VAs on green sturgeon spawning and egg incubation.

Overall, the four phases of Alternative 2 would have similar positive effects and negligible negative effects on water temperature conditions for green sturgeon spawning and egg incubation depending on phase, location, month, and water year type (Table O-67).

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts and possible beneficial impacts on spawning habitat depending on the Alternative 2 phase, location, month, and water year type due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have beneficial impacts and minor adverse impacts on spawning and egg incubation depending on location, month, and water year type due to differences in water temperature.

Larval and Juvenile Rearing and Emigration

The green sturgeon spawning period is from April through July, so the larval period is considered to be April through September. The green sturgeon juvenile stage begins when metamorphosis of the larva is complete, typically at about 45 days post hatch. The juveniles rear in the Sacramento River from about May through December. During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near the Cow Creek confluence to the Delta (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). Effects of flow and water temperature on green sturgeon larvae and juveniles may occur from April through December in the Sacramento River when analyzing the two life stages together.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

CalSim 3 Flows

CalSim 3 modeling for the Sacramento River at RBDD indicates that mean monthly flows during the April through September period of larval rearing are generally similar between the No Action Alternative and all four phases of Alternative 2 with a few exceptions. As described previously, moderately higher mean flows are predicted in April of the drier water year types under all four phases of Alternative 2. Under Alternative 2 With TUCP Without VA flows are predicted to moderately decrease in May through August of critically dry water years and under Alternative 2 Without TUCP with Systemwide VA flows are predicted to moderately decrease in June of all water year types except for wet water years (Table O-186 through Table O-189). Moderate increases in mean flow from No Action Alternative to Alternative 2 in April may not be substantial enough to have a positive effect on larval green sturgeon. The August and September reductions in flow from the No Action Alternative to Alternative 2 under all four phases would potentially affect green sturgeon larvae adversely because, as discussed in Section O.1.3.2.5, *Green Sturgeon, Southern DPS*, there appears to be a positive relationship between annual outflow and abundance of green sturgeon larvae and juveniles, but this conclusion is highly uncertain.

CalSim 3 modeling for the Sacramento River at Hamilton City indicates that mean monthly flows during the period of juvenile rearing and emigration, May through December, are generally similar between the No Action Alternative and all four phases of Alternative 2 except for higher flows under all phases of Alternative 2 during October and November in critically dry water years (Table O-194 through Table O-197). Reductions in flows occur in June (with TUCP Without VA and without TUCP with Systemwide VA), July (with TUCP Without VA), and September (without TUCP with Systemwide VA) of drier water years and in June (without TUCP with Systemwide VA) of above normal water years. These reductions in flow could adversely affect green sturgeon juveniles under the four phases of Alternative 2 because, as discussed in

Section O.1.3.2.5, *Green Sturgeon, Southern DPS*, there may be a positive relationship between annual outflow and abundance of green sturgeon, but this conclusion is highly uncertain.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 64.4°F upper threshold for larvae from May through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 220 for Bend Bridge and Table 222 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 66.2°F range of optimal juvenile bioenergetic performance during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 224 for Bend Bridge and Table 226 for Hamilton City.

Results for the three analyses are summarized in Table O-68. Table O-68, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 64.4°F upper water temperature limit for newly hatched larvae, there were zero and five month-water year type combinations (0% and 25.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-68). There were zero and one combinations (0% and 5%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. For the 59°F to 66.2°F range of optimal juvenile bioenergetic performance, there were zero and one combinations (0% and 6.7%, respectively) with favorable results at Bend Bridge and Hamilton City, respectively. There were five and zero combinations (33.3% and 0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive or negative water temperature-related effects of Alternative 2 With TUCP Without VA on green sturgeon larval and juvenile rearing and emigration depending on location, month, and water year type.
- Under **Alternative 2 Without TUCP Without VA** for the 64.4°F upper water temperature limit for newly hatched larvae, there were one and three month-water year type combinations (5% and 15.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-68). There were no combinations (0%) with unfavorable results at Bend Bridge and Hamilton City. For the 59°F to 66.2°F range of optimal juvenile bioenergetic performance, there were zero and one combinations (0% and 6.7%, respectively) with favorable results at Bend Bridge and Hamilton City, respectively. There were six and zero combinations (40.0% and 0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive or negative water temperature-related effects of Alternative 2 Without TUCP Without VA on green sturgeon larval and juvenile rearing and emigration depending on location, month, and water year type.

- Under **Alternative 2 Without TUCP Delta VA** for the 64.4°F upper water temperature limit for newly hatched larvae, there were zero and six month-water year type combinations (0% and 30.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-68). There were zero (0%) with unfavorable results at Bend Bridge and Hamilton City. For the 59°F to 66.2°F range of optimal juvenile bioenergetic performance, there were zero and one combinations (0% and 6.7%, respectively) with favorable results at Bend Bridge and Hamilton City, respectively. There were five and zero combinations (33.3% and 0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive or negative water temperature-related effects of Alternative 2 Without TUCP Delta VA on green sturgeon larval and juvenile rearing and emigration depending on location, month, and water year type.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 64.4°F upper water temperature limit for newly hatched larvae, there were zero and five month-water year type combinations (0% and 25.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-68). There were zero and one combinations (0% and 5.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. For the 59°F to 66.2°F range of optimal juvenile bioenergetic performance, there were zero and one combinations (0% and 6.7%, respectively) with favorable results at Bend Bridge and Hamilton City, respectively. There were five and zero combinations (33.3% and 0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 Without TUCP Systemwide VAs on green sturgeon larval and juvenile rearing and emigration.

Overall, the four phases of Alternative 2 would have similar positive effects and negative effects on water temperature conditions for green sturgeon larval and juvenile rearing and emigration (Table O-68).

Summary

Alternative 2 relative to the No Action Alternative is expected to have possible minor adverse impacts on rearing and emigration depending on Alternative 2 phase, location, month, and water year type due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have beneficial impacts and adverse impacts on rearing and emigration depending on location, month, and water year type due to differences in water temperature.

Adult Upstream Migration and Holding

Green sturgeon adults enter the Sacramento River from the Delta as early as February to make their way upstream to spawn in deep pools from the GCID oxbow (near Hamilton City) to the Cow Creek confluence. After spawning, the adults hold in the river for varying amounts of time, but typically emigrate back to the San Francisco Estuary and the ocean from about October through December (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). With the extended adult holding period, effects of flow and water temperature on adult upstream migration and holding may occur from February through December.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

CalSim 3 Flows

Flows during the February through December period of green sturgeon immigration, spawning and holding would generally be similar between Alternative 2 and the No Action Alternative at RBDD, Hamilton City, and Wilkins Slough (Table O-186 through Table O-197). Notable exceptions include substantially higher mean monthly flows under Alternative 2 at all three locations during April (without TUCP Without VA, without TUCP with Delta VA, and without TUCP with Systemwide VA) and November (all phases) of critically dry water years, and moderate flow reductions in summer months at RBDD during critically dry years for all phases (Table O-186 through Table O-197). Increases in mean flow from No Action Alternative to Alternative 2 in April and November may or may not be substantial enough to have a positive effect on larval green sturgeon. All of the more notable flow differences occur within a range of river flows (~3,000 cfs to 12,000 cfs) that are not expected to substantially affect upstream passage of migrating green sturgeon, but summer flow reductions under all phases of Alternative 2 at Hamilton City and RBDD could result in reduced habitat quality in holding pools, adversely affecting holding adults.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52°F to 69.4°F range for adult migration during April through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 204 for Bend Bridge and Table 206 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 52°F to 73.4°F range for adult holding year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 212 for Bend Bridge and Table 214 for Hamilton City.

Results for the two analyses are summarized in Table O-69. Table O-69 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%. If the exceedance or occurrence value was >10% lower under the alternative relative to the No Action Alternative, the result is termed "Favorable". If the exceedance or occurrence value was >10% higher under the alternative relative to the No Action Alternative, the result is termed "Unfavorable". The 10% value was chosen to represent a level of difference between the alternative and the No Action Alternative that could have a biologically meaningful effect on the species but considers the coarse definition in the data (e.g., a difference in just one of the 14 above normal water years represents a 7% difference). This value should not be interpreted as a significance threshold.

- Under **Alternative 2 With TUCP Without VA** for the 52°F to 69.4°F range for adult migration, there were no month-water year type combinations (0% of total combinations during the period, respectively) with favorable or unfavorable results at both Bend Bridge and Hamilton City, respectively (Table O-69). For the 59°F to 73.4°F range for adult holding, there were no combinations (0%) with favorable results at both Bend Bridge and Hamilton City. There were 12 and two combinations (20.0% and 3.3%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest

that there would be negative effects and negligible positive water temperature-related effects of Alternative 2 With TUCP Without VA on green sturgeon adult upstream migration and holding.

- Under **Alternative 2 Without TUCP Without VA**, for the 52°F to 69.4°F range for adult migration, there were no month-water year type combinations (0% of total combinations during the period, respectively) with favorable or unfavorable results at both Bend Bridge and Hamilton City, respectively (Table O-69). For the 59°F to 73.4°F range for adult holding, there were no combinations (0%) with favorable results at both Bend Bridge and Hamilton City. There were 13 and two combinations (21.7% and 3.3%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be negative water temperature-related effects of Alternative 2 Without TUCP Without VA on green sturgeon adult upstream migration and holding.
- Under **Alternative 2 Without TUCP Delta VA,** for the 52°F to 69.4°F range for adult migration, there were no month-water year type combinations (0% of total combinations during the period, respectively) with favorable or unfavorable results at both Bend Bridge and Hamilton City, respectively (Table O-69). For the 59°F to 73.4°F range for adult holding, there were no combinations (0%) with favorable results at both Bend Bridge and Hamilton City. There were 12 and one combinations (20.0% and 1.7%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be negative water temperature-related effects of Alternative 2 without TUCP Delta VA on green sturgeon adult upstream migration and holding.
- Under **Alternative 2 Without TUCP Systemwide VAs,** for the 52°F to 69.4°F range for adult migration, there were no month-water year type combinations (0% of total combinations during the period, respectively) with favorable or unfavorable results at both Bend Bridge and Hamilton City, respectively (Table O-69). For the 59°F to 73.4°F range for adult holding, there were one and zero month-water year type combinations (1.7% and 0%, respectively) with favorable results at Bend Bridge and Hamilton City, respectively. There were 12 and one combinations (20.0% and 1.7%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be negative water temperature-related effects of Alternative 2 without TUCP Systemwide VAs on green sturgeon adult upstream migration and holding are identical to Alternative 2 Without TUCP Without VAs (Table O-69).

Overall, the four phases of Alternative 2 would have similar negative effects on water temperature conditions for green sturgeon adult upstream migration and holding (Table O-69).

<u>Summary</u>

Alternative 2 relative to the No Action Alternative is expected to have possible beneficial impacts and adverse impacts on upstream migration and holding habitats depending on the Alternative 2 phase, location, month, and water year type due to differences in water temperature. Alternative 2 relative to the No Action Alternative is expected to have adverse impacts on upstream migration and holding depending on location, month, and water year type due to differences in water temperature.

O.5.11.2 San Joaquin River

Green sturgeon are also present in the San Joaquin River, but at considerably lower numbers than white sturgeon. Anglers have reported catching green sturgeon in the San Joaquin River and one adult green sturgeon was captured by Reclamation in April of 2020 (Root et al. 2020 [research note]). Although the reported presence of green sturgeon in the San Joaquin River coincides with the spawning migration period of green sturgeon within the Sacramento River, no evidence of spawning has been detected (Section O.1.8.2.3, *Green Sturgeon, Southern DPS*).

Potential Changes to Green Sturgeon from Seasonal Operations

CalSim 3 Flows

Since green sturgeon spawning has not been confirmed in the San Joaquin River, life stage analyses were not performed. It is assumed that adult green sturgeon could be in the San Joaquin River during all months of the year.

During the evaluated months, CalSim 3 estimates of mean monthly flows at Vernalis under all four phases of Alternative 2 range from about 673 cfs for July of critically dry water years with TUCP Without VA to over 13,000 cfs for February of wet water years with and without TUCP Without VA (Table O-242 through Table O-245). Generally, flows remain similar between The No Action Alternative and all four phases of Alternative 2. CalSim 3 results predict moderately to substantially increased flows under all four phases of Alternative 2 compared to the No Action Alternative for June through September of critically dry water years (up to 34% in July and August under all phases except Alternative 2 With TUCP Without VA) (Table O-242 through Table O-245). Increased flows are also predicted for July of above and below normal water years (up to 6%) under Alternative 2 Without TUCP with Systemwide VA (Table O-243). Because green sturgeon are uncommon in the San Joaquin River and can easily relocate to other parts of the Bay Delta system that have adequate flow, it is not anticipated that flow reductions under the four phases of Alternative 2 would have an effect on green sturgeon compared to the No Action Alternative. Increased flows predicted for the majority of the months may have a positive effect on adult green sturgeon.

Summary

Alternative 2 relative to the No Action Alternative is expected to have possible beneficial impacts on adult green sturgeon due to differences in flow. Due to the lack of information about green sturgeon life stages in the San Joaquin River, a temperature analysis was not done for this species in this geography.

O.5.11.3 Bay-Delta

Juvenile Rearing and Emigration

After hatching, larvae and juveniles migrate downstream toward the Delta. Juveniles are believed to use the Delta for rearing for the first one to three years of their lives before moving out to the ocean and are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, especially within the central Delta and Suisun Bay/Marsh (Section O.1.9.1.5, *Green Sturgeon, Southern DPS*).

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

Differences in hydrology in the Delta under the four phases of Alternative 2 compared with the No Action Alternative may have effects on flow routing into junctions and the hydrodynamic footprint of the export facilities. These possible differences were evaluated using several quantitative models which estimate the spatial extent of influence of exports under CVP and SWP diversions and estimate the proportion of flow entering a Delta junction: Zone of Influence and Flow into Junctions. In addition to these two analyses, a Delta Outflow vs. Sturgeon YCI regression analysis was done for the two sturgeon species to evaluate flow effects on sturgeon year class index.

Zone of Influence

Differences in hydrology under the four phases of Alternative 2 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions.

With incremental decreases in OMR under all four phases of Alternative 2 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under the four phases of Alternative 2 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2, *Zone of Influence*).

Flow into Junctions

Alternative 2 relative to the No Action Alternative may have effects on the flow into the Head of Old River and CVP junctions due to differences in flow. These possible differences were evaluated using DSM2-HYDRO outputs. For a detailed description of how flows under the four phases of Alternative 2 may impact the flow at Head of Old River and CVP, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2, Flow into Junctions).

Under all four phases of Alternative 2 and for most OMR bins except -3,500, the predicted proportion of flow entering the CVP is less than the No Action Alternative, although the predicted difference was negligible (up to ± 0.0467 for Alternative 2 Without TUCP Delta VA). Exceptions include the -2,000 OMR bin, with slightly greater change in predicted proportion of flow into CVP for Alternative 2 With TUCP Without VA (-0.069) or Alternative 2 Without TUCP Without VA (-0.0631) indicating that slightly less flow will be routed into CVP under these conditions compared to the No Action Alternative.

Under all four phases of Alternative 2 and for all OMR bins, the predicted differences in proportion of flow entering the HOR compared to the No Action Alternative are negligible (either positive or negative, but always lower than ± 0.008),

Delta Outflow vs. Sturgeon YCI

There are currently no tools available to directly evaluate the effect of spring outflow on green sturgeon thus white sturgeon are used as a proxy species for green sturgeon. To evaluate the effect of spring outflow on green sturgeon a Delta Outflow vs Year-Class Strength[1] regression analysis was done. This analysis is a response to the NMFS Green Sturgeon Recovery Plan that suggested larval abundance and distribution may be influenced by spring and summer outflow. The recovery plan also suggested that recruitment may be highest in wet years, making water flow an influential habitat parameter (National Marine Fisheries Service 2018a:12). As noted by NMFS (2018b:12), there are correlations between white sturgeon and Delta outflow, which have previously been used to infer potential effects on green sturgeon (ICF International 2016).

In contrast to white sturgeon, there are currently no quantitative relationships established between green sturgeon and Delta flows. There appears to be a positive relationship between annual outflow and abundance in RSTs at Red Bluff Diversion Dam of green sturgeon larvae and juveniles (Heublein et al. 2017a). More recently, CDFW found that catch per unit effort of yearling juvenile green sturgeon sampled in the Delta was about 10 times as high in years following wet water years as in years following dry and critically dry water years (Beccio 2021). These factors are generally suggestive of a positive relationship with flow, but it is uncertain the extent to which such effects may reflect water operations.

The Delta Outflow Year-Class Strength regression analysis found statistically significant positive correlations between white sturgeon year-class strength and Delta outflow for April-May and March-July. The analysis is used as a surrogate for green sturgeon. For the April-May Delta outflow, the average overall YCI values would be generally similar between the four phases of Alternative 2 (10.7 to 11.2) and the No Action Alternative (11.2) (Table O-70). The same is true for the March-July Delta outflow, with the average overall YCI values for the four phases of Alternative 2 ranging from 16.3 to 16.6 compared to 16.7 for the No Action Alternative (Table O-71). Any effects of Alternative 2 on green sturgeon relative to the No Action Alternative are expected to be limited given the limited differences in average Delta flow conditions between the two alternatives over all water year types during the specified months. For more detailed information see summaries presented in Attachment J.2*, Sturgeon Year Class Index and Delta Outflow*.

Summary

Alternative 2 relative to the No Action Alternative is expected to influence flow into the HOR and CVP junctions. Alternative 2 relative to the No Action Alternative is expected to have negligible impact on flow into HOR while differences at CVP are best described between phases of Alternative 2 with and without VA due to differences in flow: Alternative 2 With TUCP Without VA and without TUCP Without VA are expected to have slightly less flow into CVP at OMR -2,000 and Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA are expected to have negligible impacts on flow into CVP. Impacts of pumping under all four phases of Alternative 2 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of

[1] Year-class strength in this case is an index of year-class abundance based on age-0 and age-1 white sturgeon abundance indices from otter trawling by the San Francisco Bay Study (Fish 2010).

riverine flow and thus more susceptible to changes in pumping (ZOI). Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on juvenile green sturgeon year class strength using white sturgeon as a proxy for green sturgeon due to differences in flow.

Potential Changes to Entrainment of Southern DPS Green Sturgeon

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on green sturgeon entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

<u>Salvage Density</u>

- **Alternative 2 With TUCP Without VAs**
    - Predictions from the salvage density model for green sturgeon include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of green sturgeon at SWP Banks Pumping Plant for the months January, and March of all water year types Alternative 2 With TUCP Without VAs was greater than or equal to predicted average monthly loss under the No Action Alternative for the wet, dry, and critically dry water year types with up to 6% increase in predicted loss for wet water year types. For above normal, and below normal water year types Alternative 2 With TUCP Without VAs had a lower predicted loss of green sturgeon at Banks compared to the No Action Alternative with up to a 4% reduction in loss for the above normal water year types (Table O-72). Predicted average monthly loss of green sturgeon at CVP Jones Pumping Plant for all the months June through July Alternative 2 With TUCP Without VAs had equal or lower predicted average monthly loss compared to the No Action Alternative, with up to a 14% reduction in predicted loss for dry water year types (Table O-73). It should be noted that loss of green sturgeon at both facilities is rare and infrequent with such low values of predicted loss, that the percent differences may not be representative. For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.
- **Alternative 2 Without TUCP Without VAs**
    - Predictions from the salvage density model for green sturgeon include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of green sturgeon at SWP Banks Pumping Plant for the months January, and March of all water year types Alternative 2 Without TUCP Without VAs was less than or equal to predicted average monthly loss under the No Action Alternative for all water year types except for the wet water year type that had an increase of 7%. For all other water year types Alternative 2 Without TUCP Without VAs had a lower or equal predicted loss of green sturgeon

at Banks compared to the No Action Alternative with up to a 4% reduction in loss for the above normal water year types (Table O-72). Predicted average monthly loss of green sturgeon at CVP Jones Pumping Plant for all the months June through July Alternative 2 Without TUCP Without VAs had equal or lower predicted average monthly loss compared to the No Action Alternative, with up to a 13% reduction in predicted loss for dry water year types (Table O-73). It should be noted that loss of green sturgeon at both facilities is rare and infrequent, with such low values of predicted loss the percent differences may not be representative. For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

- **Alternative 2 Without TUCP With Delta VAs**
    - Predictions from the salvage density model for green sturgeon include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of green sturgeon at SWP Banks Pumping Plant for the months January, and March of all water year types Alternative 2 Without TUCP with Delta VAs was less than or equal to predicted average monthly loss under the No Action Alternative for all water year types except for the wet water year type that had an increase of 4%. For all other water year types Alternative 2 Without TUCP with Delta VAs had a lower or equal predicted loss of green sturgeon at Banks compared to the No Action Alternative with up to a 18% reduction in loss for the above normal water year types (Table O-72). Predicted average monthly loss of green sturgeon at CVP Jones Pumping Plant for all the months June through July Alternative 2 Without TUCP with Delta VAs had equal or lower predicted average monthly loss compared to the No Action Alternative for all water year types, with up to a 12% reduction in predicted loss for dry water year types (Table O-73).
- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for green sturgeon include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of green sturgeon at SWP Banks Pumping Plant for the months January, and March of all water year types Alternative 2 Without TUCP Systemwide VAs was less than or equal to predicted average monthly loss under the No Action Alternative for all water year types except for the wet water year type that had an increase of 3%. For all other water year types Alternative 2 Without TUCP Systemwide VAs had a lower or equal predicted loss of green sturgeon at Banks compared to the No Action Alternative with up to a 18% reduction in loss for the above normal water year types (Table O-72). Predicted average monthly loss of green sturgeon at CVP Jones Pumping Plant for all the months June through July Alternative 2 Without TUCP Systemwide VAs had

equal or lower predicted average monthly loss compared to the No Action Alternative for all water year types, with up to a 10% reduction in predicted loss for dry water year types (Table O-73). It should be noted that loss of green sturgeon at both facilities is rare and infrequent, with such low values of predicted loss the percent differences may not be representative. For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on the entrainment of juvenile green sturgeon at both facilities due to differences in flow. Results from the quantitative model show possible beneficial impacts, but since green sturgeon are salvaged so rarely, the numbers may not be representative.

Adult Upstream Migration and Holding

Adult green sturgeon move through the Delta from February through April to get to spawning locations in the upper Sacramento River. Following their initial spawning run upriver, adults split into two out migration groups, the "early" out migration group may migrate immediately back downstream through the Delta during May and June, or the "late" out migration group may hold for a few weeks to months in the upper river before moving back downstream during November through January (Section O.1.9.1.5, *Green Sturgeon, Southern DPS*).

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

Delta Outflow vs. Sturgeon YCI

The Delta outflow vs Sturgeon YCI regression analysis results apply to all life stages of green sturgeon found in the Bay Delta. The regression analysis, used as a surrogate for green sturgeon, found statistically significant positive correlations between white sturgeon year-class strength and Delta outflow for April-May and March-July. Under the four phases of Alternative 2, April-May Delta outflow average overall YCI values would be up to 4.7% lower (Table O-70) and the March-July Delta outflow values would be up to 2.2% lower (Table O-71) compared to the No Action Alternative. Refer to the analysis in Section O.5.11.3.1, *Larval and Juvenile Rearing and Emigration* and Attachment J.2, *Sturgeon Year Class Index and Delta Outflow*, for additional details.

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible flow-related impacts on adult green sturgeon year class strength using white sturgeon as a proxy for green sturgeon.

O.5.12 Delta Smelt

O.5.12.1 Bay-Delta

Adult Migration and Spawning

During winter, adult Delta smelt initiate upstream spawning migration in association with "first flush" flow events (Sommer et al. 2011). Others report this seasonal change as a multi-directional and more circumscribed dispersal movement to freshwater areas throughout the Delta region (Murphy and Hamilton 2013). By late winter-spring, after arriving in freshwater staging habitats, adult Delta smelt hold until spawning commences during favorable water temperatures (Bennett 2005; Grimaldo et al. 2009; Sommer et al. 2011; Damon et al. 2016). Delta smelt spawn over a wide area throughout much of the Delta, including the Sacramento River and San Joaquin River confluence, the upper Sacramento River, and Cache Slough as well as into Suisun Marsh and the Napa River as conditions allow (Brown et al. 2014; Murphy and Hamilton 2013). Spawning of Delta smelt has not been observed in the wild (Moyle et al. 2016).

Potential Changes to Delta Smelt from Seasonal Operations

<u>CalSim 3 X2 Modeled X2 Position</u>

The position of X2 under Alternative 2 was similar to the No Action Alternative (Table O-198 through Table O-201) during the adult Delta smelt migration and spawning period, only varying zero to four km from the No Action Alternative, likely having negligible impacts on adult Delta smelt in the winter and spring.

<u>USFWS Delta Smelt Life Cycle Model</u>

The geometric mean of the expected rate of change in abundance across years (1995-2015), lambda (λ), for the Alternative 2 phases ranged from 0.90 to 0.94 (Attachment F.4., *Delta Smelt Life Cycle Model with Entrainment*). The geometric means of the expected population growth rate varied more widely across water year types and showed positive growth rates under wetter meteorology and negative growth rates under drier meteorology. During wet and above normal water years, λ ranged from 1.21to 1.24 under the four phases of Alternative 2 (i.e., from a 21% to a 24% increase in abundance). Conversely, changes in λ were negative during below normal, dry and critically dry water year types, with λ ranging from 0.70 to 0.73 (i.e., from a -30% to a -27% decline in abundance) during those water year types under the four phases of Alternative 2. Compared to the No Action Alternative, the results for each phase of Alternative 2 ranged from 5% lower to 4% higher in terms of population growth rates, depending on the water year type. The largest difference in growth rates compared to the No Action Alternative was predicted during wet and above normal water years, with the difference ranging from 3-5% lower depending on the Alternative 2 phase. Nevertheless, in that case both No Action Alternative and each phase of Alternative 2 resulted in population growth rates greater than 20% per year on average during wet and above normal water years (Attachment F.4., *Delta Smelt Life Cycle Model with Entrainment*).

Revised Maunder and Deriso (MDR) Life Cycle Model

Life cycle analysis with the MDR model for each of the Alternative 2 phases indicated negligible impact on Delta smelt population growth compared to the No Action Alternative. Differences in single-year λ values did not exceed +/-10% across all modeled years (1995-2015), and the geometric mean of λ was 0.75 for all Alternative 2 phases and the No Action Alternative (Attachment F.1, *Maunder and Deriso in R Model*).

In the MDR model, survival from the sub-adult to adult stage can be influenced by winter covariates which are averaged across the December to February period. Model selection retained combined Old and Middle River flow (OMR) and mean Secchi depth at South Delta monitoring stations as significant covariates of sub-adult survival, with coefficients of 0.477 and 0.542, respectively. Although differences in hydrology between the Alternatives would be expected to influence turbidity, the relationship is complex and was not able to be addressed for this analysis. Within the MDR, impacts on sub-adult survival are therefore related only to differences in OMR between the Alternatives. Mean winter OMR differed negligibly from the No Action Alternative for all of the Alternative 2 phases (-1.1% to 0.6% change), further indicating minimal potential for impacts on sub-adult to adult Delta smelt survival via the modeled pathway.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the winter in the LSZ showed significant relationships for 5 zooplankton taxa; *Daphnia* adults, decapod larvae, *Eurytemora affinis* adults, other calanoid adults, and other calanoid copepods. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 2, when compared to the No Action Alternative, for *Daphnia* adults, there was a 20% expected CPUE increase during the critically dry water year type for the with phases without VAs. There was no expected change in CPUE in the wet, above normal, below normal, and dry water year type for all phases and during the critically dry water year type for the phases with VAs. Results for decapod larvae CPUE were negligible when rounded to the nearest whole integer (values were 0) across all WYT and scenarios. *E. affinis* adults had the largest expected CPUE increase of 2% during the dry water year type for all phases and for the critically dry water year type for the without TUCP, no VA phase. There was no expected change in CPUE in the above normal water year type for the phases without VAs, and the phase with Delta VAs, in the below normal water year type for the no TUCP, Delta VA phase and in the critically dry water year type for the with TUCP Without VA phase, and phases with VAs. For other calanoid copepod adults (*Acartia* spp., unidentified calanoids, *Sinocalanus doerrii*, *Tortanus* spp., and Diaptomidae), the largest expected CPUE increase of 6% was during the below normal water year type for the phases without VAs and the Systemwide VA phase. There was no expected change in CPUE in the wet water year type for the phases with VAs, in the above normal water year type for the phases without VAs and the Delta VA phase; similarly, CPUE wasn't expected to change in the below normal water year type for the Delta VA phase and in the dry and critically dry water year type for all phases. For other calanoid copepod copepodites (*Acartia* spp., *Acartiella* spp., unidentified calanoids, *Eurytemora affinis*, *Sinocalanus doerrii*, *Tortanus* spp., and Diaptomidae), there was a 3% expected CPUE increase during the dry water year type for all phases and during the critically dry water year type for the without TUCP Without VA phase. There was no expected change in CPUE in the wet water year type for the phases with VAs, during the above normal water year type for the phase without VAs and the Delta VA phase, and during the critically dry water year type for phases

with VAs (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 2 during the winter were generally only slightly (<5%) different from the No Action Alternative except in January of critically dry water year types for the phases without VAs which showed an increase resulting in no to minor increases in zooplankton CPUE (Table O-206 through Table O-209).

Analysis of CPUE with outflow during the spring showed significant relationships for the 5 zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 2, when compared to the No Action Alternative, cladocerans (except *Daphnia*), had the largest expected CPUE increase of 20% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 4% during the above normal water year type for the phases without VAs. *E. affinis* adults had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal water year type for the with TUCP Without VA phase. Harpacticoids had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal water year type and the below normal water year type for the phases without VAs. Other calanoid adults had the largest expected CPUE increase of 14% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal and below normal water year type for the with TUCP no VA phase. Other calanoid copepodites had the largest expected CPUE increase of 10% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal and the below normal water year type for the phases without VAs. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflow under Alternative 2 during the spring generally decreased in May for the wet, above normal, and below normal water year types for all phases except the phase with systemwide VAs, when compared to the No Action Alternative. Flows were higher for the phase with systemwide VAs in March and April and higher in March for the phase with Delta VAs. Flows were also higher during the critically dry water year type for all phases except the with TUCP no VA phase (Table O-206 through Table O-209). As a result, zooplankton CPUE showed increases during the critically dry water year type in the spring for all phases except the with TUCP no VA phase and during the below normal, dry and critically dry water year type for the systemwide VA phase.

<u>Summary</u>

Alternative 2 relative to the No Action Alternative is expected to have beneficial to adverse impacts on adult Delta smelt migration and spawning due to differences in flow. Under Alternative 2 CPUE of Delta Smelt prey species was only minorly (<5%) different from the No Action Alternative except in January of critically dry water year types for the phases without VAs which showed an increase resulting in no to minor increases in zooplankton CPUE during the winter, while in the spring zooplankton CPUE increased during the critically dry water year type in the spring for all phases except the with TUCP no VA phase and during the below normal, dry and critically dry water year type for the systemwide VA phase. Results from the revised Maunder and Deriso life cycle model indicate that under Alternative 2 there would be minimal potential impacts on sub-adult to adult Delta smelt survival. Compared to the No Action

Alternative, the USFWS lifecycle model results for each phase of Alternative 2 ranged from being equal to No Action Alternative during below normal, dry, and critically dry dry year types to 8% lower in terms of population growth rates during wet and above normal water year types for the phases without VAs. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the winter and spring, which is expected to have negligible impacts on adult Delta smelt migration and spawning.

Potential Changes to Entrainment of Delta Smelt

Alternative 2 relative to the No Action Alternative is expected to affect the entrainment of adult Delta Smelt. Entrainment varies annually and depends on a combination of hydrology, turbidity, and export rates due to differences in flow (see Smith et al. 2021). Historic salvage shows adult Delta smelt are entrained in the Delta Fish Collection Facilities, however in more recent years fewer fish have been entrained likely due to a combination of changes to operations and the continued decline of the Delta smelt population. While the USFWS life cycle model does incorporate entrainment, it was not used to evaluate entrainment of adult Delta smelt. Instead, OMR flows were used to evaluate changes between Alternative 2 and the No Action Alternative. Assumptions and uncertainty associated with the USFWS life cycle model are found in Attachment F.4, *Delta Smelt Life Cycle Model with Entrainment*.

<u>CalSim 3 OMR Values</u>

Modeled CalSim 3 results indicated OMR combined flows under Alternative 2 when compared to the No Action Alternative were more and less negative depending on the phase and month from January to June (Table O-210 through Table O-213). There were more negative OMR flow values in April and May for the phases without VAs and in May for the phases with VAs compared to the No Action Alternative. This is expected to have an adverse effect on entrainment of adult Delta smelt. There were less negative OMR flow values in June for the phases without VAs, March and June for the phase with Delta VAs, and March, April and June for the phase with systemwide VAs, which are expected to have a beneficial effect on entrainment of adult Delta smelt.

<u>Summary</u>

Alternative 2 relative to the No Action Alternative is expected to range from adverse to beneficial impacts on the entrainment of adult Delta smelt due to differences in flow. OMR values were more negative during April and May across all water year types for the phases without VAs and in May for the phases with VAs compared to the No Action Alternative, which would have adverse impacts on adult Delta smelt entrainment. OMR values were less negative during June for phases without VAs, March, and June for the phase with Delta VAs, and March, April and June for the phase with systemwide VAs, which is expected to have beneficial impacts on adult Delta smelt entrainment.

Eggs and Larvae

Eggs hatch after an average of 10 days in the spring and planktonic larvae are transported (advected) from freshwater regions by the Sacramento River and tidal flows from March through May. The larval stage lasts for an average of 30 days. The nonpelagic habitats used by larval Delta smelt before they move into the pelagic areas are not known (Swanson et al. 1998; Sommer et al. 2011).

Potential Changes to Delta Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 2 was similar to the No Action Alternative (Table O-198 through Table O-201) during the larval Delta smelt period, only varying 0-4 km from the No Action Alternative, likely having negligible effects on larval Delta smelt in the spring.

Revised Maunder and Deriso Life Cycle Model

Life cycle analysis with the revised Maunder and Deriso Model in R (MDR) did not identify any significant covariates of recruitment, and so did not evaluate effects on eggs or early larval stages.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the spring showed significant relationships for the 5 zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 2, when compared to the No Action Alternative, cladocerans (except *Daphnia*), had the largest expected CPUE increase of 20% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 4% during the above normal water year type for the phases without VAs. *E. affinis* adults had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal water year type for the with TUCP Without VA phase. Harpacticoids had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal water year type and the below normal water year type for the phases without VAs. Other calanoid adults had the largest expected CPUE increase of 14% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal and below normal water year type for the with TUCP no VA phase. Other calanoid copepodites had the largest expected CPUE increase of 10% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal and the below normal water year type for the phases without VAs. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflow under Alternative 2 during the spring generally decreased in May for the wet, above normal, and below normal water year types for all phases except the phase with systemwide VAs, when compared to the No Action Alternative. Flows were higher for the phase with systemwide VAs in March and April and higher in March for the phase with Delta VAs. Flows were also higher during the critically dry water year type for all phases except the with TUCP no VA phase (Table O-206 through Table O-209). As a result, zooplankton CPUE showed increases during the critically dry water year type in the spring for all phases except the with TUCP no VA phase and during the below normal, dry and critically dry water year type for the systemwide VA phase.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor adverse to beneficial impacts on Delta smelt larvae depending on the Alternative 2 phase and water year type due to differences in flow. Compared to the No Action Alternative, CPUE of Delta smelt prey species is expected to minorly decrease during the wet year type (-1%) for all phases, and during all water year types except the critically dry water year type for the phases without VAs. CPUE increased during all water year types except for the wet water year type for phase with systemwide VAs and during the dry and critically dry water year type for the phase with Delta VAs. Results from the revised Maunder and Deriso life cycle model did not identify any significant covariates of recruitment, and so did not evaluate impacts on eggs or early larval stages. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the spring which are expected to have no impact on larval Delta smelt.

Potential Changes to Entrainment of Delta Smelt

Particle Tracking Model (PTM)

The CalSim 3 model simulated operational conditions under a range of OMR and inflow conditions from the Sacramento and San Joaquin rivers, with the DSM2 PTM module allowing for an assessment of entrainment of neutrally buoyant passive particles (a proxy for larval Delta smelt, generally distributed throughout the water column) at export facilities (Attachment I.8, *Particle Tracking Fate Modeling of Larval Smelt Entrainment*). PTM analysis was only considered for the larval Delta smelt life stage since modeling suggests later Delta smelt life stages are likely not neutrally buoyant and have a behavioral response to maintain horizontal position in the estuary (Gross et al. 2021, Kimmerer and Nobriga 2008). Results discussed here are expressed as percent of particles with a fate of *Entrained at Exports*. Please refer to Attachment I.3, *Delta Export Zone of Influence Analysis*, for keys to inflow and OMR bins codes, including corresponding Sacramento and San Joaquin rivers flow ranges and mean OMR and Exports flow ranges. While a complete set of detailed results is presented in Attachment I.8, *Particle Tracking Fate Modeling of Larval Smelt Entrainment*, the following narrative focuses on three injection regions when assessing potential entrainment effects from the perspective of varying inflows (Inflow bins: *Sacramento River, San Joaquin River,* and *Yolo Bypass Region*) and one injection region when assessing potential effects from the perspective of OMR net flows (OMR bins: *San Joaquin River Region*).

Inflow Bins

Depending on inflow conditions, an average of 0 to 12% of particles injected within the Sacramento River region would be entrained at export facilities under the four phases of Alternative 2, compared to 0 to 14% under the No Action Alternative. The average percentage of particles entrained at exports ranged from 28% lower than for the No Action Alternative for Alternative 2 Without TUCP Systemwide VAs under "himed" inflow conditions (1 *vs* 2%) to 63% higher than the No Action Alternative for Alternative 2 With TUCP Without VA and Alternative 2 Without TUCP Without VA under "medhi" inflow conditions (but note that the absolute entrainment remained low at around 2%).

Depending on inflow conditions, an average of 45 to 90% of particles injected within the San Joaquin River region would be entrained at export facilities under the four phases of Alternative 2, compared to 45 to 87% under the No Action Alternative. Differences in potential entrainment compared to the No Action Alternative ranged from -13% for Alternative 2 Without TUCP Delta VA and Alternative 2 Without TUCP Systemwide VA under "himed" inflow conditions to +27% for Alternative 2 With TUCP Without VA and Alternative 2 without TUCP Without VA under "medhi" inflow conditions. Although not discussed here in detail, a similar pattern was observed for other injection regions with moderate potential for particles entrainment. Alternative 2 Without TUCP Delta VA and Alternative 2 Without TUCP Systemwide VA would lead to substantial reductions in the average percentage of particles entrained compared to the No Action Alternative under "himed" inflow conditions (up to -28% for the Central Delta injection region or -30% for the Mokelumne River injection region). Alternative 2 With TUCP Without VA would lead to the largest increases in potential entrainment under "medhi" inflow conditions compared to the No Action Alternative (up to +67% for the Central Delta injection region or +64% for the Mokelumne River injection region).

Depending on inflow conditions, an average of 0 to 4% of particles injected within the Yolo Bypass region would be entrained at export facilities under the four phases of Alternative 2, compared to 0 to 5% under the No Action Alternative. Differences in potential entrainment compared to the No Action Alternative ranged from -27% under Alternative 2 Without TUCP Systemwide VAs under "medlo" inflow conditions to +64% for Alternative 2 Without TUCP Without VA under "medhi" inflow conditions (note, however, that average entrainment for this injection region remained low between 0 and 4%).

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), there was a range of -7% to +24% between the average percentage of particles entrained under all four phases of Alternative 2 and when compared to the No Action Alternative.

OMR Bins

Depending on OMR flow conditions, an average of 56 to 77% of particles injected within the San Joaquin River region would be entrained at export facilities under the four phases of Alternative 2, compared to 57 to 87% under the No Action Alternative. Potential entrainment ranged from 14% lower under Alternative 2 Without TUCP Without VA when compared to the No Action Alternative for the -5000 OMR bin (75% *vs* 87%) to 7% higher under Alternative 2 With TUCP Without VA and Alternative 2 Without TUCP Without VA for the -3500 bin (73 *vs* 68%). Although not discussed here in detail, a similar pattern was observed for other injection regions with moderate potential for particles entrainment at export facilities (Mokelumne River, Sacramento River, Central Delta): all four phases of Alternative 2 would generally lead to substantial reductions in the average percentage of particles entrained compared to the No Action Alternative for the most negative OMR index (-5000: -40 to -62%), increases for intermediate OMR index (-3500: +16% to +38%) and either little or variable change under the less negative OMR index (-2000: --13% to +27%).

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), regardless of OMR flow conditions, there was generally little difference between the average percentage of particles entrained under all four phases of Alternative 2 and under the No Action Alternative (-4 to +3%).

Summary

Alternative 2 relative to the No Action Alternative for injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta) is expected to generally have beneficial to adverse impacts on the entrainment of larval Delta smelt for all particle origins, inflow groupings, and OMR groupings due to differences in flow.

Juveniles

During and after larval rearing in freshwater, many young Delta smelt move with river and tidal currents during the early summer to remain in favorable rearing habitats, often moving into low salinity (≤ 6 psu) areas to avoid seasonally warm and highly transparent waters that typify many areas in the central Delta (Nobriga et al. 2008). Juvenile Delta smelt rearing habitat is correlated with salinity, particularly the position of the LSZ, and other habitat attributes such as turbidity and temperature. Delta smelt also rear in upstream areas such as the Cache Slough complex and Sacramento Deep Water Ship Channel, depending on habitat conditions (Sommer and Mejia 2013). Studies indicate that in fall, prior to spawning, juvenile and sub-adult Delta smelt tend to remain in the LSZ (Sommer et al. 2011), though they can be found in the lower San Joaquin River, Suisun and San Pablo bays, the Sacramento River and San Joaquin River confluence, Cache Slough, and the lower Sacramento River (Murphy and Hamilton 2013).

Potential Changes to Delta Smelt from Seasonal Operations

Alternative 2 relative to the No Action Alternative is anticipated have to effects on juvenile Delta smelt including the location and size of the LSZ (as indexed by X2 position), estimated summer and fall habitat, population growth rate, and prey availability due to differences in flow. These possible differences were evaluated using several quantitative models.

CalSim 3 X2 Modeled X2 Position

While Delta smelt can occupy a wide range of habitats and salinities, historically a majority of Delta smelt reside in or near the low salinity zone (LSZ, 0.5–6 psu) (Merz et al. 2011, Moyle et al. 1992). X2 (the location of the 2 psu salinity isohaline measured as its distance in kilometers from the Golden Gate Bridge is located) has been used as a proxy for the LSZ (MacWilliams et al. 2015, Kimmerer et al. 2013, Jassby et al. 1995). The position of X2 responds to CVP and SWP operations as well as precipitation, because more freshwater outflow through the Bay-Delta results in a more seaward X2 position; saltwater is unable to intrude further landward while less outflow results in a more landward X2 position. The size of the LSZ is largest when X2 is below 50 km in San Pablo Bay and second largest between 60 and 75 km, when the LSZ is in Suisun Bay (Kimmerer et al. 2013). The size of the LSZ is smallest when X2 is located near the Carquinez Strait (X2 ~ 50-60 km) and at the confluence of the Sacramento and San Joaquin rivers (X2 ~ 80-85 km).

The position of X2 under Alternative 2 was similar to the No Action Alternative (Table O-198 through Table O-201) during the juvenile Delta smelt period, only varying zero to three km from the No Action Alternative, likely having negligible effects on juvenile Delta smelt in the summer and fall.

Habitat Suitability Index

Juvenile Delta smelt summer and fall habitat was estimated for different water year types (wet, above normal, below normal, dry, and critical) using the Bever et al. (2016) habitat suitability index (Bever HSI) and the Bever HSI with a water temperature threshold of 22° Celsius (22C HSI), where the Bever HSI value is multiplied by 0 when water temperature is greater than 22° C and by 1 when water temperature is less than or equal to 22° C. The temperature threshold of 22ºC was used based on sub-lethal physiological and behavioral effects observed in multiple studies (Davis et al. 2022, Hammock et al. 2022, Komoroske et al. 2021, Lewis et al. 2021, Davis et al. 2019, Komoroske et al. 2015).

Under Alternative 2 with a TUCP and without Voluntary Agreements, both the mean Bever HSI and mean 22C HSI for subregions targeted by the summer fall habitat action (Yolo Bypass, which includes the Cache Slough Complex and Sacramento Deepwater Shipping Channel; Lower Sacramento River; Confluence; Suisun Marsh; northwest Suisun Bay) were 2% lower to less than 1% higher than under the No Action Alternative, depending on water year type. The largest differences under Alternative 2 with a TUCP and without Voluntary Agreements are predicted during the below normal water year for both mean Bever HSI (2% lower) and mean 22C HSI (2% lower). The smallest differences are predicted during the above normal water year for mean Bever HSI (0%) and during the critical water year for mean 22C HSI (< 1% higher).

Under Alternative 2 without a TUCP and without Voluntary Agreements, mean Bever HSI for subregions targeted by the summer fall habitat action was 2% lower to 6% higher than under the No Action Alternative, depending on water year type. Under Alternative 2 without a TUCP and without Voluntary Agreements, the mean 22C HSI for the summer fall habitat action subregions was 2% lower to less than 1% higher than under the No Action Alternative, depending on water year type. The largest differences under Alternative 2 without a TUCP and without Voluntary Agreements are predicted during the critical water year for mean Bever HSI (6% higher) and during the below normal water year for mean 22C HSI (2% lower). The smallest differences are predicted during the above normal water year for mean Bever HSI (0%) and mean 22C HSI (< 1% higher).

Under Alternative 2 without a TUCP and with Delta Voluntary Agreements, mean Bever HSI for subregions targeted by the summer fall habitat action was 1% lower to 4% higher than under the No Action Alternative, depending on water year type. Under Alternative 2 without a TUCP and with Delta Voluntary Agreements, the mean 22C HSI for the summer fall habitat action subregions was 6% lower to 2% higher than under the No Action Alternative, depending on water year type. The largest differences under Alternative 2 without a TUCP and with Delta Voluntary Agreements are predicted during the critical water year for both mean Bever HSI (4% higher) and mean 22C HSI (6% lower). The smallest differences are predicted during the above normal water year for mean Bever HSI (< 1% higher) and during the below normal water year for mean 22C HSI (0%).

Under Alternative 2 without a TUCP and with all Voluntary Agreements, mean Bever HSI for subregions targeted by the summer fall habitat action was 1% lower to 5% higher than under the No Action Alternative, depending on water year type. Under Alternative 2 without a TUCP and with all Voluntary Agreements, the mean 22C HSI for the summer fall habitat action subregions was 4% lower to 2% higher than under the No Action Alternative, depending on water year type. The largest differences under Alternative 2 without a TUCP and with all Voluntary Agreements are predicted during the critical water year for mean Bever HSI (5% higher) and mean 22C HSI (4% lower). The smallest differences are predicted during the dry water year for mean Bever HSI (0%) and during the below normal water year type for 22C HSI (0%).

The results of the HSI analyses suggest that across all phases of Alternative 2 may result in no or minor increases (0%–6%) and minor decreases (< 1%–6%) in suitable habitat depending on water year type and the application of a temperature threshold in comparison to the No Action Alternative and would likely have negligible to minor adverse and minor beneficial impacts on juvenile Delta smelt summer and fall habitat.

Revised Maunder and Deriso Life Cycle Model

Survival between the post-larval and juvenile stages is influenced by summer variables, and model selection identified two significant covariates: cumulative June-August outflow and June-August mean water temperature with coefficients of 0.354 and -0.351, respectively (Attachment F.1, *Maunder and Deriso in R Model*). Although differences in hydrology between the alternatives would be expected to influence temperature, the relationship is complex and was not able to be addressed for this analysis. Within the MDR, impacts on post-larval survival are therefore related only to differences in summer outflow between the alternatives. Across the four phases, mean summer outflow was 0-1% lower than the No Action Alternative, suggesting that negligible impact on the survival of post-larval Delta smelt would result.

The preferred set of covariates identified through extensive model selection did not include any parameters that differed between alternatives (Attachment F.1, *Maunder and Deriso in R Model*). Mean Delta water temperature and Secchi depth were the selected parameters for the fall period, which correspond to juvenile survival in the MDR model. Although hydrological differences between the alternatives would potentially impact these variables, the relationships between flow, temperature and turbidity are complex, and were not able to be modeled for this exercise. As such, juvenile Delta smelt survival under Alternative 2 was the same as under the No Action Alternative.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the fall showed significant relationships for two taxa; *E. affinis* adults and mysids. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 2, when compared to the No Action Alternative, for *E. affinis* there was no expected change in CPUE across all water types and phases of Alternative 2. However, the expected CPUE for *E. affinis* during the fall was very low (1–3 individuals per cubic meter) and unlikely to impact Delta smelt juveniles. Mysids had the largest expected increase of 14% during the dry water year type for the without TUCP Systemwide VA phase. Mysid CPUE was not expected to change for the wet and below water year types across all phases; the dry water year type for the phases without VAs and the Delta VA phase; and the critically dry water year type across all phases (Attachment J.3, *Zooplankton-Delta Outflow*

Analysis). The CalSim 3 simulated average Delta outflows under Alternative 2 during the fall were generally only slightly (<5%) different from the No Action Alternative for all phases (Table O-206 through Table O-209). As a result, zooplankton CPUE was generally similar to the No Action Alternative.

Summary

Alternative 2 relative to the No Action Alternative is expected to have a negligible to minor impacts on juvenile Delta smelt due to differences in flow. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the summer and fall, which is expected to have negligible impacts on juvenile Delta smelt. The results of the HSI analyses suggest that Alternative 2 depending on water year type and the application of a water temperature threshold in comparison to the No Action Alternative would likely have negligible to minor adverse and beneficial impacts on juvenile Delta smelt summer and fall habitat. Results from the revised Maunder and Deriso life cycle model suggest negligible impact on the survival of post-larval Delta smelt under all phases of Alternative 2. Under Alternative 2, CPUE of Delta smelt prey species was not related to outflow in the summer and tis expected to be similar to the No Action Alternative during the fall.

Potential Changes to Entrainment of Delta Smelt

Alternative 2 relative to the No Action Alternative is expected to affect the entrainment of juvenile Delta smelt due to differences in flow. Entrainment varies annually and depends on a combination of hydrology, turbidity, and export rates (see Smith et al. 2021). Historic salvage shows juvenile Delta smelt are entrained in the Delta Fish Collection Facilities, however in more recent years fewer fish have been entrained likely due to a combination of changes to operations and the continued decline of the Delta smelt population. While the USFWS life cycle model does incorporate entrainment, it was not used to evaluate entrainment of juvenile Delta smelt. Instead, OMR flows were used to evaluate changes between Alternative 2 and the No Action Alternative.

CalSim 3 OMR Values

OMR combined flows ranged from similar to less negative under Alternative 2 when compared to the No Action Alternative from June to November, which would have negligible to positive effects on entrainment of juvenile Delta smelt (Table O-210 through Table O-213). Across all phases, OMR flow was less negative in June, which would have beneficial effects on juvenile Delta smelt entrainment. Across all other months through November, in general OMR flows were similar to the No Action Alternative across all phases, which would have negligible effects on juvenile Delta smelt entrainment.

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible to beneficial impacts on the entrainment of juvenile Delta smelt due to differences in flow. Alternative 2 relative to the No Action Alternative is in general less advers across all phases in June, which would have beneficial impacts on juvenile Delta smelt, and similar to the No Action Alternative from July to November, which is expected to have negligible impact due to differences in flow.

O.5.13 Longfin Smelt

O.5.13.1 Bay Delta

Adult Migration and Spawning

Longfin smelt are anadromous and spawn in fresh or low-salinity water in the Bay-Delta (Grimaldo et al. 2017), generally at 2 years of age (Moyle 2002). A portion of the population migrate from the ocean into the San Francisco Estuary and move upstream to spawn during late fall through winter, with most spawning occurring from November through April (California Department of Fish and Wildlife 2009a). Spawning locations have been estimated using field observations of gravid females and yolk-sac larvae (Grimaldo et al. 2017, Lewis et al. 2019) and through particle-tracking modeling (Gross et al. 2022) to suggest spawning extends farther seaward than previously thought (Moyle 2002). Based on these studies, longfin smelt appear to spawn in the low-salinity zone where brackish and freshwaters meet (Grimaldo et al. 2017), and in tidal wetlands of south San Francisco Bay and San Pablo Bay when hydrological conditions favor spawning in more seaward regions (Lewis et al. 2020, Grimaldo et al. 2020). These regions include marshes of the Petaluma watershed, Napa-Sonoma watershed, Sacramento-San Joaquin watershed, and Coyote Creek watershed (Lewis et al. 2020, Hobbs et al. 2015).

Potential Changes to Longfin Smelt from Seasonal Operations

Alternative 2 relative to the No Action Alternative is expected to have effects on adult migrating and spawning longfin smelt including X2 position and prey availability.

<u>CalSim 3 Modeled X2 Position</u>

The position of X2 under Alternative 2 was similar to the No Action Alternative (Table O-198 through Table O-201) during the adult longfin smelt migration and spawning period, only varying zero to fourkm from the No Action Alternative, likely having negligible impacts on adult longfin smelt in the fall, winter and spring.

<u>Zooplankton CPUE-Outflow Analysis</u>

Analysis of CPUE with outflow during the fall showed significant relationships for two taxa; *E. affinis* adults and mysids. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 2, when compared to the No Action Alternative, for *E. affinis* there was no expected change in CPUE across all water types and phases of Alternative 2. However, the expected CPUE for *E. affinis* during the fall was very low (1–3 individuals per cubic meter) and unlikely to impact longfin smelt. Mysids had the largest expected increase of 14% during the dry water year type for the without TUCP Systemwide VA phase. Mysid CPUE was not expected to change for the wet and below water year types across all phases; the dry water year type for the phases without VAs and the Delta VA phase; and the critically dry water year type across all phases (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 2 during the fall were generally only slightly (<5%) different from the No Action Alternative for all phases (Table O-206 through Table O-209). As a result, zooplankton CPUE was generally similar to the No Action Alternative.

Analysis of CPUE with outflow during the winter in the LSZ showed significant relationships for five zooplankton taxa; *Daphnia* adults, decapod larvae, *Eurytemora affinis* adults, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 2, when compared to the No Action Alternative, for *Daphnia* adults, there was a 20% expected CPUE increase during the critically dry water year type for the with phases without VAs. There was no expected change in CPUE in the wet, above normal, below normal, and dry water year type for all phases and during the critically dry water year type for the phases with VAs. Results for decapod larvae CPUE were negligible when rounded to the nearest whole integer (values were 0) across all WYT and scenarios. *E. affinis* adults had the largest expected CPUE increase of 2% during the dry water year type for all phases and for the critically dry water year type for the without TUCP, no VA phase. There was no expected change in CPUE in the above normal water year type for the phases without VAs, and the phase with Delta VAs, in the below normal water year type for the no TUCP, Delta VA phase and in the critically dry water year type for the with TUCP Without VA phase, and phases with VAs. For other calanoid copepod adults (*Acartia* spp., unidentified calanoids, *Sinocalanus doerrii*, *Tortanus* spp., and Diaptomidae), the largest expected CPUE increase of 6% was during the below normal water year type for the phases without VAs and the Systemwide VA phase. There was no expected change in CPUE in the wet water year type for the phases with VAs, in the above normal water year type for the phases without VAs and the Delta VA phase; similarly, CPUE wasn't expected to change in the below normal water year type for the Delta VA phase and in the dry and critically dry water year type for all phases. For other calanoid copepod copepodites (*Acartia* spp., *Acartiella* spp., unidentified calanoids, *Eurytemora affinis*, *Sinocalanus doerrii*, *Tortanus* spp., and Diaptomidae), there was a 3% expected CPUE increase during the dry water year type for all phases and during the critically dry water year type for the without TUCP Without VA phase. There was no expected change in CPUE in the wet water year type for the phases with VAs, during the above normal water year type for the phase without VAs and the Delta VA phase, and during the critically dry water year type for phases with VAs (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 2 during the winter were generally only slightly (<5%) different from the No Action Alternative except in January of critically dry water year types for the phases without VAs which showed an increase resulting in no to minor increases in zooplankton CPUE (Table O-206 through Table O-209).

Analysis of CPUE with outflow during the spring showed significant relationships for the 5 zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 2, when compared to the No Action Alternative, cladocerans (except *Daphnia*), had the largest expected CPUE increase of 20% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 4% during the above normal water year type for the phases without VAs. *E. affinis* adults had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal water year type for the with TUCP Without VA phase. Harpacticoids had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal water year type and the below normal water year type for the phases without VAs. Other calanoid adults had the largest expected CPUE increase of

14% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal and below normal water year type for the with TUCP no VA phase. Other calanoid copepodites had the largest expected CPUE increase of 10% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal and the below normal water year type for the phases without VAs. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflow under Alternative 2 during the spring generally decreased in May for the wet, above normal, and below normal water year types for all phases except the phase with systemwide VAs, when compared to the No Action Alternative. Flows were higher for the phase with systemwide VAs in March and April and higher in March for the phase with Delta VAs. Flows were also higher during the critically dry water year type for all phases except the with TUCP no VA phase (Table O-206 through Table O-209). As a result, zooplankton CPUE showed increases during the critically dry water year type in the spring for all phases except the with TUCP no VA phase and during the below normal, dry and critically dry water year type for the systemwide VA phase.

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on adult longfin smelt migration and spawning due to differences in flow. Compared to the No Action Alternative, CPUE of longfin smelt prey species is expected to generally minorly change during the fall, winter and increase in the spring depending on Alternative 2 phase and water year type. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the fall, winter and spring which are expected to have a negligible impact on adult longfin smelt migration and spawning.

Potential Changes to Entrainment of Longfin Smelt

Alternative 2 relative to the No Action Alternative is expected to affect the entrainment of adult longfin smelt due to differences in flow. Entrainment varies annually and depends on a combination of hydrology and export rates.

CalSim 3 Modeled X2 Position

Modeling analysis of adult longfin salvage presented in CDFW (2020) predicted increased adult salvage when X2 was near 65 km and when X2 was beyond 75 km. During periods of high outflow adult longfin smelt are less likely to be entrained because the low salinity zone is further away from the Delta, and more individuals may spawn in areas where freshwater flow creates ideal spawning environments. The increase in salvage when X2 was at 65 km is believed to be due to adult longfin staging in Suisun Bay before migrating into the Delta.

The position of X2 under Alternative 2 was similar to the No Action Alternative (O.5-25, O.5-26, O.5-27, O.5-28) during the adult longfin smelt migration and spawning period, only varying 0–4 km from the No Action Alternative.

CalSim 3 Total Exports and OMR Values

An effects analysis of adult longfin smelt entrainment at CVP and SWP facilities found that salvage was increased with fish proximity to the facilities and the magnitude of negative OMR flows caused by the export facilities (CDFW 2020). The analysis noted that this is an additive

effect; salvage only increased when multiple factors (e.g. increased proximity to export facilities, high exports, and highly negative OMR) were considered. The model predicted the magnitude of salvage events increased when total Delta exports increased and when OMR values were more negative than -5000 cfs, however the analysis was not able to identify the underlying mechanisms for the -5000 cfs threshold.

Total exports during the adult longfin smelt migration and spawning period under Alternative 2 were relatively similar to the No Action Alternative for most months but did increase in April for the phases without VAs and decreased in March for the phases with VAs. OMR combined flows were generally similar compared to the No Action Alternative for most months, but were more negative in April without VAs and was less negative in March for phases with VAs (Table O-210 through Table O-213). OMR combined flows for all phases were less negative than the -5000 cfs threshold. Compared to the No Action Alternative, there is likely a minor adverse effect for the phases without VAs and a minor beneficial effect for the phases with VAs.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor adverse to minor beneficial impacts on entrainment of adult longfin smelt during migration and spawning due to differences in flow. Compared to the No Action Alternative, the position of X2 only varied–zero to four km under Alternative 2, likely having a negligible impact on adult longfin smelt. Compared to the No Action Alternative, under Alternative 2, exports were higher and OMR values were more negative in April for the phases without VAs and exports were lower and OMR values were less negative in March for the phases with VAs, likely resulting in a minor adverse impacts for the phases without VAs and a minor beneficial impacts for the phases with VAs.

Eggs and Larvae

In the San Francisco Estuary, most longfin smelt larvae hatch between December and May, and rarely outside of this range (Baxter 1999). Longfin smelt larvae are most abundant in the water column usually from January through April (Bureau of Reclamation 2008). Larval longfin smelt rear in low salinity to brackish water (2–12 ppt; Grimaldo et al. 2017) and in tidal wetlands of San Pablo Bay (Sonoma Creek, Napa River, and Petaluma River) and south San Francisco Bay (Alviso Marsh Complex and salt pond restoration areas) (Hobbs et al. 2015; Lewis et al. 2020). The spatial distribution of these larvae reflects the year-to-year variation in freshwater outflow which affects the geographic location of the low-salinity zone during the winter and spring (Dege and Brown 2004; Grimaldo et al. 2020). During high outflow years, the low salinity zone can extend into San Pablo Bay. Within the low-salinity zone and adjacent waters, larvae have been commonly collected in both littoral (nearshore) and pelagic (offshore) habitats.

Potential Changes to Longfin Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 2 was similar to the No Action Alternative (Table O-198 through Table O-201) during the larval longfin smelt period, only varying zero to four km from the No Action Alternative, likely having negligible impacts on larval longfin smelt in the spring.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the spring showed significant relationships for the five zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 2, when compared to the No Action Alternative, cladocerans (except *Daphnia*), had the largest expected CPUE increase of 20% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 4% during the above normal water year type for the phases without VAs. *E. affinis* adults had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal water year type for the with TUCP Without VA phase. Harpacticoids had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal water year type and the below normal water year type for the phases without VAs. Other calanoid adults had the largest expected CPUE increase of 14% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal and below normal water year type for the with TUCP no VA phase. Other calanoid copepodites had the largest expected CPUE increase of 10% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal and the below normal water year type for the phases without VAs. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflow under Alternative 2 during the spring generally decreased in May for the wet, above normal, and below normal water year types for all phases except the phase with systemwide VAs, when compared to the No Action Alternative. Flows were higher for the phase with systemwide VAs in March and April and higher in March for the phase with Delta VAs. Flows were also higher during the critically dry water year type for all phases except the with TUCP no VA phase (Table O-206 through Table O-209). As a result, zooplankton CPUE showed increases during the critically dry water year type in the spring for all phases except the with TUCP no VA phase and during the below normal, dry and critically dry water year type for the systemwide VA phase.

Summary

Alternative 2 relative to the No Action Alternative is expected to have both adverse and beneficial impacts on longfin smelt larvae due to differences in flow. Compared to the No Action Alternative, CPUE of longfin smelt prey species is expected to minorly decrease during the wet year type (-1%) for all phases, and during all water year types except the critically dry water year type for the phases without VAs. CPUE increased during all water year types except for the wet water year type for phase with systemwide VAs and during the dry and critically dry water year type for the phase with Delta VAs. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the spring which are expected to have negligible impacts on larval longfin smelt.

Potential Changes to Entrainment of Longfin Smelt

Alternative 2 relative to the No Action Alternative is expected to have effects on entrainment of longfin smelt larvae due to differences in flow. These possible differences were evaluated using a quantitative model.

Particle Tracking Model (PTM)

Inflow Bins

Depending on inflow conditions, an average of 1 to 16% (SO) or 1 to 13% (NB) of particles injected within the Sacramento River region would be entrained at export facilities under the four phases of Alternative 2, compared to 1 to 16% (SO) and 1 to 13% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 37% (SO) or 38% (NB) lower for Alternative 2 Without TUCP system-wide VA than for the No Action Alternative under "lomed" inflow conditions, to 9% higher than for the No Action Alternative for Alternative 2 Without TUCP system-wide VA (SO) and 8% higher than the No Action Alternative for Alternative 2 Without TUCP Delta VA under "hilo" inflow conditions (NB).

Depending on inflow conditions, an average of 0 to 4% (SO) or 0 to 3% (NB) of particles injected within the Western Delta region would be entrained at export facilities under the four phases of Alternative 2, compared to 0 to 4% (SO) and 0 to 3% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 41% lower than the No Action Alternative for Alternative 2 With TUCP system-wide VA under "lomed" conditions for both SO and NB particles, to 62% higher for Alternative 2 Without TUCP Delta VA under "hihi" conditions (SO) and 98% higher for Alternative 2 Without TUCP Delta VA and Alternative 2 Without TUCP system-wide VA under "hihi" conditions (NB). Note however that under those high flow conditions, the average percentage of particles entrained at exports would remain extremely low (close to 0 for both alternative 2 and the No Action Alternative).

Depending on inflow conditions, an average of 0 to 7% (SO) or 0 to 5% (NB) of particles injected within the Yolo Bypass region would be entrained at export facilities under the four phases of Alternative 2, compared to 0 to 8% (SO) and 0 to 5% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 38% lower for both SO and NB particles for Alternative 2 Without TUCP system-wide VA than for the No Action Alternative under "lomed" inflow conditions, to 15% higher than for the No Action Alternative for Alternative 2 Without TUCP Delta VA (SO) and 16% higher for Alternative 2 Without TUCP system-wide VA (NB) under "hilo" inflow conditions.

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), regardless of inflow conditions, there was generally a difference between the average percentage of particles entrained under Alternative 4 and under the No Action Alternative (-9 to +2% NB and SO).

OMR bins

Depending on OMR flow conditions, an average of 16 to 81% (SO) or 15 to 79% (NB) of particles injected within the Central Delta region would be entrained at export facilities under the four phases of Alternative 2, compared to 24 to 81% (SO) and 22 to 79% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 31% lower under Alternative 2 Without TUCP Delta VA than under the No Action Alternative for the -2000 OMR bin for both SO and NB particles, to 16% higher under Alternative 2 Without TUCP Delta VA (SO and NB) and Alternative 2 Without TUCP System-wide VA (NB) than under the No Action Alternative for the -3500 OMR bin.

Depending on OMR flow conditions, an average of 17 to 79% (SO) or 16 to 76% (NB) of particles injected within the Mokelumne River region would be entrained at export facilities under the four phases of Alternative 2, compared to 23 to 78% (SO) and 21 to 75% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 26% lower (SO) or 27% lower (NB) under Alternative 2 Without TUCP Delta VA than under the No Action Alternative for the -2000 OMR bin, to 16% higher (both SO and NB) under Alternative 2 Without TUCP Delta VA for the -3500 OMR bin.

Depending on OMR flow conditions, an average of 1 to 16% (SO) or 1 to 13% (NB) of particles injected within the Yolo Bypass region would be entrained at export facilities under the four phases of Alternative 2, compared to 2 to 16% (SO) and 1 to 13 % (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 50% lower (SO) and 51% lower (NB) under Alternative 2 Without TUCP system-wide VA than under the No Action Alternative for the -2000 OMR bin, to 18% higher under Alternative 2 Without TUCP System-wide VA (SO) and 21% higher under Alternative 2 Without TUCP Delta VA (NB) for the -3500 OMR bin.

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), regardless of OMR flow conditions, there was generally little difference between the average percentage of particles entrained under Alternative 4 and under the No Action Alternative (-3 to +1% NB and SO).

Summary

The percentage of particles entrained at exports were generally similar between surface-oriented particles representative of yolk-sac larval longfin smelt and neutrally buoyant particles representative of >10mm larval longfin smelt. Alternative 2 relative to the No Action Alternative for injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta) is expected to have a mostly similar or beneficial impact on the entrainment of larval longfin smelt, depending on particle origin, inflow grouping, and OMR grouping due to differences in flow.

Juveniles

Juveniles have been detected throughout the San Francisco Estuary and rarely in some Delta tributaries (Merz et al. 2013). Juveniles gradually move seaward as they grow and as water temperatures increase in the late spring and early summer (Rosenfield and Baxter 2007; Tobias and Baxter 2021). Seasonal patterns in abundance and occurrence in the nearshore ocean suggest that the population is at least partially anadromous (Rosenfield and Baxter 2007; Garwood 2017). The detection of longfin smelt within the estuary throughout the year and geochemical analysis of otoliths suggests longfin smelt in the San Francisco Estuary utilize several life history strategies (Lewis et al. 2019).

Potential Changes to Longfin Smelt from Seasonal Operations

Alternative 2 relative to the No Action Alternative is expected to have effects on juvenile longfin smelt including X2 position, abundance, and prey availability. These possible differences were evaluated using several quantitative models.

CalSim 3 X2 Modeled X2 Position

Longfin smelt utilize low salinity zone (LSZ, 0.5–6 psu) habitat for spawning and rearing (Grimaldo et al. 2017, Merz et al. 2013, Hobbs et al. 2010). X2 (the distance of 2 psu salinity isohaline from the Golden Gate Bridge) has been used as a proxy for the LSZ (MacWilliams et al. 2015, Kimmerer et al. 2013, Jassby et al. 1995). The position of X2 responds to CVP and SWP operations, the more freshwater outflow into the Bay-Delta results in a more seaward X2 position; saltwater is unable to intrude further landward while less outflow results in a more landward X2 position. The size of the LSZ is largest when X2 is below 50 km in San Pablo Bay and second largest between 60 and 75 km, when the LSZ is in Suisun Bay (Kimmerer et al. 2013). The size of the LSZ is smallest when X2 is located near the Carquinez Strait (X2 ~ 50-60 km) and at the confluence of the Sacramento and San Joaquin rivers (X2 ~ 80-85 km).

The position of X2 under Alternative 2 was similar to the No Action Alternative (Table O-198 through Table O-201) during the juvenile longfin smelt period, only varying 0-4 km from the No Action Alternative, likely having negligible impacts on juvenile longfin smelt in the spring and summer.

Longfin Smelt Abundance–Outflow Analysis

Juvenile longfin smelt abundance as represented by the Fall Midwater Trawl index of abundance is predicted to be similar between each of the phases of Alternative 2 and the No Action Alternative, i.e., plus or minus 5%, depending on the water year type and specific phase of Alternative 2 (Attachment J.1, *Longfin Smelt Outflow*, Table 3). During critically dry water years, Alternative 2 is predicted to result in longfin smelt abundance that is between 1% lower to 4% higher than the No Action Alternative. For all phases of Alternative 2, predicted longfin smelt abundance during wet water years is between 0% to 2% lower than the No Action Alternative.

Zooplankton CPUE-Outflow Analysis

Under Alternative 2, when compared to the No Action Alternative, cladocerans (except *Daphnia*), had the largest expected CPUE increase of 20% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 4% during the above normal water year type for the phases without VAs. *E. affinis* adults had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal water year type for the with TUCP Without VA phase. Harpacticoids had the largest expected increase of 11% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal water year type and the below normal water year type for the phases without VAs. Other calanoid adults had the largest expected CPUE increase of 14% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 3% during the above normal and below normal water year type for the with TUCP no VA phase. Other calanoid copepodites had the largest expected CPUE increase of 10% during the critically dry water year type for the without TUCP Systemwide VA phase and the largest expected CPUE decrease of 2% during the above normal and the below normal water year type for the phases without VAs. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflow under Alternative 2 during the spring generally decreased in May for the wet, above

normal, and below normal water year types for all phases except the phase with systemwide VAs, when compared to the No Action Alternative. Flows were higher for the phase with systemwide VAs in March and April and higher in March for the phase with Delta VAs. Flows were also higher during the critically dry water year type for all phases except the with TUCP no VA phase (Table O-206 through Table O-209). As a result, zooplankton CPUE showed increases during the critically dry water year type in the spring for all phases except the with TUCP no VA phase and during the below normal, dry and critically dry water year type for the systemwide VA phase.

During the summer months (May to August), the zooplankton-outflow analysis showed no significant relationships between outflow and zooplankton CPUE. Several studies have previously found relationships between abundance of zooplankton taxa and outflow during the summer (e.g. Kimmerer 2002b, Kimmerer et al. 2018), while other studies have found mixed effects (Frantzich et al. 2021) or no effects (Sommer et al. 2020) of increased flow on zooplankton abundance. Evaluating possible benefits of increased outflow and flow pulses during summer may be difficult given sampling frequency and the effect size of increases to zooplankton abundances (Brandon et al. 2021).

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor adverse and beneficial impacts on juvenile longfin smelt depending on the phase and water year type due to differences in flow. Juvenile longfin smelt abundance as represented by the Fall Midwater Trawl index of abundance is predicted 1%–3% lower depending on the Alternative 2 phase during wet years compared to the No Action Alternative and 0 to 4% higher depending on the Alternative 2 phase during critically dry years compared to the No Action Alternative. Compared to the No Action Alternative, CPUE of longfin smelt prey species was only minorly (<5%) different except in January of critically dry water year types for the phases without VAs which showed an increase resulting in no to minor increases in in zooplankton CPUE during the winter, and the CPUE is expected to be similar to the No Action Alternative during the fall. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the spring and summer which are expected to have a negligible impact on juvenile longfin smelt.

Potential Changes to Entrainment of Longfin Smelt

Longfin Smelt Outflow Entrainment

The regression from Grimaldo et al. (2009) between April-May juvenile longfin smelt entrainment and Old and Middle River flows was used to assess potential differences in salvage between modeled alternatives. The analysis does not account for changes in operations since the USFWS 2008 and 2009 biological opinions, changes in population size over time, turbidity, juvenile behavior, and geographic shifts in distribution during higher outflow years.

Changes in OMR flows under Alternative 2 compared with the No Action Alternative may have an impact on LFS salvage. Compared to the No Action Alternative, for the with TUCP no VA phase, predicted salvage increases ranged from 29% during the critically dry water year type to 181% during the above normal water year type. For the without TUCP no VA phase, predicted salvage increases ranged from 23% during the critically dry water year type to 181% during the above normal water year type. For the without TUCP Delta VA phase, predicted salvage increases ranged from 8% during the dry water year type to 103% during the wet water year

type. For the without TUCP Systemwide VA phase, predicted salvage ranged from a 4% decrease during the dry water year type to a 98% increase during the wet water year type. Alternative 2 had higher negative mean April-May OMR values across most water year types for all phases. Overall modeling for Alternative 2 suggests that longfin smelt salvage would increase substantially when compared to the No Action Alternative, particularly for the with TUCP no VA, without TUCP no VA, and without TUCP Delta VA phases. Substantial effects were seen during certain water year types for the without TUCP Systemwide VA phase (e.g. wet) but a minor decrease in salvage was seen for the dry water year type. (Attachment I.4, *Longfin Smelt Salvage-OMR Relationship*).

Summary

Alternative 2 relative to the No Action Alternative is expected to have an adverse impact on the entrainment of longfin smelt in all water year types except in a dry water year type under Alternative 2 Without TUCP Systemwide VA which is expected to have a minor beneficial impact due to differences in flow.

O.5.14 Fall-run and Late Fall-run Chinook Salmon ESU

O.5.14.1 Sacramento River

Spawning and Egg/Alevin Incubation

Fall-run Chinook salmon typically spawn in the Sacramento River, primarily between Keswick Dam and RBDD from October through December, with incubation occurring from October through April. Peak spawning time for late fall-run Chinook salmon generally is from January through April (National Marine Fisheries Service 2009a), with incubation typically lasting for approximately seven to 13 months between April and June (Moyle 2002). See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under the four phases of Alternative 2, differences in mean spawning WUA are generally lower than the No Action Alternative across the water year types and phases and are higher in critically dry water years under Alternative 2 With TUCP Without VA (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between the four phases of Alternative 2 and the No Action Alternative is a 1.5% increase in critically dry water years under Alternative 2 With TUCP Without VA. The largest reduction in estimated spawning habitat is a -2.1% decrease in above normal water year types under Alternative 2 Without TUCP Delta VA.

The monthly median values of spawning WUA under the four phases of Alternative 2 are similar to the No Action Alternative in September, October, and December and slightly lower in November (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Estimated spawning WUA median values for all the modeled alternatives are relatively similar in September and October, and slightly lower in November and December. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently highest in

December when compared to other spawning months (Table O-182 through Table O-185). This results in lower spawning WUA results because the fall-run Chinook salmon spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 3,000 to 6,000 cfs).

Overall, the spawning habitat analysis based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 may have a minor (less than 2.5%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. The results of the spawning habitat analysis based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 may have a minor (less than 2.5%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. Out of the four months of potential fall-run Chinook salmon spawning, September and October have the highest estimated spawning WUA across all alternatives.

Fall-run Chinook Salmon: Redd Dewatering Analysis

Under the four phases of Alternative 2, the fall-run Chinook salmon redd dewatering results show a consistent reduction in redd dewatering potential from wet and above normal water year types to critically dry water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation is expected for fall-run Chinook salmon because their spawning occurs in the fall, with incubation extending into early winter. During wet winters, periodic storms and high runoff increase flow fluctuations, which tends to result in greater redd dewatering. In drier winters, flow fluctuations are reduced and fewer redds are potentially dewatered. Differences in redd dewatering potential between the four phases of Alternative 2 and the No Action Alternative are variable, with mostly small increases and reductions in all water year types. The largest difference is an increase of 15.6% for critically dry water years under Alternative 2 Without TUCP Without VA The largest reduction is 7.2% for below normal water years under Alternative 2 Without TUCP Without VA. For individual months, redd dewatering for all four phases of Alternative 2 is highest for September spawning (Attachment L.4, *Sacramento River Redd Dewatering Analysis*).

Overall, the results indicate that redd dewatering potential under the four phases of Alternative 2 would mostly be higher than under the No Action Alternative, but most difference are relatively small, especially on an absolute scale.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 235 for Keswick Dam and Table 236 for RBDD. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 238 for Keswick Dam and Table 239 for RBDD. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during December through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 241 for Keswick Dam and Table 242 for RBDD.

Results for the three analyses are summarized in Table O-74. Table O-74, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 42.1°F to 55°F spawning initiation range analysis, there were zero and one month-water year type combinations (0% and 5.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-74). There were four and one combinations (20.0% to 5.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results at Keswick Dam and RBDD. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero and one combinations (0% and 5.0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were no combinations (0%) with unfavorable results at either location. These results suggest that there would be minor or negligible positive and negative water temperature-related effects of Alternative 2 With TUCP Without VA on fall-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 42.1°F to 55°F spawning initiation range analysis, there were zero and one month-water year type combinations (0% and 5.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-74). There were two and zero combinations (10.0% and 0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there were one and zero combinations (5.0% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were no combinations (0%) with unfavorable conditions at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were no combinations (0%) with favorable or unfavorable results at Keswick Dam and RBDD.. These results suggest that there would be minor or negligible positive and negative water temperature-related effects of Alternative 2 Without TUCP Without VA on fall-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Delta VA** for the 42.1°F to 55°F spawning initiation range analysis, there were zero month-water year type combinations (0%) with favorable results at Keswick Dam and RBDD (Table O-74). There were five and one combinations (25.0% and 5.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable conditions at Keswick Dam and RBDD. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero and one month-water year type combinations (0% and 5.0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were no combinations with unfavorable results at either location. These results suggest that there would be minor positive and negative water temperature-related effects of Alternative 2 Without TUCP Without VA on fall-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 42.1°F to 55°F spawning initiation range analysis, there were zero and one month-water year type combinations (0% and 5.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-74). There were four and one combinations (20.0% to 5.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results at both Keswick Dam and RBDD. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero and one combinations (0% and 5.0%, respectively) with favorable results at Keswick Dam and RBDD, respectively, and no combinations (0%) with unfavorable results at either location. These results suggest that there would be minor or negligible positive and negative water temperature-related effects of Alternative 2 Without TUCP Without VA on fall-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.

Overall, the four phases of Alternative 2 would have negligible positive and negative water temperature-related effects to fall-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River (Table O-74).

Fall-run Chinook Salmon: Sacramento River Pulse Flows

To increase outmigration survival of Chinook salmon, Reclamation would release up to 150 TAF in pulse flow(s) each water year, typically in the spring, to benefit Chinook salmon in the Sacramento River watershed when the pulse does not interfere with the ability to meet temperature objectives or other anticipated operations of the reservoir. Reclamation will schedule this pulse after coordination through the Sacramento River Group and Shasta Operations Team and may include coordinating timing with natural flow events, potential storage management operations and/or pulse flows in tributaries. There may be unintentional adverse impacts of spring pulse flows on redd dewatering from sudden drops in flow. However, redd surveys occur during the pulse flow period and redd dewatering has not been observed.

Fall-run Chinook Salmon: Summary

The differences in seasonal operations in the Sacramento River between Alternative 2 and the No Action Alternative are expected to have minor impacts on fall-run Chinook salmon spawning habitat and incubation in the Sacramento River. Under Alternative 2, changes in flows may result in minor increases or decreases in spawning habitat area, with September and October having the greatest spawning WUA. Fall-run Chinook salmon redd dewatering potential under Alternative 2 is generally slightly higher than under the No Action Alternative, except for appreciable increases in critically dry and below normal water year types for some Alternative 2 phases. There may be redd dewatering following spring pulse flow events, though this has not been observed during redd surveys. Alternative 2 would cause adverse and negligible beneficial water temperature-related impacts to fall-run Chinook salmon spawning and egg/alevin incubation conditions in the Sacramento River.

Late Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under the four phases of Alternative 2, differences in mean spawning WUA are generally lower than or similar to the No Action Alternative across the water year types and phases (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between the four phases of Alternative 2 and the No Action Alternative is a

0.4% increase in critically dry water years under Alternative 2 Without TUCP Systemwide VA. The largest reduction in estimated spawning habitat is a -2.0% decrease in dry water year types under Alternative 2 With TUCP Without VA.

The monthly median values of spawning WUA under the four phases of Alternative 2 are similar to the No Action Alternative throughout the three spawning months (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are also relatively similar across all three spawning months. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are highest in February but all three months are above 8,000 cfs (Table O-182 through Table O-185). This results in spawning WUA results that are approximately the same across all three months because the late fall-run Chinook salmon spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 3,000 to 6,000 cfs).

The results of the spawning habitat analysis based on CalSim 3 simulated flows suggest that the four phases of Alternative 2 may have a minor (less than 2.5%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. The three months of potential late fall-run Chinook salmon spawning have similar estimated spawning WUA across all alternatives.

Late Fall-run Chinook Salmon: Redd Dewatering Analysis

The results for both the No Action Alternative and Alternative 2 show large and consistent variations in percentage of late fall-run Chinook salmon redds dewatered with water year type, varying from high redd dewatering in wet water years to low redd dewatering in critically dry water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation reflects flow conditions for the winter and spring months when late fall-run Chinook salmon spawning and incubation occurs. During wet winters and springs, periodic storms and high runoff increase flow fluctuations, which tends to result in greater redd dewatering. In drier years, flow fluctuations are reduced and fewer redds are dewatered. Most differences in mean redd dewatering potential between the four phases of Alternative 2 and the No Action Alternative are small, but some are large, at least in terms of absolute differences. These differences include a 39.2% decrease in redd dewatering under Alternative 2 Without TUCP With Delta VA in critically dry water years and 20.2% and 18.7% increases under Alternative 2 Without TUCP With Systemwide VA in critically dry and dry water years, respectively (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). In terms of absolute differences, the largest difference is a 1.4% increase under Alternative 2 Without TUCP With Systemwide VA. Overall, the results indicate that redd dewatering potential under the four phases of Alternative 2 would be largely similar to results under the No Action Alternative, with consistently small absolute differences.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 267 for Keswick Dam and Table 268 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*,

Table 270 for Keswick Dam and Table 271 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 273 for Keswick Dam and Table 274 for below Clear Creek.

Results for the three analyses are summarized in Table O-75. Table O-75, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 with TUCP Without VA** for the 42.1°F to 55°F spawning initiation range analysis, there were zero and one month-water year type combinations (0% and 5.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and Clear Creek, respectively (Table O-75). There was one and zero combinations (5.0% and 0%, respectively) with unfavorable results at Keswick Dam and below Clear Creek. For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were four and five combinations (20.0% and 25.0%, respectively) with favorable results at Keswick Dam and Clear Creek, respectively. There were no combinations (0%) with unfavorable results at both locations. These results suggest that there would be positive water temperature-related effects of Alternative 2 With TUCP Without VA on late fall-run Chinook salmon spawning initiation, egg incubation, and fry emergence, and negligible negative effects to these life stages.
- Under **Alternative 2 Without TUCP Without VA** for the 42.1°F to 55°F spawning initiation range analysis, there were zero and one month-water year type combinations (0% and 5.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and Clear Creek, respectively (Table O-75). There were one and zero combinations (5.0% and 0%, respectively) with unfavorable results at Keswick Dam and Clear Creek, respectively. For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were four and five combinations (20.0% and 25.0%, respectively) with favorable results at Keswick Dam and Clear Creek, respectively. There were no combinations (0%) with unfavorable results at both locations. These results suggest that there would be positive water temperature-related effects of Alternative 2 Without TUCP Without VA on late fall-run Chinook salmon spawning initiation, egg incubation, and fry emergence, and negligible negative effects to these life stages.
- Under **Alternative 2 Without TUCP Delta VA** for the 42.1°F to 55°F spawning initiation range analysis, there were zero and one month-water year type combinations (0% and 5.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and Clear Creek, respectively (Table O-75). There were zero combinations (0%) with unfavorable results at Keswick Dam and Clear Creek. For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or

unfavorable results at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were four and five combinations (20.0% and 25.0%, respectively) with favorable results at Keswick Dam and Clear Creek, respectively. There were no combinations (0%) with unfavorable results at both locations. These results suggest that there would be positive water temperature-related effects of Alternative 2 Without TUCP Delta VA on late fall-run Chinook salmon spawning initiation, egg incubation, and fry emergence.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 42.1°F to 55°F spawning initiation range analysis, there were zero and two month-water year type combinations (0% and 10.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and Clear Creek, respectively, and no combinations with unfavorable results at both locations (Table O-75). For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were four and five combinations (20.0% and 25.0%, respectively) with favorable results at Keswick Dam and Clear Creek, respectively, and no combinations (0%) with unfavorable results at both locations. These results suggest that there would be positive water temperature-related effects of Alternative 2 Without TUCP Systemwide VAs on late fall-run Chinook salmon spawning initiation, egg incubation, and fry emergence.

Overall, the four phases of Alternative 2 would have similar positive water temperature-related effects and negligible negative effects to late fall-run Chinook salmon spawning and egg/incubation in the Sacramento River (Table O-75).

Late Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on spawning behavior and redd dewatering from sudden drops in flow. However, redd surveys occur during the pulse flow period and redd dewatering has not been observed.

Late Fall-run Chinook Salmon: Summary

The differences in seasonal operations in the Sacramento River between Alternative 2 and the No Action Alternative are expected to have similar impacts on late fall-run Chinook salmon spawning habitat and incubation in the Sacramento River. Under Alternative 2, changes in flows may result in negligible increases or decreases in spawning habitat area. Late fall-run Chinook salmon redd dewatering potential under Alternative 2 is largely similar to the No Action Alternative. There may be changes to spawning behavior and redd dewatering with spring pulse flow events, but redd dewatering has not been observed during the pulse flow period. Alternative 2 would cause beneficial and negligible adverse water temperature-related impacts to late fall-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.

Juvenile Rearing and Emigration

The majority of young fall-run Chinook salmon migrate to the ocean during the first few months following emergence, mostly between January through June. Late fall-run Chinook salmon juveniles typically enter the ocean after seven to 13 months of rearing in freshwater, generally between October and February. See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Fry Rearing Habitat Analysis

Under the four phases of Alternative 2, mean fry rearing WUA is variable depending on the phase and water year type but have less than a 2% difference compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The only increase in mean fry rearing habitat is under Alternative 2 With TUCP Without VA, with a 0.3% increase in critically dry water year types in comparison the No Action Alternative. The largest reduction in mean fry rearing habitat is under Alternative 2 With TUCP Without VA, with a 1.8% decrease in dry water year types in comparison the No Action Alternative.

The monthly median values of fry rearing WUA under the four phases of Alternative 2 are similar throughout the fry rearing months December through March (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The results during December, January, and March show little variation in the third quartile of the WUA distributions. This occurs because the fry rearing WUA curves peak at the lowest flows encountered in the river (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and Keswick Dam flow releases are frequently low during these months in critically dry water years when Shasta Reservoir is operated to rebuild storage volume (Table O-182 through Table O-185). The first quartile is much wider because a greater range of flows affect the fry rearing WUA values below the median.

The results of the fall-run Chinook salmon fry rearing habitat analysis suggest that the four phases of Alternative 2 in comparison to the No Action Alternative may have a minor (less than 2%) increase and/or decrease in estimated fry rearing habitat across all water year types. The estimated fry rearing habitat are similar from December through March under the four phases of Alternative 2 (less than a 5% difference).

Fall-run Chinook Salmon: Juvenile Rearing Habitat Analysis

Under the four phases of Alternative 2, mean juvenile rearing is variable depending on the phase and water year type but have less than a 3% difference in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated juvenile rearing habitat is under Alternative 2 With TUCP Without VA and the No Action Alternative, with a 2.8% increase in critically dry water year types. The largest decrease in estimated juvenile rearing habitat is under Alternative 2 Without TUCP Systemwide VA and the No Action Alternative, with a 0.8% decrease in below normal water year types.

The monthly median value of juvenile rearing WUA under the four phases of Alternative 2 are similar to the No Action Alternative February through June (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). During the juvenile rearing period, the median WUA values steadily decline from the highest median WUA values in March to the lowest median WUA values in July. The lower juvenile rearing WUA values in June result from releases in the summer months above 7,000 cfs (Table O-182 through Table O-185) and estimated peak juvenile rearing at flows below 5,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The results of the fall-run Chinook salmon juvenile rearing habitat analysis suggest that the four phases of Alternative 2 in comparison to the No Action Alternative are expected to have a minor (less than 3%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in the mainstem upper Sacramento River.

Fall-run Chinook Salmon: Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. The four phases of Alternative 2 differ in how juvenile stranding of fall-fun fry varies with water year type (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). All the phases except Alternative 2 Without TUCP Systemwide VA have the highest mean fall-run stranding in wet water years and the lowest stranding in critically dry years. Under Alternative 2 Without TUCP Systemwide VA, the lowest mean stranding is in below normal water years. The four phases of Alternative 2 show similar patterns of variation across the four principal months of fall-run Chinook salmon fry rearing, with the highest stranding in February and the lowest in March (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The means of fall-run Chinook salmon fry stranding under the four phases of Alternative 2 differ inconsistently from the means under the No Action Alternative. However, large reductions in stranding are more prevalent than large increases with reductions of greater than >10% under Alternative 2 Without TUCP Without VA and Alternative 2 Without TUCP Delta VA in critically dry water years and under Alternative 2 Without TUCP Systemwide VA in below normal and above normal water year types. The largest increases in mean stranding of fall-run fry are 8.4% and 6.1% for dry water years under Alternative 2 Without TUCP Delta VA and Alternative 2 Without TUCP Systemwide VA, respectively.

Overall, fall-run juvenile stranding for fry under the four phases of Alternative 2 differs inconsistently in comparison to the No Action Alternative, but reductions are larger and more frequent than increases for all four phases.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 247 for Keswick Dam, Table 248 for Red Bluff Diversion Dam, and Table 249 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 251 for Keswick Dam, Table 251 for Red Bluff Diversion Dam, and Table 253 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 255 for Keswick Dam, Table 256 for Red Bluff Diversion Dam, and Table 257 for Hamilton City.

Results for the three analyses are summarized in Table O-78. Table O-78, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at all locations (Table O-78). There were zero to three combinations (0% to 15.0%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations (0%) with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to ten combinations (0% to 50.0%) with favorable results depending on location. There would be no combinations (0%) with unfavorable results at all locations. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 With TUCP Without VA on fall-run Chinook salmon juvenile rearing and emigration.
- Under **Alternative 2 Without TUCP Without VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at any location (Table O-78). There were zero to three combinations (0% to 15.0%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations (0%) with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to nine combinations (0% to 45.0%) with favorable results depending on location. There would be no combinations (0%) with unfavorable results at all locations. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 Without TUCP Without VA on fall-run Chinook salmon juvenile rearing and emigration.
- Under **Alternative 2 Without TUCP Delta VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at all locations (Table O-78). There were zero to three combinations (0% to 15.0%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations (0%) with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to seven combinations (0% to 35.0%) with favorable results depending on location. There would be no combinations (0%) with unfavorable results at all locations. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 Without TUCP Delta VA on fall-run Chinook salmon juvenile rearing and emigration.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at all locations (Table O-78). There were one to three combinations (5% to 15.0%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations (0%) with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to seven combinations (0%

to 35.0%) with favorable results depending on location. There would be no combinations (0%) with unfavorable results at all locations. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 Without TUCP Systemwide VAs on fall-run Chinook salmon juvenile rearing and emigration.

Overall, the four phases of Alternative 2 would have similar water temperature-related effects to fall-run Chinook salmon juvenile rearing and outmigration in the Sacramento River. All four phases would have both positive and negative effects on juvenile rearing and outmigration.

Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

Fall-run Chinook Salmon: Summary

Under Alternative 2, differences in seasonal operations in the Sacramento River are largely expected to have minor impacts on fall-run Chinook salmon fry and juvenile rearing habitat and behavior. There would be minor changes in WUA for fall-run Chinook salmon fry rearing in all water year types relative to the No Action Alternative. There would also be a minor to negligible increase in juvenile rearing habitat in all phases of Alternative 2 and all water year types, but similar estimated habitat in the mainstem upper Sacramento River on an average monthly basis. Fry stranding would be both increased and decreased under all phases of Alternative 2, however the increase in stranding was greater and more frequent than the decreases in stranding. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. Under all phases of Alternative 2, fall-run Chinook salmon rearing fry and juveniles would experience more unfavorable water temperature conditions below Keswick Dam and near the RBDD for growth, smoltification, and vulnerability to predators, but more favorable conditions for juveniles with regards to pathogen virulence below RBDD. Alternative 2 is expected to have beneficial and adverse water temperature-related impacts on fall-run Chinook salmon rearing in the Sacramento River.

Late Fall-run Chinook Salmon: Fry Rearing Habitat Analysis

Under the four phases of Alternative 2, mean fry rearing WUA generally decreases in all water year types in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Under the four phases of Alternative 2, mean fry rearing WUA generally decreases in all water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat is under Alternative 2 Without TUCP Without VA, with a 0.2% increase in above normal water year types in comparison the No Action Alternative. The largest reduction in estimated fry rearing habitat is under Alternative 2 Without TUCP with Systemwide VA, with a 1.7% decrease in below normal water year types in comparison the No Action Alternative.

On a monthly scale, the median value of fry rearing WUA under Alternative 2 is 11% lower than the No Action Alternative in April but similar in March, May, and June (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The median fry rearing WUA values under the modeled alternatives are similar across the months of May and June, and highest in March. The lower fry rearing WUA values in May and June result from releases in the summer months

above 7,000 cfs (Table O-182 through Table O-185) and estimated peak fry rearing at flows below 5,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The monthly median values of fry rearing WUA under the four phases of Alternative 2 is up to 11% lower than the No Action Alternative in April but similar in March, May, and June (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The median fry rearing WUA values under the modeled alternatives are similar across the months of May and June, and highest in March. The lower fry rearing WUA values in May and June result from releases in the summer months above 7,000 cfs (Table O-182 through Table O-185) and estimated peak fry rearing at flows below 5,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The results of the late fall-run Chinook salmon fry rearing habitat analysis suggest that the four phases of Alternative 2 in comparison to the No Action Alternative may have a minor (less than 2%) increase and/or decrease in estimated fry rearing habitat across all water year types and the greatest reduction in estimated habitat may occur in April (11%) in the mainstem upper Sacramento River.

<u>Late Fall-run Chinook Salmon: Fry Stranding Analysis</u>

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. The four phases of Alternative 2 show a similar pattern of variation in how stranding of late fall-fun fry varies with water year type (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). All four phases have the highest mean late fall-run Chinook salmon stranding in wet water years, the next highest in critically dry years, and relatively small differences among the other three water year types. The four phases of Alternative 2 show similar patterns of variation across the four principal months of late fall-run Chinook salmon fry rearing, with the highest stranding in March, the lowest in May, and intermediate stranding in April and June (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The means of late fall-run Chinook salmon fry stranding under the four phases of Alternative 2 are consistently lower than those under the No Action Alternative in wet through dry water year types, but are consistently higher, and generally much higher, in critically dry water year types (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The largest reductions in stranding are 20.1% and 31.4% for above normal and below normal water year types, respectively, under Alternative 2 Without TUCP Systemwide VA. The largest increases, ranging from 30.2% to 41.4%, occur in critically dry water years under Alternative 2 Without TUCP Without VA, Alternative 2 Without TUCP Delta VA, and Alternative 2 Without TUCP Systemwide VA.

Overall, changes in late fall-run Chinook salmon juvenile stranding for fry under the four phases of Alternative 2 versus the No Action Alternative differ greatly between critically dry water years and the other water year types. In critically dry water years, stranding for three of the four phases is much higher than under the No Action Alternative, while in the other water year types stranding is consistently lower for all four phases of Alternative 2 as compared to the No Action Alternative.

Late Fall-run Chinook Salmon: Juvenile Rearing Habitat Analyses

Mean juvenile rearing WUA under the four phases of Alternative 2 in comparison to the No Action Alternative, constitute both increase and reductions depending on the phase and water year type, but are below a 3% difference (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated juvenile rearing habitat is under Alternative 2 With TUCP Without VA and the No Action Alternative, with a 2.8% increase in critically dry water year types. The largest reduction in estimated juvenile rearing habitat is under Alternative 2 With TUCP Without VA and the No Action Alternative, with a 0.6% decrease in below normal water year types.

The monthly median values of juvenile rearing WUA under the four phases of Alternative 2 are similar to the No Action Alternative May through September (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The juvenile rearing WUA values under the modeled alternatives gradually decrease from May until the lowest estimated values in July. The highest median WUA values occur in September across all alternatives. The lower juvenile rearing WUA values in June and July result from releases in the summer months above 7,000 cfs (Table O-182 through Table O-185) and estimated peak juvenile rearing at flows below 5,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The results of the fall-run Chinook salmon juvenile rearing habitat analysis suggest that the four phases of Alternative 2 in comparison to the No Action Alternative may have a minor (less than 3%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in the mainstem upper Sacramento River.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 279 for Keswick Dam, Table 280 for Red Bluff Diversion Dam, and Table 281 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 283for Keswick Dam, Table 284 for Red Bluff Diversion Dam, and Table 285 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 287 for Keswick Dam, Table 288 for Red Bluff Diversion Dam, and Table 289 for Hamilton City.

Results for the three analyses are summarized in Table O-77. Table O-77, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to two month-water year type combinations (0% to 3.6% of total combinations during the period) with favorable results depending on

location (Table O-77). There were one to three combinations (1.8% to 5.5%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to 14 combinations (0% to 25.5%) with favorable results depending on location. There were no combinations (0%with unfavorable results at each location. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 With TUCP Without VA on late fall-run Chinook salmon juvenile rearing and emigration.

- Under **Alternative 2 Without TUCP Without VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to two month-water year type combinations (0% to 3.6% of total combinations during the period) with favorable results depending on location (Table O-77). There were one to five combinations (1.8% to 9.1%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to 14 combinations (0% to 25.5%) with favorable results depending on location. There were zero combinations (0%) with unfavorable results depending on location. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 Without TUCP Without VA on late fall-run Chinook salmon juvenile rearing and emigration.
- Under **Alternative 2 Without TUCP Delta VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were one to four month-water year type combinations (1.8% to 7.3% of total combinations during the period) with favorable results depending on location (Table O-77). There were one to three combinations (1.8% to 5.5%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to 11 combinations (0% to 20.0%) with favorable results depending on location. There were zero and one combinations (0% to 1.8%) with unfavorable results depending on location. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 Without TUCP Delta VA on late fall-run Chinook salmon juvenile rearing and emigration.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to three month-water year type combinations (0% to 5.5% of total combinations during the period) with favorable results depending on location (Table O-77). There were two to three combinations (3.6% to 5.5%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to 11 combinations (0% to 20.0%) with favorable results depending on location. There were zero to one combinations (0% to 1.8%) with unfavorable results depending on location. These results suggest that there would be positive and negative water temperature-related effects of Alternative 2 Without TUCP Systemwide VAs on late fall-run Chinook salmon juvenile rearing and emigration.

Overall, the four phases of Alternative 2 would have similar water temperature-related effects to fall-run Chinook salmon juvenile rearing and outmigration in the Sacramento River. All four phases would have both positive and negative water temperature-related effects on juvenile rearing and outmigration (Table O-77).

Late Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

Late Fall-run Chinook Salmon: Summary

Under Alternative 2, differences in seasonal operations in the Sacramento River are largely expected to have minor impacts on late fall-run Chinook salmon fry and juvenile rearing habitat and behavior. There would be minor changes (both increases and decreases) in WUA for late fall-run Chinook salmon fry rearing in all water year types relative to the No Action Alternative. Changes in late fall-run Chinook salmon fry stranding would be minor, both increases and decreases under all phases of Alternative 2 under all water year types. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. Late fall-run Chinook salmon rearing fry and juveniles would experience minor changes in favorable and unfavorable water temperature conditions below Keswick Dam and near the RBDD for growth, smoltification, and vulnerability to predators, and more favorable conditions protecting them from virulent pathogens. Alternative 2 is expected to have beneficial and adverse water temperature-related impacts on late fall-run Chinook salmon rearing in the Sacramento River.

Adult Upstream Migration and Holding

Fall-run Chinook salmon migrate upstream past RBDD on the Sacramento River from July to December, and late fall-run Chinook salmon migrate upstream past RBDD from October through December (National Marine Fisheries Service 2009a). Like spring-run, adult late fall-run Chinook salmon typically hold in the river for 1 month to 3 months before spawning, while fall-run Chinook salmon generally spawn shortly after entering freshwater. See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

- **Alternative 2 With TUCP Without VA:** During the October through December period of adult fall-run and late fall-run Chinook salmon upstream migration and holding, the mean monthly flows under Alternative 2 With TUCP with VA at Sacramento River below Red Bluff Diversion Dam, Keswick Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative with the greatest increase in November (15%) at Keswick Dam and Wilkins Slough during critically dry years (Table O-182, Table O-186, Table O-190, Table O-194).

- **Alternative 2 Without TUCP Without VA:** During the October through December period of adult fall-run and late fall-run Chinook salmon upstream migration and holding, the mean monthly flows under Alternative 2 Without TUCP Without VA at Sacramento River below Red Bluff Diversion Dam, Keswick Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative with the greatest increase in November (15%) at Keswick Dam and Wilkins Slough during critically dry years (Table O-182, Table O-186, Table O-190, Table O-194).
- **Alternative 2 Without TUCP Delta VA:** During the October through December period of adult fall-run and late fall-run Chinook salmon upstream migration and holding, the mean monthly flows under Alternative 2 Without TUCP with Delta VA at Sacramento River below Red Bluff Diversion Dam, Keswick Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative with the greatest increase in November (12-15%) at all locations during critically dry years (Table O-182, Table O-186, Table O-190, Table O-194).
- **Alternative 2 Without TUCP Systemwide VA:** During the October through December period of adult fall-run and late fall-run Chinook salmon upstream migration and holding, the mean monthly flows under Alternative 2 Without TUCP Systemwide VA at Sacramento River below Red Bluff Diversion Dam, Keswick Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative with the greatest increase in November (12%) at Keswick Dam during critically dry years (Table O-182, Table O-186, Table O-190, Table O-194).

Overall, the four phases of Alternative 2 would have similar flows compared to the No Action Alternative. Flows at Hamilton City and Wilkins Slough are sufficient to allow passage and holding for all four phases during all water year types. The average monthly flows across all water year types under all phases of Alternative 2 between June and December would be greater than 5,000 cfs at Wilkins Slough, greater than 6,200 cfs at Hamilton City, greater than 6,700 cfs at RBDD, and greater than 5,900 cfs at Keswick Dam (Tables O-182 through O-197). Flows at in the Sacramento River under all phases of Alternative 2 would be high enough (> 3,250 cfs) to allow upstream passage.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 227 for Keswick Dam, Table 228 for Red Bluff Diversion Dam, and Table 229 for Hamilton City. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 231 for Keswick Dam, Table 232 for Red Bluff Diversion Dam, and Table 233 for Hamilton City.

Results are summarized in Table O-78. Table O-78, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 37.9°F to 68°F successful adult migration range analysis, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at each location (Table O-78). There were zero to one combinations (0% to 3.3%) with unfavorable results depending on location. For the 59.9°F adult pathogen virulence threshold analysis, there were zero to four combinations (0% to 16.7%) with favorable results and no combinations (0%) with unfavorable results depending on location. These results suggest that there would be positive effects of Alternative 2 With TUCP Without VA on water temperature conditions for fall-run Chinook salmon adult migrants in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 37.9°F to 68°F successful adult migration range analysis, there were zero to one month-water year type combinations (0% to 3.3% of total combinations during the period) with favorable results depending on location (Table O-78). There were zero and one combinations (0% to 3.3%) with unfavorable results depending on location. For the 59.9°F adult pathogen virulence threshold analysis, there were one to four combinations (0% to 13.3%) with favorable results and zero combinations (0%) with unfavorable results depending on location. These results suggest that there would be positive effects of Alternative 2 Without TUCP Without VA on water temperature conditions for fall-run Chinook salmon adult migrants in the Sacramento River.
- Under **Alternative 2 Without TUCP Delta VA** for the 37.9°F to 68°F successful adult migration range analysis, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at all locations (Table O-78). There were zero and one combinations (0% to 3.3%) with unfavorable results depending on location. For the 59.9°F adult pathogen virulence threshold analysis, there were zero to four combinations (0% to 16.7%) with favorable results and zero and one combinations (0% to 3.3%) with unfavorable results depending on location. These results suggest that there would be positive effects of Alternative 2 Without TUCP Delta VA on water temperature conditions for fall-run Chinook salmon adult migrants in the Sacramento River.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 37.9°F to 68°F successful adult migration range analysis, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at all locations (Table O-78). There were 0 to 1 combinations (0% to 3.3%) with unfavorable results depending on location. For the 59.9°F adult pathogen virulence threshold analysis, there were zero to four combinations (0% to 13.3%) with favorable results and zero and one combinations (0% to 3.3%) with unfavorable results depending on location. These results suggest that there would be positive effects of Alternative 2 Without TUCP Delta VA on water temperature conditions for fall-run Chinook salmon adult migrants in the Sacramento River.

Overall, the four phases of Alternative 2 would have similar water temperature-related effects to fall-run Chinook salmon adult migration and holding in the Sacramento River. All four phases would have positive effects and negligible negative effects on adult migration and holding (Table O-78).

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 259 for Keswick Dam, Table 260 for Red Bluff Diversion Dam, and Table 261 for Hamilton City. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 262 for Keswick Dam, Table 263 for Red Bluff Diversion Dam, and Table 264 for Hamilton City.

Results are summarized in Table O-79. Table O-79, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 37.9°F to 68°F successful adult migration range analysis, there were zero month-water year type combinations (0% to 2.5% of total combinations during the period) with favorable results depending on location (Table O-79). There were no combinations (0%) with unfavorable results at all locations. For the 59.9°F adult pathogen virulence threshold analysis, there would be zero to two combinations (0% to 10.0%) with favorable results and no combinations (0%) with unfavorable results depending on location. These results suggest that there would be positive effects of Alternative 2 With TUCP Without VA on water temperature conditions for late fall-run Chinook salmon adult migrants in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 37.9°F to 68°F successful adult migration range analysis, there were zero to one month-water year type combinations (0% to 2.5% of total combinations during the period) with favorable results depending on location (Table O-79). There were zero and one combinations (0% to 2.5%) with unfavorable results depending on location. For the 59.9°F adult pathogen virulence threshold analysis, there would be one to three combinations (2.5% to 7.5%) with favorable results and zero combinations (0%)with unfavorable results depending on location. These results suggest that there would be negligible effects of Alternative 2 Without TUCP Without VA on water temperature conditions for late fall-run Chinook salmon adult migrants in the Sacramento River.
- Under **Alternative 2 Without TUCP Delta VA** for the 37.9°F to 68°F successful adult migration range analysis, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at all locations (Table O-79). There were zero and one combinations (0% to 2.5%) with unfavorable results depending on location. For the 59.9°F adult pathogen virulence threshold analysis, there would be zero to two combinations (0% to 5.0%) with favorable results and zero and one combinations (0% to 2.5%) with unfavorable results depending on location. These results suggest that there would be negligible effects of Alternative 2 Without TUCP Delta VA on water temperature conditions for late fall-run Chinook salmon adult migrants in the Sacramento River.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 37.9°F to 68°F successful adult migration range analysis, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at all locations (Table O-79). There were zero and one combinations (0% to 2.5%) with unfavorable results depending on location. For the 59.9°F adult pathogen virulence threshold analysis, there would be zero to two combinations (0% to 5.0%) with favorable results and zero and one combinations (0% to 2.5%) with unfavorable results depending on location. These results suggest that there would be negligible effects of Alternative 2 Without TUCP Systemwide VAs on water temperature conditions for late fall-run Chinook salmon adult migration and holding in the Sacramento River.

Overall, three of the four phases of Alternative 2 would have similar small or negligible water temperature-related effects on late fall-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River (Table O-79).

Sacramento River Pulse Flows

Fall-run and late fall-run adult migration is outside the spring pulse flow period.

Summary

Under all phases of Alternative 2, differences in seasonal operations in the Sacramento River are largely expected to have similar impacts caused by flows and water temperature conditions on fall-run Chinook salmon and late fall-run Chinook salmon adult migration and holding compared to the No Action Alternative. There would be a beneficial and negligible adverse water temperature-related effects under all phases of Alternative 2 on both fall-run and late fall-run Chinook salmon.

O.5.14.2 Clear Creek

Spawning and Egg Incubation

Fall-run Chinook salmon typically spawn in Clear Creek from late September through early December, (Earley et al. 2013). Fall-run typically emerge from the gravel in December through March. Timing of peak late-fall spawning in the Sacramento River, January through April, was used as a proxy for Clear Creek. Late fall-run Chinook salmon incubation and emergence is estimated to occur from March through June.

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under the four phases of Alternative 2, mean spawning WUA increases in all water year types compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The greatest increase in estimated spawning habitat is a 6.9% increase in critically dry water year types under Alternative 2 Without TUCP with Delta VA. There are no anticipated reductions in mean spawning WUA under the four phases of Alternative 2 in comparison to the No Action Alternative.

The mean values of spawning WUA by month are higher in November and December and lower in October under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the three months, December is expected to have the highest spawning WUA values under Alternative 2.

The spawning habitat analysis suggests that the four phases of Alternative 2 may have a beneficial effect (1.7-6.9% increase) in fall-run Chinook salmon estimated spawning habitat in Clear Creek across water year types when compared to the No Action Alternative.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 237 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 240 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during December through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 243 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-80. Table O-80, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 42.1°F to 55°F spawning initiation range analysis, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-80). For the 59.9°F pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero (0%) combinations with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on fall-run Chinook salmon spawning and egg incubation in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-80).

Overall, the four phases of Alternative 2 would have similar negligible effects on water temperature conditions for fall-run Chinook salmon spawning and egg incubation in Clear Creek (Table O-80), relative to the No Action Alternative.

Fall-run Chinook Salmon: Summary

Differences in seasonal operations in Clear Creek between the four phases of Alternative 2 and the No Action Alternative are expected to have a beneficial impact with a potential 1.7-6.9% WUA increase for fall-run Chinook salmon estimated spawning habitat in Clear Creek across water year types when compared to the No Action Alternative. Differences in water temperature between the four phases of Alternative 2 and the No Action Alternative are expected to have similar negligible impacts on spawning and egg incubation.

Late Fall-run Chinook Salmon: CalSim 3 Flows

Under the four phases of Alternative 2, average flows released below Whiskeytown Dam would be reduced from in February and June and higher in January and March through May (Table O-218 through Table O-221) when compared to the No Action Alternative. The largest flow decrease under Alternative 2, compared to the No Action Alternative, occur in June of all water year types, and in February in wet, above normal, and below normal water years. There would be mostly flow increases under Alternative 2 compared to the No Action Alternative that occur in January, March, and May are in all water year types. Under Alternative 2 compared to the No Action Alternative, the average of all water year flow simulations project flow decreases June through October and February and increases November through January and March through May.

Using peak spawning flows of 300-350 cfs from the fall-run WUA curves as a proxy for potential late-fall-run spawning habitat changes under Alternative 2 suggest that despite some decreases, when averaged across all water year types, flows would remain near peak spawning flows of 300 cfs from January (301 cfs) through March (280 cfs). Under Alternative 2, there would be an increase in spawning habitat available for late fall-run Chinook salmon as a result of flows in Clear Creek.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 269 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 272 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 275 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-81. Table O-81, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2** for the 42.1°F to 55°F range for spawning initiation temperature analysis, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results below Whiskeytown Dam (Table O-81). For the 59.9°F pathogen virulence threshold, there were no month-water year type combinations (0%) with favorable or unfavorable results below Whiskeytown Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were no month-water year type combinations (0%) with favorable or unfavorable results below Whiskeytown Dam.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-81).

Overall, the four phases of Alternative 2 would have similar negligible effects on water temperature conditions for fall-run Chinook salmon spawning and egg incubation in Clear Creek (Table O-81).

Late Fall-run Chinook Salmon: Summary

During the late-fall Chinook salmon spawning and egg incubation periods (January through June), the mean monthly flows under the four phases of Alternative 2 would generally have an increase in January, March, April and May, but moderate to substantial decrease in June and February when averaged across all water year types. This would result in substantial beneficial impacts to late fall-run Chinook salmon for the majority of the spawning and incubation period, but there would be substantial adverse impacts for a portion of the life stage as well. Water temperature results suggest that there would be negligible water temperature-related effects of all phases of Alternative 2 on late fall-run Chinook salmon spawning and egg incubation in Clear Creek.

Juvenile Rearing and Emigration

The majority of young fall-run Chinook salmon migrate to the ocean during the first few months following emergence, mostly between January through June. Late fall-run Chinook salmon juveniles typically enter the ocean after seven to 13 months of rearing in freshwater, generally between October and February (Moyle 2002).

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Fry Rearing Habitat Analysis

Under the four phases of Alternative 2, mean fry rearing WUA decreases in all water year types compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean fry rearing WUA under the four phases of Alternative 2 in comparison to the No Action Alternative. The greatest reduction in estimated fry rearing habitat is a 2.3% decrease in dry water year types under all four phases of Alternative 2.

The mean values of fry rearing WUA by month are slightly lower under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The four fry rearing months are expected to have similar fry rearing WUA values.

The results of the fry rearing habitat analysis indicate that the four phases of Alternative 2 in comparison to the No Action Alternative may have an adverse effect (less than 3% decrease) in estimated fall-run Chinook salmon fry rearing habitat across all water year types in Clear Creek.

Fall-run Chinook Salmon: Juvenile Rearing Habitat Analyses

Under the four phases of Alternative 2, mean juvenile rearing WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under the four phases of Alternative 2 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between the four phases Alternative 2 and the No Action Alternative is a 11.3% decrease in critically dry water year types under Alternative 2 Without TUCP Without VA. On average across all water year types, there is a 4.1 to 4.8% reduction in estimated juvenile rearing habitat under the four phases of Alternative 2.

The mean values of juvenile rearing WUA by month are lower June through September and higher in May under Alternative 2 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the five months, May and June are expected to have the highest juvenile rearing WUA values.

The results of the juvenile rearing habitat analyses indicate that the four phases of Alternative 2 in comparison to the No Action Alternative may have a minor adverse impact (4.1-4.8% decrease) in fall-run Chinook salmon juvenile rearing habitat across all water year types.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 250 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 254 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 258 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-82. Table O-82, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-82). For the 75.2°F UILT for rearing and migrating juveniles, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F juvenile pathogen virulence threshold, there

were no month-water year type combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VA** were identical to those for Alternative 2 Without TUCP Without VA (Table O-82).

Overall, all four phases of Alternative 2 would have similar negligible effects on water temperature conditions for fall-run Chinook salmon juvenile rearing and emigration in Clear Creek (Table O-82).

Fall-run Chinook Salmon: Summary

Differences in seasonal operations in Clear Creek between the four phases of Alternative 2 and the No Action Alternative may a minor adverse impact in estimated fall-run Chinook salmon rearing habitat across all water year types in Clear Creek when compared to the No Action Alternative. Differences in water temperature between the four phases of Alternative 2 and the No Action Alternative are expected to have negligible impacts on fall-run Chinook salmon juvenile rearing and emigration.

Late Fall-run Chinook Salmon: CalSim 3 Flows

Under the four phases of Alternative 2 average flows released below Whiskeytown Dam would be reduced from June through October and higher November through January and March through May in most water year types (Table O-218 through Table O-221) when compared to the No Action Alternative. The largest decrease under Alternative 2 compared to the No Action Alternative occur in June through August of all water year types, except critically dry year types when it would occur in June and September. The largest increases under Alternative 2 compared to the No Action Alternative occur in December, January, March, and May all water year types, except critically dry year types when it would occur in January, February, and May. Under Alternative 2 compared to the No Action Alternative, the average of all water year flow simulations project flow decreases June through October and February and increases November through January and March through May.

Using the fall-run Chinook salmon WUA curves as a proxy, optimal flows for maximum late fall-run Chinook salmon juvenile rearing habitat is 300-400 cfs. Under Alternative 2 With TUCP Without VA from March through September during juvenile rearing periods for late fall-run Chinook salmon, flows are expected to be higher than under the No Action Alternative by up to 36% for averaged flows by month across water year types, increasing available habitat. Flows are expected to be decreased June through October, up to 31% lower by average monthly flow across water year types. Results are very similar under all phases of Alternative 2. There would be both a decrease and an increase in juvenile and fry rearing habitat available for late fall-run Chinook salmon as a result of flows in Clear Creek.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation

vulnerability during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 282 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 286 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 290 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-83. Table O-83, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-83). For the 75.2°F UILT for rearing and migrating juveniles, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F juvenile pathogen virulence threshold, there were no month-water year type combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on late fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VA** were identical to those for Alternative 2 Without TUCP Without VA (Table O-83).

Overall, all 4 phases of Alternative 2 would have similar negligible effects on water temperature conditions for late fall-run Chinook salmon juvenile rearing and emigration in Clear Creek (Table O-83).

<u>Late Fall-run Chinook Salmon: Summary</u>

The change in seasonal operations in Clear Creek between all phases of Alternative 2 and the No Action Alternative is expected to have both adverse impacts and beneficial impacts to late fall-run Chinook salmon juvenile rearing and emigration. Under Alternative 2, changes in flows in Clear Creek in June through October would result in substantial adverse impacts to rearing and emigrating juveniles, but flows in November through May would result in moderate to substantial beneficial impacts to rearing and emigrating juveniles. All phases of Alternative 2 would have similar negligible effects on water temperature conditions for late fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

Adult Upstream Migration and Holding

Fall-run Chinook salmon may arrive at Clear Creek before spawning from July through early December. Adult late fall-run Chinook salmon migrate and arrive slightly later and do not need to hold and mature before spawning from November into January.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: CalSim 3 Flows

Under the four phases of Alternative 2 average flows released below Whiskeytown Dam would generally be lower June through October and higher November through January and March through May in most water year types simulated (Table O-218 through Table O-221) when compared to the No Action Alternative. The largest decrease under Alternative 2 compared to the No Action Alternative occur in June through August of all water year types, except critically dry year types when it would occur in June and September. The largest increases under Alternative 2 compared to the No Action Alternative occur in December, January, March, and May all water year types, except critically dry year types when it would occur in January, February, and May. Under Alternative 2 compared to the No Action Alternative, the average of all water year flow simulations project flow decreases June through October and February, and increases November through January and March through May.

- **Alternative 2 With TUCP Without VA:** During the fall and late-fall Chinook salmon migration and holding period (July through December), the mean monthly flows under Alternative 2 With TUCP Without VA would be slightly to significant lower during the first half with an average reduction of 25% during July, 20% in August, 10% in September, and 13% in October. Alternatively, the flows would be higher during November (13% average) and December (31% average increase) providing a moderately beneficial impact.
- **Alternative 2 Without TUCP Without VA:** During the fall and late-fall Chinook salmon migration and holding period (July through December), the mean predicted monthly flows under Alternative 2 Without TUCP Without VA are very similar to that of Alternative 2 With TUCP Without VA.
- **Alternative 2 Without TUCP Delta VA:** During the fall and late-fall Chinook salmon migration and holding period (July through December), the mean predicted monthly flows under Alternative 2 Without TUCP Without VA are very similar to that of Alternative 2 With TUCP Without VA.
- **Alternative 2 Without TUCP Systemwide VA:** During the fall and late-fall Chinook salmon migration and holding period (July through December), the mean predicted monthly flows under Alternative 2 Without TUCP Without VA are very similar to that of Alternative 2 With TUCP Without VA.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 230 for Clear Creek below

Whiskeytown Dam. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 234 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-84. Table O-84, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 37.9°F to 68°F successful adult migration range, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-84). For the 59.9°F adult pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be no effect of Alternative 2 With TUCP Without VA on fall-run Chinook salmon adult upstream migration and holding in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-84).

Overall, the four phases of Alternative 2 would have no effect on water temperature conditions for fall-run Chinook salmon adult upstream migration and holding in Clear Creek (Table O-84).

<u>Fall-run Chinook Salmon: Summary</u>

There may both adverse and beneficial impacts of seasonal operations in Clear Creek on fall-run Chinook salmon adult upstream migration and holding based on analyses of simulated flows and water temperature under Alternative 2 in comparison to the No Action Alternative. Under Alternative 2 compared to the No Action Alternative, the average of all water year flow simulations project flow decreases June through October and February, and increases November through January. Water temperature results suggest that there would be no impact of Alternative 2 on fall-run Chinook salmon adult upstream migration and holding and pathogen virulence in Clear Creek below Whiskeytown Dam.

<u>Late Fall-run Chinook Salmon: CalSim 3 Flows</u>

Results of the CalSim 3 models are discussed in the fall-run section above and are similar under all four phases of Alternative 2. During the period of late fall-run adult migration (November - January), the average flow released below Whiskeytown Dam would be increased by 27% on average across all water year types when compared to the No Action Alternative (Table O-218 through Table O-221). The only exception is in December of a critically dry year there is a negligible 2% reduction in modeled flow. These results suggest there would be an increase in suitable migration and holding habitat available for adult late fall-run Chinook salmon as a result of flows in Clear Creek.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature above the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 262 for Clear Creek below Whiskeytown Dam. Full results of the percent of months with water temperature outside the 59.9°F adult pathogen virulence threshold analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 266 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-85. Table O-85, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 37.9°F to 68°F successful adult migration range, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-85). For the 59.9°F adult pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on late fall-run Chinook salmon adult upstream migration and holding in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-85).

Overall, the four phases of Alternative 2 would have no effect on water temperature conditions for late fall-run Chinook salmon adult upstream migration and holding in Clear Creek (Table O-85).

Late Fall-run Chinook Salmon: Summary

Flows would be increased under all four phases of Alternative 2 during the months of late fall-run Chinook salmon adult migration. The only exception is a negligible decrease of 1% during critically dry years in December. Under the four phases of Alternative 2 there would be no impact on water temperature conditions for late fall-run Chinook salmon adult upstream.

O.5.14.3 Lower American River

Spawning and Egg Incubation

Spawning occurs from about mid-October through early February, with peak spawning from mid-October through December. Fall-run chinook salmon spawning occurs within an 18-mile stretch from Paradise Beach to Nimbus Dam; however, most spawning occurs in the uppermost three miles (California Department of Fish and Wildlife 2012a). Chinook salmon egg and alevin incubation occurs in the lower American River from about mid-October through April. There is high variability from year to year; however, most incubation occurs from about mid-October through February.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Spawning Habitat—Flow Analysis

The American River WUA curve peaks at about 2,000 cfs (Attachment M.3, *American River Weighted Usable Area Analysis*) and flows under Alternative 2 are consistently well above this level in the wetter water years. Under the four phases of Alternative 2, fall-run Chinook salmon mean spawning WUA varies modestly among water year types with no obvious pattern except that the means for each water year type are similar across the four phases (Attachment M.3, *American River Weighted Usable Area Analysis*). The highest means are for above normal water year types and the lowest are for wet water years. Mean spawning WUA is consistently lower under all the phases of Alternative 2 than under the No Action Alternative, but only the reductions for critically dry water year types are large, ranging from 7.8% lower for Alternative 2 Without TUCP Without VA to 5.4% lower for Alternative 2 With TUCP Without VA (Attachment M.3, *American River Weighted Usable Area Analysis*). For all three months of the fall-run spawning season, estimated median spawning WUA under the four phases of Alternative 2 are modestly lower than the medians under the No Action Alternative (Attachment M.3, *American River Weighted Usable Area Analysis*). Median WUA for all alternatives is higher in October than November or December because flows, on average, are lower in October (Table O-226 through Table O-229). The fall-run spawning WUA curve (Attachment M.3, *American River Weighted Usable Area Analysis*) peaks at relatively low flows (below 3,000 cfs).

Overall, mean spawning WUA is consistently lower under all the phases of Alternative 2 than under the No Action Alternative, but only reductions for critically dry water year types are moderately large.

Redd Dewatering

The results of the analysis for redd dewatering potential for lower American River fall-run Chinook salmon indicate that mean redd dewatering potential under the four phases of Alternative 2 is consistently highest in wet water years and generally lowest in critically dry and below normal water years (Attachment M.1, *American River Redd Dewatering Analysis*). The higher redd dewatering potential in wet years likely results from a greater frequency of large flow fluctuations in wet water year types. Redd dewatering is consistently higher under the four phases of Alternative 2 than under the No Action Alternative. The increases are greater than 20% for all four phases of Alternative 2, including in above normal water years for Alternative 2 With TUCP Without VA and Alternative 2 Without TUCP Without VA and in below normal water years for Alternative 2 Without TUCP Delta VA and Alternative 2 Without TUCP Systemwide VA (Attachment M.1, *American River Redd Dewatering Analysis*). The size of some of these differences, which are relative differences rather than absolute difference, may be misleading; absolute differences are generally much smaller for these analyses, ranging from 1.4% to 2.5% for the four increases noted above. For the individual months of fall-run Chinook salmon spawning in the lower American River, median redd dewatering potential increases from spawning in October to that in December, reflecting the somewhat higher flows and likelihood of flow fluctuations over this period (Table O-226 through Table O-229).

Overall, mean redd dewatering is higher under the four phases of Alternative 2 than under the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 42.1°F to 55°F range for spawning initiation during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 63 for Hazel Avenue and Table 64 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult spawning pathogen virulence threshold during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 65 for Hazel Avenue and Table 66 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence during October through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 67 for Hazel Avenue and Table 68 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F fry pathogen virulence threshold during October through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 69 for Hazel Avenue and Table 70 for Watt Avenue.

Results for the four analyses are summarized in Table O-86. Table O-86, as described in Section O.4.12.3.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 42.1°F to 55°F range for spawning initiation, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue, (Table O-86). For the 59.9°F pathogen virulence threshold for spawning adults, there was zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue. For the 42.8°F to 56°F range for egg incubation and fry emergence analysis, there were zero and one month-water year type combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero and one month-water year type combinations (0.0% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold analysis, there were zero month-water type combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Without VA** for the 42.1°F to 55°F range for spawning initiation, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue (Table O-86). For the 59.9°F pathogen virulence threshold for spawning adults, there were zero combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue. For the 42.8°F to 56°F range for egg incubation and fry emergence analysis, there was one month-water year type combination (3.3%) with favorable results at both Hazel and Watt Avenue. There were zero and one month-water type combinations (0.0% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold analysis, there were zero and one month-water type combinations (0% and 3.3%, respectively) with favorable results at Hazel

Avenue and Watt Avenue, respectively. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

- Under **Alternative 2 Without TUCP Delta VA** for the 42.1°F to 55°F range for spawning initiation, there were zero combinations (0%) with favorable results at both Hazel and Watt Avenue, respectively (Table O-86). There were zero and one combinations (0% and 2.9%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for spawning adults, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue, respectively. For the 42.8°F to 56°F range for egg incubation and fry emergence analysis, there were zero and one month-water year type combinations (0.0% and 3.3%, respectively) with favorable results at both Hazel Avenue and Watt Avenue. Similarly, there were zero and one month-water year type combinations (0.0% and 3.3%, respectively) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 59.9°F fry pathogen virulence threshold analysis, there were zero month-water type combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watts Avenue.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 42.1°F to 55°F range for spawning initiation, there were zero combinations (0%) with favorable results at both Hazel and Watt Avenue (Table O-86). There were zero and one combinations (0% and 2.9%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for spawning adults, there were zero and one month-water year type combinations (0.0% and 2.9%, respectively) with favorable results at both Hazel and Watt Avenue. There were zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 42.8°F to 56°F range for egg incubation and fry emergence analysis, there were zero and one month-water type combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watts Avenue, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 59.9°F fry pathogen virulence threshold analysis, there were zero and one month-water type combinations (0.0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watts Avenue. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

Overall, these results suggest that four Alternative 2 phases would have similar positive (2.9-3.3% favorable) and negative (2.9-3.3% unfavorable) water temperature-related effects on fall-run Chinook salmon spawning and egg incubation in the lower American River at Hazel Avenue and Watt Avenue.

<u>Summary</u>

Differences in seasonal operations in the lower American River between the four phases of Alternative 2 and the No Action Alternative potentially have a negative impact on fall-run Chinook salmon habitat, with results for critically dry water year types having the largest decrease in WUA at 5.4% lower for Alternative 2 With TUCP Without VA to 7.8% lower for Alternative 2 Without TUCP Without VA. Similarly, redd dewatering is higher under the four phases of Alternative 2 and a potential significant negative impact could occur the large reductions in dry and critically dry years, including a 35.0% reduction for critically dry water

years under Alternative 2 With TUCP Without VA. The water temperature models suggest that Alternative 2 would have positive and negative water temperature-related effects during the fall-run Chinook salmon spawning and egg incubation and fry rearing periods in lower American River at Hazel Avenue and Watt Avenue.

Juvenile Rearing and Emigration

Chinook salmon fry emergence occurs from January through mid-April, and juvenile rearing extends from January to about mid-July (Williams 2001). Most Chinook salmon out-migrate from the lower American River as fry from December to July; out-migration peaks in February and March (Snider and Titus 2002; Pacific States Marine Fisheries Commission 2014).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

CalSim 3 modeling during the periods of juvenile rearing and emigration in the lower American River below Nimbus Dam indicate that the simulated flow releases below Nimbus Dam Alternative 2 compared to the No Action Alternative would generally be similar all months of wet water year types and the most different in critically dry year types (Table O-226 through Table O-229). For Alternative 2 With TUCP Without VA, simulations show there may be an increase in flows in December (31%)and July (6%) while decreases may occur on November (6%),February (10%), March (13%),April (8%), June (8%), August (9%), and September (9%) of critically dry type years; all other year types would be similar or the same as the No Action Alternative most months out of the year. Under all other phases of Alternative 2, simulations show there may be an increase in flows in March, April, and June, with increases in April around 100% while decreases may occur July through February and May of critically dry type years; all other year types would be similar or the same as the No Action Alternative most months out of the year. However, all Alternative 2 phases projected for all water year types show average results may be the same or similar projections of the No Action Alternative.

Similar to below Nimbus Dam, CalSim 3 modeling indicates that simulated flow releases in the lower American River at H street Alternative 2 compared to the No Action Alternative would generally be similar all months of wet water year types and the most different in critically dry year types; in critically dry water year types increases and decreases are generally anticipated nearly year-round (Table O-230 through Table O-233). During implementation of Alternative 2 With TUCP Without VA, simulations show that as below Nimbus Dam there may be an increase in flows in December (31%)and July (6%) resulting in a potentially moderate beneficial effect while decreases may occur June, August through November and February through April of critically dry type years potentially a moderate negative effect. All other year types would be similar or the same as the No Action Alternative during most months out of the year. Similarly, under all other phases of Alternative 2, the simulations show that there may be an increase in flows in March, April, and June while decreases may occur from July through February and May of critically dry type years; all other year types would be similar or the same as the No Action Alternative most months out of the year. However, all Alternative 2 phases projected for all water year types show average results may be the same or similar projections of the No Action Alternative, except the final phase when there is an increase for averaged April projections.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 71 for Hazel Avenue and Table 72 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F upper incipient lethal temperature (UILT) for juveniles during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 73 for Hazel Avenue and Table 74 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 75 for Hazel Avenue and Table 76 for Watt Avenue.

Results for the three analyses are summarized in Table O-87. Table O-87, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.12.3.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability, there were zero and one month-water year type combinations (0% and 4.0%, respectively) with favorable results at both Hazel and Watt Avenue, respectively (Table O-87). There were zero month-water year type combinations (0.0%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 75.2°F upper incipient lethal temperature (UILT) for juveniles, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue. month-water year type combination For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration, there were zero month-water year type combinations (0%) with favorable and unfavorable results at Hazel Avenue and Watt Avenue month-water year type combination.
- Under **Alternative 2 Without TUCP Without VA** for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability, there were zero and two month-water year type combinations (0.0% and 8.0%, respectively) with favorable results at Hazel and Watt Avenue, respectively (Table O-87). There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 75.2°F upper incipient lethal temperature (UILT) for juveniles, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue. For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration, there were zero month-water type combinations (0.0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue.

- Under **Alternative 2 Without TUCP Delta VA** for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability, there were zero water-month combination (0.0%) with favorable and unfavorable results at both Hazel and Watt Avenue (Table O-87). For the 75.2°F upper incipient lethal temperature (UILT) for juveniles, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue. For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration, there were zero and one month-water year type combinations (0.0% and 4.0%) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water type combinations (8.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue (Table O-87). For the 75.2°F upper incipient lethal temperature (UILT) for juveniles, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue. For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration, there were zero and one month-water type combinations (0.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water type combinations (8.0% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that four Alternative 2 phases would have positive (4% - 8% favorable) and negative (4% - 8% unfavorable) water temperature-related effects on fall-run Chinook salmon juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Differences in seasonal operations in the lower American River between the four phases of Alternative 2 and the No Action Alternative potentially have both negative and beneficial impacts on fall-run Chinook salmon habitat with the largest difference potentially occurring in critically dry years with increased flows in December (24%), January (10%), and July (12%) while decreases may occur in November (13%) and February (10%), March (10%) and April (11%). The water temperature model suggests that Alternative 2 would have beneficial and adverse water temperature-related impacts to fall-run Chinook salmon juvenile rearing and outmigration periods in the lower American River at Hazel Avenue and Watt Avenue.

Adult Upstream Migration and Holding

Adult fall-run Chinook salmon enter the lower American River from about mid-September through January, with peak migration from approximately mid-October through December (Williams 2001).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

CalSim 3 modeling during the periods of adult migration and emigration indicate that the simulated flow releases below Nimbus Dam Alternative 2 compared to the No Action Alternative would generally be similar all months of wet water year types except for during critically dry year types (Table O-226 through Table O-229). For Alternative 2 With TUCP Without VA, simulations show there may be an increase in flows in December (24%) and in January (10%), while decreases may occur in September (10%), October (13%), and in November (12%) during critically dry type years. All other year types would be similar as the No Action Alternative most months out of the year. Under all the other phases of Alternative 2, simulations show there may be similar decreases in flows in September through December, during critically dry type years. All other year types would be similar as the No Action Alternative most months out of the year. The largest adverse difference during this time period is Alternative 2 Without TUCP with Delta VA during November with a 24% decrease in flows, a moderate negative impact.

CalSim 3 modeling during periods of adult migration and emigration indicates that simulated flow releases at H street Alternative 2 compared to the No Action Alternative would generally be similar all months of wet water year types and the most different in critically dry year types. For Alternative 2 With TUCP Without VA, simulations show there may be an increase in flows in December (24%) and in January (10%), while decreases may occur in September (10%), October (13%), and in November (12%) during critically dry type years. All other year types would be similar as the No Action Alternative most months out of the year. The largest negative difference during this time period is Alternative 2 Without TUCP with Delta VA during November with a 25% decrease in flows, a moderate negative impact.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 59 for Hazel Avenue and Table 60 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 61 for Hazel Avenue and Table 62 for Watt Avenue.

Results for the two analyses are summarized in Table O-88. Table O-88, as described in Section O.4.13.3.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 37.9°F to 68°F successful migration range for adult fall-run Chinook salmon under, there were three and zero month-water year type combinations (8.6% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-88). There were two and three month-water year type combinations (5.7% and 8.6%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence

threshold for adult migration, there were zero month-water year type combination (0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue.

- Under **Alternative 2 Without TUCP Without VA** for the 37.9°F to 68°F successful migration range for adult fall-run Chinook salmon under, there were three and zero month-water year type combinations (8.6% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-88). There were one and four month-water year type combinations (2.9% and 11.4%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for adult migration, there were zero and one month-water year type combinations (0.0% and 2.9%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Delta VA** for the 37.9°F to 68°F successful migration range for adult fall-run Chinook salmon under, there were three and zero month-water year type combinations (8.6% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-88). There were one and two month-water year type combinations (2.9% and 5.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for adult migration, there were zero month-water year type combinations (0%) with favorable and unfavorable results at Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 37.9°F to 68°F successful migration range for adult fall-run Chinook salmon under, there were four and zero month-water year type combinations (11.4% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-88). There were zero and three month-water year type combinations (0% and 8.6%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for adult migration, there were zero and one month-water year type combinations (0% and 2.9%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

Overall, Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP Systemwide VAs the four phases of Alternative 2 would have similar positive (2.9% - 11.4% favorable) and negative (2.9% - 11.4% unfavorable) water temperature-related effects to fall-run Chinook salmon adult upstream migration and holding in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Differences in seasonal operations in the lower American River between the four phases of Alternative 2 and the No Action Alternative are expected to have a mixed negative and also impact on upstream migrating fall-run Chinook salmon, average monthly flows at below Nimbus Dam may increase in December and January a beneficial impact, but decreases may occur in September through November during critically dry type years a negative impact. Differences in temperature between the four phases of Alternative 2 and the No Action Alternative are expected to have a beneficial and adverse impact on upstream migrating fall-run Chinook salmon. There

would be increases in favorable and unfavorable conditions for successful migration for successful migration under the four phases of Alternative 2 relative to the No Action Alternative.

O.5.14.4 San Joaquin River

Fall-run Chinook salmon adults migrate upstream through the San Joaquin River past Vernalis between September and November. Juvenile fall-run Chinook salmon migrate downstream past Vernalis primarily January through May. See Section O.1.8.1 for additional information.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Under the four phases of Alternative 2 average flows released at on the San Joaquin River near Vernalis would be similar to the No Action Alternative (Table O-242 through Table O-245). All phases of Alternative 2 have a moderate increase in flows in critically dry water years during September when fall-run adult Chinook salmon are migrating upstream. The remaining months for all phases of Alternative 2 have differences in flows, either as an increase or a decrease, between 0 and ± 3%.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on fall-run Chinook salmon in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

There would be similar impacts to migrating adults and juveniles in the San Joaquin River at Vernalis. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.5.14.5 Bay-Delta

Juvenile Rearing and Emigration

Most fall-run Chinook salmon fry rear in freshwater from December through June, with out-migration as smolts occurring primarily from January through June, with presence in the Delta in December through July. In general, fall-run Chinook salmon fry abundance in the Delta increases following high winter flows. Smolts that arrive in the estuary after rearing upstream migrate quickly through the Delta and Suisun and San Pablo Bays. Late fall-run Chinook salmon migrants may be found in the Delta between December and April. See Section O.1.9.1 for additional information.

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

Differences in hydrology in the Delta under the four phases of Alternative 2 compared with the No Action Alternative may have effects on flow routing into junctions and the hydrodynamic footprint of the export facilities. These possible differences were evaluated using quantitative models which estimate the spatial extent of influence of exports under CVP and SWP diversions and estimate the proportion of flow entering a Delta junction: Zone of Influence and Flow into Junctions.

Zone of Influence

Differences in hydrology under the four phases of Alternative 2 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions.

With incremental decreases in OMR under all four phases of Alternative 2 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under the four phases of Alternative 2 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2, *Zone of Influence*).

Flow into Junctions

Alternative 2 relative to the No Action Alternative is expected to have effects on the flow into the Head of Old River and CVP junctions due to differences in flow routing. These possible differences were evaluated using DSM2-HYDRO outputs. For a detailed description of how flows under the four phases of Alternative 2 may impact the flow at Head of Old River and CVP, see Alternative 2, Sacramento River Winter-run Chinook Salmon ESU (Section O.5.8.2, *Flow into Junctions*).

Under all four phases of Alternative 2 and for most OMR bins except -3,500, the predicted proportion of flow entering the CVP is less than the No Action Alternative, although the predicted difference was negligible (up to ± 0.0467 for Alternative 2 Without TUCP Delta VA). Exceptions include the -2,000 OMR bin, with slightly greater change in predicted proportion of flow into CVP for Alternative 2 With TUCP Without VA (-0.069) or Alternative 2 Without TUCP Without VA (-0.0631) indicating that slightly less flow will be routed into CVP under these conditions compared to the No Action Alternative.

Under all four phases of Alternative 2 and for all OMR bins, the predicted differences in proportion of flow entering the HOR compared to the No Action Alternative are negligible (either positive or negative, but always lower than ± 0.008),

Summary

Alternative 2 relative to the No Action Alternative is expected to influence flow into the Head of Old River and CVP junctions due to differences in seasonal operations. Alternative 2 relative to the No Action Alternative is expected to have negligible impact on flow into HOR while differences at CVP are best described between phases of Alternative 2 with and without VA due to differences in flow: Alternative 2 With TUCP Without VA and without TUCP Without VA are expected to have slightly less flow into CVP at OMR -2,000 and Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA are expected to have negligible impacts on flow into CVP. Impacts of pumping under Alternative 2 relative to the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Fall-run / Late Fall-run Chinook Salmon ESU

Salvage Density

- **Alternative 2 With TUCP Without VAs—Fall-run Chinook Salmon**
    - Predictions from the salvage density model for fall-run Chinook salmon include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through July and all water year types Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for all water year types. Predicted average monthly loss at Banks under Alternative 2 With TUCP Without VAs had a range from 29% higher for critically dry water year types to 78% higher for below normal water year types (Table O-89). Predicted average monthly loss of fall-run Chinook salmon at CVP Jones Pumping Plant for the months of November through August and all water year types Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for below normal, and critically dry water year types. Wet, above normal, and dry water year types had equal or lower predicted salvage at Jones. The range of predicted loss for fall-run Chinook salmon at Jones under Alternative 2 With TUCP Without VAs compared to the No Action Alternative was from 1% lower in above normal water year types to 5% higher for critically dry water year types (Table O-90). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.
- **Alternative 2 With TUCP Without VAs—Late Fall-run Chinook Salmon**
    - Predictions from the salvage density model for late fall-run Chinook salmon include mean monthly total exports. Table O-175 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of late fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through April Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for wet water year types, and predicted loss was equal or lower for all other water year types. Predicted average monthly loss at Banks under Alternative 2 With TUCP Without VAs had a range from 3% lower for below normal water year types to 2% higher for critically dry water year types (Table O-91). Predicted average monthly loss of late fall-run Chinook salmon at CVP Jones Pumping Plant for the months of October through April and all water year types Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for above normal and dry water year types, and predicted loss was lower for wet, below normal, and critically dry water year types. The range of predicted loss for late fall-run Chinook salmon at

Jones under Alternative 2 With TUCP Without VAs compared to the No Action Alternative was from 5% lower in critically dry water year types to 6% higher for above normal water year types (Table O-92). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.

- **Alternative 2 Without TUCP Without VAs—Fall-run Chinook Salmon**
    - Predictions from the salvage density model for fall-run Chinook salmon include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through July and all water year types Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for all water year types. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Without VAs had a range from 21% higher for critically dry water year types to 81% higher for below normal water year types (Table O-89). Predicted average monthly loss of fall-run Chinook salmon at CVP Jones Pumping Plant for the months of November through August and all water year types Alternative 2 Without TUCP Without VAs was less or equal than predicted average monthly loss under the No Action Alternative all water year types except for critically dry water year types. The range of predicted loss for fall-run Chinook salmon at Jones under Alternative 2 Without TUCP Without VAs compared to the No Action Alternative was from 1% lower in above normal water year types to 15% higher for critically dry water year types (Table O-90). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.
- **Alternative 2 Without TUCP Without VAs—Late Fall-run Chinook Salmon**
    - Predictions from the salvage density model for late fall-run Chinook salmon include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of late fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through April and all water year types Alternative 2 Without TUCP Without VAs was equal or lower than predicted average monthly loss under the No Action Alternative for all water year types. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Without VAs had a range from 5% lower for critically dry water year types to 1% lower for wet water year types (Table O-91). Predicted average monthly loss of late fall-run Chinook salmon at CVP Jones Pumping Plant for the months of October through April and all water year types Alternative 2 Without TUCP Without VAs was less or equal than predicted average monthly loss under the No Action Alternative for wet, below normal, and dry water year types, predicted loss

was higher for above normal, and critically dry water year types. The range of predicted loss for late fall-run Chinook salmon at Jones under Alternative 2 Without TUCP Without VAs compared to the No Action Alternative was from 3% lower in below normal water year types to 6% higher for above normal water year types (Table O-92). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.

- **Alternative 2 Without TUCP Delta VAs—Fall-run Chinook Salmon**
    - Predictions from the salvage density model for fall-run Chinook salmon include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through July and all water year types Alternative 2 Without TUCP Delta VAs was greater than predicted average monthly loss under the No Action Alternative for all water year types. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Delta VAs had a range from 21% higher for critically dry water year types to 66% higher for below normal water year types (Table O-89). Predicted average monthly loss of fall-run Chinook salmon at CVP Jones Pumping Plant for the months of November through August Alternative 2 Without TUCP Delta VAs was less or equal than predicted average monthly loss under the No Action Alternative for all water year types except for critically dry water year types. The range of predicted loss for fall-run Chinook salmon at Jones under Alternative 2 Without TUCP Delta VAs compared to the No Action Alternative was from 11% lower in dry water year types to 15% higher for critically dry water year types (Table O-90). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.
- **Alternative 2 Without TUCP Delta VAs—Late Fall-run Chinook Salmon**
    - Predictions from the salvage density model for late fall-run Chinook salmon include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of late fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through April and all water year types Alternative 2 Without TUCP Delta VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Delta VAs had a range from 8% lower for critically dry water year types to 1% lower for wet water year types (Table O-91). Predicted average monthly loss of late fall-run Chinook salmon at CVP Jones Pumping Plant for the months of October through April Alternative 2 Without TUCP Delta VAs was lower than predicted average monthly loss under the No Action Alternative for wet, below normal, and dry water year types, predicted loss was higher for above normal, and critically dry

water year types. The range of predicted loss for late fall-run Chinook salmon at Jones under Alternative 2 Without TUCP Delta VAs compared to the No Action Alternative was from 4% lower in below normal water year types to 7% higher for above normal water year types (Table O-92). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.

- **Alternative 2 Without TUCP Systemwide VAs—Fall-run Chinook Salmon**
    - Predictions from the salvage density model for fall-run Chinook salmon include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through July and all water year types Alternative 2 Without TUCP Systemwide VAs was greater than predicted average monthly loss under the No Action Alternative. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Systemwide VAs had a range from 24% higher for critically dry water year types to 68% higher for below normal water year types (Table O-89). Predicted average monthly loss of fall-run Chinook salmon at CVP Jones Pumping Plant for the months of November through August Alternative 2 Without TUCP Systemwide VAs was less than predicted average monthly loss under the No Action Alternative for all water year types except for critically dry water year types. The range of predicted loss for fall-run Chinook salmon at Jones under Alternative 2 Without TUCP Systemwide VAs compared to the No Action Alternative was from 12% lower in dry water year types to 14% higher for critically dry water year types (Table O-90). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.
- **Alternative 2 Without TUCP Systemwide VAs—Late Fall-run Chinook Salmon**
    - Predictions from the salvage density model for late fall-run Chinook salmon include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative. Predicted average monthly loss of late fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through April and all water year types Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly loss under the No Action Alternative for all water year types. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Systemwide VAs had a range from 8% lower for critically dry water year types to 1% lower for wet water year types (Table O-91). Predicted average monthly loss of late fall-run Chinook salmon at CVP Jones Pumping Plant for the months of October through April Alternative 2 Without TUCP Systemwide VAs was less than predicted average monthly loss under the No Action Alternative for wet, below normal, and dry water year types, predicted loss was higher for above normal and

critically dry water year types. The range of predicted loss for late fall-run Chinook salmon at Jones under Alternative 2 Without TUCP Systemwide VAs compared to the No Action Alternative was from 4% lower in below normal water year types to 7% higher for above normal water year types (Table O-91). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.

Summary

The predicted monthly entrainment of fall-run Chinook salmon at Banks Pumping Plant is expected to be substantially increased under all phases of Alternative 2 compared to the No Action Alternative, causing substantial impacts to fall-run Chinook salmon. The predicted monthly entrainment of fall-run Chinook salmon at the Jones Pumping Plant would be similar to the No Action Alternative except during critically dry water year types, when there would be a predicted moderate increase in entrainment. Late fall-run Chinook salmon entrainment at both Banks and Jones Pumping Plants would be similar under all phases of Alternative 2 compared with the No Action Alternative.

Potential Changes to Through Delta Survival of Fall-run / Late Fall-run Chinook Salmon ESU

Delta Passage Model

The DPM simulates migration of Chinook salmon smolts entering the Delta from the Sacramento River, Mokelumne River, and San Joaquin River and estimates survival to Chipps Island. For this application, only survival of fish entering the Delta from the Sacramento River are evaluated. The DPM uses available time-series data and values taken from empirical studies or other sources to parameterize model relationships and inform uncertainty, thereby using the greatest amount of data available to dynamically simulate responses of smolt survival to changes in water management. (Attachment I.6, *Delta Passage Model*). The major model functions in the DPM are listed under winter-run Chinook salmon (Section *O.4.8.2*).

Fall-run Chinook Salmon

- Under **Alternative 2 With TUCP Without VA**, in all except critically dry water years, predicted mean survival of fall-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.002. There is not a substantial difference in predicted proportion of fall-run Chinook salmon surviving to Chipps Island between Under Alternative 2 With TUCP Without VA and the No Action Alternative.

- Under **Alternative 2 Without TUCP Without VA**, in all except critically dry water years, predicted mean survival of fall-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative. However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.007. There is not a substantial difference in predicted proportion of fall-run Chinook salmon surviving to Chipps Island between Under Alternative 2 Without TUCP Without VA and the No Action Alternative.

- Under **Alternative 2 Without TUCP Delta VA**, in all except critically dry water years, predicted mean survival of fall-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative. However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.007. There is not a substantial difference in predicted proportion of fall-run Chinook salmon surviving to Chipps Island between Under Alternative 2 Without TUCP Delta VA and the No Action Alternative.

- Under **Alternative 2 Without TUCP Systemwide VA**, in all except wet water years, predicted mean survival of fall-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative. However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.008. There is not a substantial difference in predicted proportion of fall-run Chinook salmon surviving to Chipps Island between Under Alternative 2 Without TUCP Systemwide VA and the No Action Alternative.

Late Fall-run Chinook Salmon

- Under **Alternative 2 With TUCP Without VA**, in all water year types, predicted mean survival of late fall-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). However, the change in mean predicted survival to Chipps Island in all water year types less than or equal to ± 0.001. There is not a substantial difference in predicted proportion of late fall-run Chinook salmon surviving to Chipps Island between Under Alternative 2 With TUCP Without VA and the No Action Alternative.

- Under **Alternative 2 Without TUCP Without VA**, in all except below normal and critically dry water years, predicted mean survival of late-fall-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative. The change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.001.

- Under **Alternative 2 Without TUCP Delta VA**, in all except critically dry water years, predicted mean survival of late fall-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative. The change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.002.

- Under **Alternative 2 Without TUCP Systemwide VA**, in all except critically dry water years, predicted mean survival of late-fall-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative. The change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.001.

<u>Summary</u>

There would be negligible differences in through Delta survival of both fall-run and late fall-run Chinook salmon through the Delta to Chipps Island compared to the No Action Alternative.

O.5.14.6 Stanislaus River

Spawning and Egg Incubation

Peak spawning for fall-run Chinook salmon in the Stanislaus River typically occurs in November with roughly 7% of spawning occurring prior to November 1, and 2% prior to October 15. The few redds created during late September and early October are typically in the reach just below Goodwin Dam with spawning typically ending in December.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Spawning Habitat—Flow Analysis

The results for fall-run Chinook salmon under the four phases of Alternative 2 show consistent trends of reduction in mean spawning WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the shape of the fall-run spawning WUA curves (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which show reduced WUA with increased flow, except at the lowest and highest flows (less than about 200 cfs to 500 cfs and greater than about 1,000 cfs, respectively). CalSim 3 mean monthly flows below Goodwin Dam, which is immediately upstream of the WUA study reach, are 200 cfs or above in all water year types, with flow generally increasing from critically dry to wet water years during all months of the October through December fall-run spawning period, except December (Table O-234 through Table O-237). The mean spawning WUA estimates for all the phases of Alternative 2 are little different from those of the No Action Alternative in all water year types, ranging from 2.7% lower in below normal water years under Alternative 2 With TUCP Without VA to 0.6% higher in dry water year types under all phases of Alternative 2 except Alternative 2 With TUCP Without VA (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fall-run spawning period, spawning WUA medians under the four phases of Alternative 2 are lower in October than in November or December because of the higher mean flows in October (Table O-234 through Table O-237). Medians are higher under the four phases of Alternative 2 than under the No Action Alternative in November and December and are about the same in October (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

Overall, the results indicate that mean spawning WUA for fall-run Chinook salmon are about the same for the four phases of Alternative 2 and the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 55 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult spawning pathogen virulence threshold during October through January are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 56 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 57 for Orange Blossom Bridge. Full results

of the analysis assessing the percent of months with water temperature above the 59.9°F fry pathogen virulence threshold during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 58 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-93. Table O-93, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.14.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 42.1°F to 55°F range for spawning initiation there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge (Table O-93). For the 59.9°F adult spawning pathogen virulence threshold there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 59.9°F fry pathogen virulence threshold there were also no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-93).

Overall, the four phases of Alternative 2 would have similar negligible water temperature-related effects to fall-run Chinook salmon spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

Differences in seasonal operations in the Stanislaus River between the four phases of Alternative 2 and the No Action Alternative during spawning and incubation periods potentially have generally similar or beneficial impacts on fall-run Chinook salmon habitat. Spawning habitat area is expected to be generally similar under the four phases of Alternative 2 compared to the No Action Alternative. The water temperature model suggests Alternative 2 would have minor beneficial water temperature-related impacts to fall-run Chinook salmon spawning and egg incubation lower American River at Hazel Avenue and Watt Avenue. There would be similar conditions for growth, smoltification, predation vulnerability and pathogen virulence.

Juvenile Rearing and Emigration

Fall-run juvenile rearing in the Stanislaus River typically occurs from January through May (Stanislaus River Fish Group 2004). Fry migration generally occurs from January through March, followed by smolt migration from April through May (Bureau of Reclamation 2012).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Rearing Habitat—WUA Flow Analysis

The results for fall-run fry rearing WUA under the four phases of Alternative 2 show consistent trends of reduction in mean spawning WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the fall-run fry WUA curves, which show reduced WUA with increased flow, especially in the Orange Blossom Bridge and Riverbank reaches (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which are the longest segments of the study. Mean fry rearing WUAs under the phases of Alternative 2 are higher than under the No Action Alternative in all water year types, ranging from 2.7% higher in above normal water years for all four phases of Alternative 2 to 7.2% higher in critically dry water years for all four phases (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fry rearing period, fry rearing is higher under the four phases of Alternative 2 than under the No Action Alternative in all four months (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). The differences are especially large for February.

The results for juvenile rearing WUA under the four phases of Alternative 2 show little change in mean rearing WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in juvenile rearing WUA between the four phases of Alternative 2 and the No Action Alternative are mostly small to moderate, ranging from 2.9% higher for wet water years under all four phases of the alternative to 5.5% higher for critically dry water years for all four phases (Attachment N.1, *Stanislaus River Habitat Availability Analysis).* Differences among the four phases are very small (< 0.7%) for all water year types. For the individual months of the juvenile rearing period, the medians of juvenile rearing WUA are much lower in March than in other months (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in the medians between the four phases of Alternative 2 and the No Action Alternative are consistently small.

Overall, the results indicate that fry and juvenile rearing WUA for fall-run Chinook salmon is consistently but modestly higher under the four phases of Alternative 2 than under the No Action Alternative.

Rearing Habitat—ASH Flow Analysis

The results of the Area of Suitable Habitat (ASH) analysis for fall-run fry and juvenile rearing are quite different from the rearing WUA results described above. The mean ASH estimates vary more strongly with water year type for both fry and juvenile fall-run, consistently increasing from critically dry to wet years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the overall relationship between flow and ASH for both life stages determined from modeling and field studies (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in fry and juvenile ASH between the four phases of Alternative 2 and the No Action Alternative are modest, which is consistent with the results of the rearing WUA analyses. For the fry, difference between the four phases of Alternative 2 and the No Action Alternative range from 1.8% lower for dry water years under all four phases of Alternative 2 to 1.6% higher for critically dry years under all phases of Alternative 2 except Alternative 2 With TUCP Without VA. Both increases and reductions are larger for juveniles than

for fry, ranging from 5.4% lower in below normal water years under all phases of Alternative 2 except Alternative 2 With TUCP Without VA to 4.9% higher in dry water years for the same three phases of Alternative 2 (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fall-run fry rearing period, median ASH under the four phases of Alternative 2 relative to the No Action Alternative are higher in February, lower in April, and about the same in March and May.

Overall, the results indicate that fry and juvenile rearing ASH for fall-run Chinook salmon are largely similar under the four phases of Alternative 2 and the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 59 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F upper incipient lethal temperature (UILT) for juveniles during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 60 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis* Table 61 for Orange Blossom Bridge.

Results for the three analyses are summarized in Table O-94. Table O-94, as with all similar temperature analysis results tables in this EIS and as described in Section O.4.14.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability there were two month-water year type combinations (10.0%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-94). For the 75.2°F upper incipient lethal temperature (UILT) for juvenile fall-run Chinook salmon there were no month-water year type combinations (0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration there was zero month-water year type combination (0.0%) with favorable results and 1 combination (5.0%) unfavorable results at Orange Blossom Bridge.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-94).

Overall, the four phases of Alternative 2 would have similar positive water temperature-related effects to fall-run Chinook salmon juvenile rearing and emigration in the Stanislaus River at Orange Blossom Bridge.

Summary

Differences in seasonal operations in the Stanislaus River between the four phases of Alternative 2 and the No Action Alternative during juvenile rearing and emigration periods are expected to a have minor adverse and minor to moderate beneficial impacts on fall-run Chinook salmon. The two rearing habitat analyses suggest a minor to moderate beneficial impacts and minor adverse impacts from flow under the four phases of Alternative 2, depending on water year type. The water temperature model suggests that the four phases of Alternative 2 would have minor beneficial water temperature-related impacts to fall-run Chinook salmon spawning and egg incubation lower American River at Hazel Avenue and Watt Avenue. There would be similar conditions for growth, smoltification, predation vulnerability and pathogen virulence.

Adult Upstream Migration and Holding

Fall-run Chinook salmon adults generally migrate upstream from late September through December with peak migration from late October through early November in the Stanislaus River.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

For the period of adult migration and holding of fall-run Chinook salmon (September through December), CalSim 3 modeling below Goodwin Dam under all phases of Alternative 2 compared to the No Action Alternative indicates that average flow released would generally be very similar (Table O-234 through Table O-237). All water year type projections for Alternative 2 show average flow projections may be the higher in December (7% average increase among all water year types) compared to the No Action Alternative, a minor beneficial effect.

Similar to below Goodwin Dam, for the period of adult migration and holding of fall-run Chinook salmon (September through December), CalSim 3 modeling at the mouth of the Stanislaus under all phases of Alternative 2 compared to the No Action Alternative indicates that average flows released would also generally be similar with the most the variation occurring in below normal and critically dry water years (Table O-238 through Table O-241). In terms of overall averages of all water year types, there is a minor potential beneficial effect during the month of September with an average 5-6% increase in predicted flow across all water year types, with the greatest beneficial effect during a critically dry year with an increase in flows of 42%.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during July through December are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 51 for Orange Blossom Bridge and Table 52 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration during July through December are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 53 for Orange Blossom Bridge and 54 for above the confluence with the San Joaquin River.

Results for the two analyses are summarized in Table O-95. Table O-95, as described in Section O.4.14.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 37.9°F to 68°F successful migration range there were no month-water year type combinations (0.0%) with favorable or unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River (Table O-95). For the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration there was also no month-water year type combinations (0.0%) with favorable or unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-95).

Overall, the four phases of Alternative 2 would have negligible water temperature related effects on adult fall-run Chinook salmon upstream migration and holding in the Stanislaus River at Orange Blossom Bridge and above the confluence of the San Joaquin River.

Summary

For the period of adult migration and holding of fall-run Chinook salmon (September through December) in the Stanislaus River, CalSim 3 modeling at both Goodwin dam and the mouth during all phases of Alternative 2 compared to the No Action Alternative indicate that average flow released would generally be very similar (Table O-234 through Table O-237). All water year type projections for Alternative 2 show average flow projections may be slightly higher providing a beneficial impact. Water temperature model results indicate there would be negligible impacts on adult fall-run Chinook salmon upstream migration and holding in the Stanislaus River at Orange Blossom Bridge and above the confluence of the San Joaquin River. There would be similar conditions for growth, smoltification, predation vulnerability and pathogen virulence.

O.5.15 White Sturgeon

O.5.15.1 Sacramento River

Spawning and Egg Incubation

Spawning occurs in deep water in the middle and lower Sacramento River from near Verona (~RM 80) to just upstream of Colusa (~RM 156) from late February to early June, peaking during March and April, (Section O.1.3.2.6, *White Sturgeon*). Because the incubation time for white sturgeon is so short, the peak impacts analysis period for incubating eggs is also considered to be March and April.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates of mean monthly flows during the March and April spawning and egg incubation period for white sturgeon at Wilkins Slough under the No Action Alternative and the four phases of Alternative 2 are summarized by phase below.

Mean monthly flow estimates during the spawning and egg incubation period under Alternative 2 With TUCP Without VA range from about 4,200 cfs for April of critically dry water years to about 18,000 cfs for March of wet water years (Table O-190). Alternative 2 Without TUCP Without VA relative to the No Action Alternative is expected to have generally small effects both months (up to 3%), but flows are higher (6%) in April of critically dry water years due to differences in flow (Table O-190). Because white sturgeon spawn in deep pools, these flow levels are likely to be adequate for spawning and egg incubation, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 With TUCP Without VA would have similar flow effects on white sturgeon eggs and embryos relative to the No Action Alternative.

Mean monthly flow estimates during the spawning and egg incubation period under Alternative 2 Without TUCP Without VA range from about 4,900 cfs for April of critically dry water years to about 18,000 cfs for March of wet water years (Table O-191). Alternative 2 Without TUCP Without VA relative to the No Action Alternative is expected to have generally small effects both months (up to 4%), but flows are substantially higher (26%) in April of critically dry water years due to differences in flow (Table O-191). Because white sturgeon spawn in deep pools, these flow levels are likely to be adequate, and possibly beneficial, for spawning and egg incubation, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 Without TUCP Without VA would have similar flow effects on white sturgeon eggs and embryos relative to the No Action Alternative.

Mean monthly flow estimates during the spawning and egg incubation period under Alternative 2 Without TUCP with Delta VA range from about 5,000 cfs for April of critically dry water years to about 18,000 cfs for March of wet water years (Table O-192). Alternative 2 Without TUCP with Delta VA relative to the No Action Alternative is expected to have generally small effects both months (up to 7%), but flows are substantially higher (29%) in April of critically dry water years (Table O-192). Because white sturgeon spawn in deep pools, these flow levels are likely to be adequate, and possibly beneficial, for spawning and egg incubation, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 Without TUCP with Delta VA would have similar flow effects on white sturgeon eggs and embryos relative to the No Action Alternative.

Mean monthly flow estimates during the spawning and egg incubation period under Alternative 2 Without TUCP with Systemwide VA range from about 5,000 cfs for April of critically dry water years to about 18,000 cfs for March of wet water years (Table O-193). Alternative 2 Without TUCP with Systemwide VA relative to the No Action Alternative is expected to have generally small effects in March of all water year types and in April of wet and dry years (up to 4%). However, flows are moderately higher (up to 8%) in April of above normal years and substantially higher (29%) in April of critically dry water years (Table O-193). Because white

sturgeon spawn in deep pools, these flow levels are likely to be adequate, and possibly beneficial, for spawning and egg incubation, so no adverse effects are expected. Therefore, it is concluded that Alternative 2 Without TUCP with Systemwide VA would have similar flow effects on white sturgeon eggs and embryos relative to the No Action Alternative.

Overall, the four phases of Alternative 2 would have similar negligible effects on flow relative to the No Action Alternative for white sturgeon spawning and egg incubation in the Sacramento River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 61°F upper limit for optimal egg incubation during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 291 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 68°F upper limit for embryo hatching during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 292 for Hamilton City.

Results for the two analyses are summarized in Table O-96. Table O-96, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 61°F upper limit for optimal egg incubation, there was one month-water year type combination (5.0% of total combinations during the period) with favorable results and no combinations (0%) with unfavorable results at Hamilton City (Table O-96). For the 68°F upper limit for embryo hatching, there were no combinations (0%) with favorable or unfavorable results at Hamilton City. These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on white sturgeon spawning and egg incubation.
- Results for **Alternative 2 Without TUCP Without VA** are identical to those of Alternative 2 With TUCP Without VA (Table O-96).
- Under **Alternative 2 With TUCP Delta VA** for the 61°F upper limit for optimal egg incubation, there was one month-water year type combination (5.0% of total combinations during the period) with favorable results and one combination (5.0%) with unfavorable results at Hamilton City (Table O-96). For the 68°F upper limit for embryo hatching, there were no combinations (0%) with favorable or unfavorable results at Hamilton City. These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on white sturgeon spawning and egg incubation.
- Results for **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-96).

Overall, the four phases of Alternative 2 would have similar negligible effects on water temperature conditions for white sturgeon spawning and egg incubation in the Sacramento River (Table O-96).

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts to possible beneficial impacts on spawning habitat for all phases, locations, months, and water year types due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on spawning and egg incubation for all phases, locations, months, and water year types due to differences in water temperature.

Larval and Juvenile Rearing and Emigration

The white sturgeon juvenile stage begins when metamorphosis of the larva is complete, typically at about 45 days post hatch (Heublein et al. 2017a, Deng et.al 2002). Therefore, since white sturgeon spawn from late February to early June, peaking in March and April, the larval period is considered to be March through June. Juvenile white sturgeon are believed to initiate a secondary dispersal (the primary dispersal occurring at the larval stage) in spring by actively swimming downstream during the night (Heublein et al. 2017a). The juvenile emigration period is considered to be April through July. Therefore, the effects analysis period for larvae and juvenile rearing and emigration is considered to be March through July.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates of mean monthly flows during the white sturgeon larval and juvenile rearing and emigration period from April to July at Wilkins Slough under the No Action Alternative and the four phases of Alternative 2 are summarized by phase below.

Mean monthly flow estimates during the larval and juvenile rearing and emigration period under Alternative 2 With TUCP Without VA range from about 3,400 cfs for May of critically dry water years to about 14,400 cfs for April of wet water years (Table O-190). Alternative 2 With TUCP Without VA relative to the No Action Alternative is expected to have generally small impacts all four months of all water years (up to 5%), with a few exceptions, due to differences in flow. Flows are higher (6%) in April of critically dry water years, and moderately lower (up to 5%) in July of dry years (Table O-190). These flow levels are likely to be adequate for larval and juvenile rearing and emigration, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 With TUCP Without VA would have similar flow effects on white sturgeon larvae and juveniles relative to the No Action Alternative.

Mean monthly flow estimates during the larval and juvenile rearing and emigration period under Alternative 2 Without TUCP Without VA range from about 3,600 cfs for May of critically dry water years to about 14,400 cfs for April of wet water years (Table O-191). Alternative 2 Without TUCP Without VA relative to the No Action Alternative is expected to have generally small effects all four months of all water years (up to 6%), with a few exceptions, due to differences in flow. Flows are moderately higher (10 to 26%) in April, May and July of critically dry water years, and moderately lower (up to 6%) in July of below normal years (Table O-191). These flow levels are likely to be adequate for larval and juvenile rearing and emigration, so no adverse

effects are expected to result. Therefore, it is concluded that Alternative 2 Without TUCP Without VA would have similar flow effects on white sturgeon larvae and juveniles relative to the No Action Alternative.

Mean monthly flow estimates during the larval and juvenile rearing and emigration period under Alternative 2 Without TUCP with Delta VA range from about 3,600 cfs for May of critically dry water years to about 14,400 cfs for April of wet water years (Table O-192). Alternative 2 Without TUCP with Delta VA relative to the No Action Alternative is expected to have generally small effects all four months of all water years (up to 4%), with a few exceptions, due to differences in flow. Flows are moderately higher (10 to 29%) in April, May, and July of critically dry water years, and moderately lower (6%) in July of below normal years (Table O-192). These flow levels are likely to be adequate for larval and juvenile rearing and emigration, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 Without TUCP with Delta VA would have similar flow effects on white sturgeon larvae and juveniles relative to the No Action Alternative.

Mean monthly flow estimates during the larval and juvenile rearing and emigration period under Alternative 2 Without TUCP with Systemwide VA range from about 3,900 cfs for May of critically dry water years to about 14,500 cfs for April of wet water years (Table O-193). Alternative 2 Without TUCP with Systemwide VA relative to the No Action Alternative is expected to have generally small effects all four months of all water years (up to 5%), with a few exceptions, due to differences in flow. Flows are moderately higher (17 to 29%) in April, May, and July of critically dry water years, moderately higher (up to 8%) in April and May of above normal and below normal years, and moderately lower (up to 9%) in June of above normal, below normal, and dry years (Table O-193). These flow levels are likely to be adequate for larval and juvenile rearing and emigration, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 Without TUCP with Systemwide VA would have similar flow effects on white sturgeon larvae and juveniles relative to the No Action Alternative.

Overall, the four phases of Alternative 2 would have negligible effects on flow relative to the No Action Alternative for white sturgeon rearing and emigration in the Sacramento River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66°F limit above which stress is observed in juvenile white sturgeon year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 293 for Hamilton City.

Results for the analysis are summarized in Table O-97. Table O-97, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 66.6°F stress limit for juvenile white sturgeon, there were three month-water year type combinations (5.0% of total combinations during the period, respectively) with favorable results and one combination (1.7%) with unfavorable results at Hamilton City (Table O-97). These results suggest that there would be negligible effects of Alternative 2 With TUCP Without VA on white sturgeon juvenile rearing and emigration.
- Under **Alternative 2 Without TUCP Without VA** for the 66.6°F stress limit for juvenile white sturgeon, there were four month-water year type combinations (6.7% of total combinations during the period, respectively) with favorable results and zero combinations (0%) with unfavorable results at Hamilton City (Table O-97). These results suggest that there would be negligible water temperature-related effects of Alternative 2 Without TUCP Without VA on white sturgeon larval and juvenile rearing and emigration.
- Under **Alternative 2 without TUCP Delta VA** for the 66.6°F stress limit for juvenile white sturgeon, there were three month-water year type combinations (5.0% of total combinations during the period, respectively) with favorable results and one combination (1.7%) with unfavorable results at Hamilton City (Table O-97). These results suggest that there would be negligible water temperature-related effects of Alternative 2 Without TUCP Without VA on white sturgeon larval and juvenile rearing and emigration.
- Results for **Alternative 2 Without TUCP Systemwide VAs** are identical to those for Alternative 2 Without TUCP Delta VA (Table O-97).

Overall, the four phases of Alternative 2 would have similar negligible positive effects on water temperature conditions for white sturgeon larval and juvenile rearing and emigration in the Sacramento River (Table O-97).

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible to beneficial impacts on rearing and emigration for all phases, locations, months, and water year types due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on rearing and emigration for all phases, locations, months, and water year types due to differences in water temperature.

Adult Upstream Migration and Holding

Adults ready for spawning likely move into the lower reaches of the Sacramento River during early winter to begin their upstream migration (Section O.1.3.2.6, *White Sturgeon*). Upstream migration appears to be rapid, with minimal holding time (Schaffter 1997, Heublein et al. 2017a). Based on rapid upstream migration, short egg incubation period, and larval presence in the Sacramento River; the adult upstream migration and holding period is considered to be December to February for this effects analysis.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates of mean monthly flows during the white sturgeon adult upstream migration and holding period from December to February at Wilkins Slough under the No Action Alternative and the four phases of Alternative 2 are summarized by phase below.

Mean monthly flow estimates during the adult upstream migration and holding period under Alternative 2 With TUCP Without VA range from about 6,200 cfs for January of critically dry water years to about 19,900 cfs for February of wet water years (Table O-190). Alternative 2 With TUCP Without VA relative to the No Action Alternative is expected to have generally small effects all three months of all water years (up to 4%) due to flows. These flow levels are likely to be adequate for adult upstream migration, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 With TUCP Without VA would have similar flow effects on white sturgeon adults relative to the No Action Alternative.

Mean monthly flow estimates during the adult upstream migration and holding period under Alternative 2 Without TUCP Without VA range from about 6,300 cfs for January of critically dry water years to about 19,900 cfs for February of wet water years (Table O-191). Alternative 2 Without TUCP Without VA relative to the No Action Alternative is expected to have minimal effects all three months of all water years (up to 4%) due to differences in flows (Table O-191). These flow levels are likely to be adequate for adult upstream migration, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 Without TUCP Without VA would have similar flow effects on white sturgeon adults relative to the No Action Alternative.

Mean monthly flow estimates during the adult upstream migration and holding period under Alternative 2 Without TUCP with Delta VA and Alternative 2 Without TUCP with Systemwide VA range from about 6,200 cfs for January of critically dry water years to about 19,900 cfs for February of wet water years (Table O-192 and Table O-193). Alternative 2 Without TUCP with Delta VA and Alternative 2 Without TUCP with Systemwide VA relative to the No Action Alternative are expected to have minimal effects all three months of all water years (up to 5%) due to flows (Table O-192 and Table O-193). These flow levels are likely to be adequate for adult upstream migration, so no adverse effects are expected to result. Therefore, it is concluded that Alternative 2 Without TUCP with Delta VA and Alternative 2 Without TUCP with Systemwide VA would have similar flow effects on white sturgeon adults relative to the No Action Alternative.

Overall, the four phases of Alternative 2 would have negligible effects on flow relative to the No Action Alternative for white sturgeon upstream migration and holding in the Sacramento River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 77°F upper limit of suitable water temperature for adult white sturgeon during November through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 294 for Hamilton City.

Results for the analysis are summarized in Table O-98. Table O-98, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 77°F upper limit of suitable water temperature for adult white sturgeon, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results (Table O-98). These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on adult white sturgeon migration and holding in the Sacramento River.
- Results for **Alternative 2 Without TUCP Without VA** Are identical to those of Alternative 2 With TUCP Without VA (Table O-98).
- Results for **Alternative 2 Without TUCP Delta VA** Are identical to those of Alternative 2 With TUCP Without VA (Table O-98).
- Results for **Alternative 2 Without TUCP Systemwide VA** Are identical to those of Alternative 2 With TUCP Without VA (Table O-98).

Overall, the four phases of Alternative 2 would have similar negligible effects on water temperature conditions for adult white sturgeon upstream migration and holding in the Sacramento River (Table O-98).

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on upstream migration and holding for all phases, locations, months, and water year types due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on upstream migration and holding for all phases, locations, months, and water year types due to differences in water temperature.

O.5.15.2 Lower American River

Limited quantitative information is available on the distribution and status of white sturgeon in the lower American River; however, small numbers of adults apparently use the lower American River, as evidenced by sturgeon report cards submitted to the CDFW by anglers in recent years (Section O.1.6.2.1, *Fish Evaluated in the Lower American River*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

Adult white sturgeon have been reported by anglers in the lower American River during all months of the year, peaking in March-April and November-December (California Department of Fish and Wildlife 2023i). During all months, CalSim 3 estimates of mean monthly flows below Nimbus Dam under Alternative 2 With TUCP Without VA range from about 724cfs for October of critically dry water years to about 12,283 cfs for February of wet water years (Table O-226). For the full simulation period average, CalSim 3 results indicate that differences in flows during

January through December would generally be minimal (up to 3%) under Alternative 2 With TUCP Without VA compared to the No Action Alternative (Table O-226).

During all months, CalSim 3 estimates of mean monthly flows at H Street under Alternative 2 With TUCP Without VA range from about 604 cfs for October of critically dry water years to about 12,307 cfs for February of wet water years (Table O-230). For the full simulation period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 3%) under Alternative 2 With TUCP Without VA compared to the No Action Alternative (Table O-230).

Adult white sturgeon have been reported by anglers in the lower American River during all months of the year, peaking in March-April and November-December (CDFW 2023g). During all months, CalSim 3 estimates of mean monthly flows below Nimbus Dam under Alternative 2 Without TUCP Without VA range from about 748 cfs for October of critically dry water years to about 12,283 cfs for February of wet water years (Table O-227). For the full simulation period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 3%) under Alternative 2 Without TUCP Without VA compared to the No Action Alternative (Table O-227).

During all months, CalSim 3 estimates of mean monthly flows at H Street under Alternative 2 Without TUCP Without VA range from about 633 cfs for October of critically dry water years to about 12,306 cfs for February of wet water years (Table O-231). For the full simulation period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 4%) under Alternative 2 Without TUCP Without VA compared to the No Action Alternative (Table O-231).

Adult white sturgeon have been reported by anglers in the lower American River during all months of the year, peaking in March-April and November-December (CDFW 2023g). During all months, CalSim 3 estimates of mean monthly flows below Nimbus Dam under Alternative 2 Without TUCP with Delta VA range from about 686 cfs for October of critically dry water years to about 12,287 cfs for February of wet water years (Table O-228). For the full simulation period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 4%) under Alternative 2 Without TUCP with Delta VA compared to the No Action Alternative (Table O-228).

During all months, CalSim 3 estimates of mean monthly flows at H Street under Alternative 2 Without TUCP with Delta VA range from about 574 cfs for October of critically dry water years to about 12,310 cfs for February of wet water years (Table O-232). For the full simulation period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 5%) under Alternative 2 Without TUCP with Delta VA compared to the No Action Alternative (Table O-232).

Adult white sturgeon have been reported by anglers in the lower American River during all months of the year, peaking in March-April and November-December (CDFW 2023g). During all months, CalSim 3 estimates of mean monthly flows below Nimbus Dam under Alternative 2 Without TUCP with Systemwide VA range from about 729 cfs for October of critically dry water years to about 12,293 cfs for February of wet water years (Table O-229). For the full simulation

period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 3%) under Alternative 2 Without TUCP with Systemwide VA compared to the No Action Alternative, with the exception of flows moderately increasing in April (6%) (Table O-229).

During all months, CalSim 3 estimates of mean monthly flows at H Street under Alternative 2 Without TUCP with Systemwide VA range from about 615 cfs for October of critically dry water years to about 12,316 cfs for February of wet water years (Table O-233). For the full simulation period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 4%) except for a moderate increase in April (7%) under Alternative 2 Without TUCP with Systemwide VA compared to the No Action Alternative. Table O-233Overall, white sturgeon are not likely to be affected by changes in flow under all four phases of Alternative 2 compared to the No Action Alternative due to their limited distribution in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 77°F upper limit of suitable water temperatures for adult white sturgeon year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 77 for Hazel Avenue and Table 78 for Watt Avenue.

Results for the analysis are summarized in Table O-99. Table O-99, as described in Section O.4.15.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 77°F upper limit of suitable water temperatures for adult white sturgeon under each phase of Alternative 2, there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-99). There were also zero month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue.
- Results for **Alternative 2 Without TUCP Without VA** are identical to those presented with Alternative 2 With TUCP Without VA (Table O-99).
- Results for **Alternative 2 Without TUCP Delta VA** are identical to those presented for Alternative 2 With TUCP Without VA and Alternative 2 Without TUCP Without VA (Table O-99).
- Results for **Alternative 2 Without TUCP Systemwide VAs** are identical to those presented for Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP Delta VA (Table O-99).

These results suggest that the Alternative 2 combinations would have negligible water temperature-related effects on non-spawning white sturgeon in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on non-spawning white sturgeon for all phases, locations, months, and water year types due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on non-spawning white sturgeon for all phases, locations, months, and water year types due to differences in water temperatures.

O.5.15.3 San Joaquin River

Little is known about white sturgeon populations inhabiting the San Joaquin River. White sturgeon spawning in the San Joaquin River was documented for the first time in 2011 and confirmed in 2012. Although most of the sturgeon likely spawn in the Sacramento River, the results of these surveys confirm that white sturgeon do spawn in the San Joaquin River in both wet- and dry-year conditions and may be an important source of production for the white sturgeon population in the Sacramento–San Joaquin River system (Section O.1.8.2.4, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 flows using the Sacramento River as a surrogate, it can be inferred that the spawning period for white sturgeon in the San Joaquin River also occurs in deep water from late February to early June, peaking during March and April, (Section O.1.8.2.4, *White Sturgeon*). Because the incubation time for white sturgeon is so short, the peak effects-analysis period for incubating eggs is also considered to be March and April. Since confirmed spawning events took place in the San Joaquin River, it is reasonable to assume that rearing larvae, emigrating juveniles, and migrating adults are also present in the San Joaquin River, but due to the lack of information on these life stages they are not part of this analysis.

During the evaluated months in the spawning period, CalSim 3 estimates of mean monthly flows at Vernalis under Alternative 2 With TUCP Without VA range from about 2,050 cfs for March of critically dry water years to about 12,500 cfs for April of wet water years (Table O-242). CalSim 3 results indicate that differences in flows during March and April would be minimal (up to 2%) under Alternative 2 With TUCP Without VA compared to the No Action Alternative (Table O-242).

During the evaluated months in the spawning period, CalSim 3 estimates of mean monthly flows at Vernalis under Alternative 2 Without TUCP Without VA range from about 2,050 cfs for March of critically dry water years to about 12,500 cfs for April of wet water years (Table O-243). CalSim 3 results indicate that differences in flows during March and April would be minimal (up to 2%) under Alternative 2 Without TUCP Without VA compared to the No Action Alternative (Table O-243).

During the evaluated months in the spawning period, CalSim 3 estimates of mean monthly flows at Vernalis under Alternative 2 Without TUCP with Delta VA range from about 2,100 cfs for March of critically dry water years to about 12,500 cfs for April of wet water years (Table O-244). CalSim 3 results indicate that differences in flows during March and April would be minimal (up to 5%) under Alternative 2 Without TUCP with Delta VA compared to the No Action Alternative (Table O-244).

During the evaluated months in the spawning period, CalSim 3 estimates of mean monthly flows at Vernalis under Alternative 2 Without TUCP with Systemwide VA range from about 2,150 cfs for March of critically dry water years to about 12,500 cfs for April of wet water years (Table O-245). CalSim 3 results indicate that differences in flows during March and April would be minimal (up to 5%) under Alternative 2 Without TUCP with Systemwide VA compared to the No Action Alternative (Table O-245).

Due to spawning occurring in deep pools, it is not anticipated that flows under all phases of Alternative 2 would have an effect on white sturgeon spawning compared to the No Action Alternative.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on white sturgeon in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on spawning white sturgeon due to differences in flow. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.5.15.4 Bay-Delta

Juvenile Rearing and Emigration

White sturgeon are believed to be most abundant within the Bay-Delta region. Juveniles can be found throughout the Delta year-round. Additionally, white sturgeon larvae have been observed to be flushed farther downstream in the Delta and Suisun Bay in high outflow years, but otherwise rear higher in the system (Section O.1.9.1.6, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

<u>CalSim 3 Flows</u>

During all months, CalSim 3 estimates of mean monthly flows in the Sacramento River at Rio Vista under Alternative 2 With TUCP Without VA range from about 3,207 cfs for August of critically dry water years to about 104,680 cfs for February of wet water years (Table O-214). For all water year types, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 5%) under Alternative 2 With TUCP Without VA compared to the No Action Alternative, with a few exceptions. Flows under Alternative 2 With TUCP Without VA in above normal water years would moderately increase in September, while critically dry water years would see increases in November and April and a decrease in August (Table O-214).

CalSim 3 estimates of mean monthly total exports of SWP and CVP under Alternative 2 With TUCP Without VA range from 1,518 cfs for July of critically dry water years to about 10,854 cfs for August of wet water years (Table O-202). For all water year types, CalSim 3 results indicate

that differences in exports during January through December would generally be minimal (up to 5%) under Alternative 2 With TUCP Without VA compared to the No Action Alternative with a few exceptions. Exports would moderately to substantially increase in April and May of all water year types (up to 36%) and moderately increase in March of wet water years (10%), September of above normal water years (10%), and November of critically dry water years (up to 9%). Exports would moderately decrease in June of above normal water years (8%), June and October of below normal water years (up to 9%), January, February, June, and July of dry water years (up to 11%), and January, March, June, July, and August of critically dry water years (up to 13%) (Table O-202). It is not anticipated that changes in exports under Alternative 2 With TUCP Without VA would have an effect on white sturgeon juveniles compared to the No Action Alternative.

During all months, CalSim 3 estimates of mean monthly flows in the Sacramento River at Rio Vista under Alternative 2 Without TUCP Without VA range from about 3,247 cfs for August of critically dry water years to about 104,640 cfs for February of wet water years (Table O-215). For all water year types, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 5%) under Alternative 2 Without TUCP Without VA compared to the No Action Alternative, with a few exceptions. Flows under Alternative 2 Without TUCP Without VA in critically dry water years would see increases in November, March and April, June and July (up to 49%) (Table O-215).

CalSim 3 estimates of mean monthly total exports of SWP and CVP under Alternative 2 Without TUCP Without VA range from 1,419 cfs for August of critically dry water years to about 10,302 cfs for August of wet water years (Table O-203). In most months for all water year types, CalSim 3 results indicate that differences in exports from January through December would be minimal (up to 5%) under Alternative 2 Without TUCP Without VA compared to the No Action Alternative with a few exceptions. Exports would increase in April and May of all water year types (up to 36%) and increase in March of wet water years (9%), September of above normal water years (10%), and July and September of critically dry water years (up to 13%). Exports would decrease in June of above normal water years (8%), June and October of below normal water years (up to 12%), January, February, June, and July of dry water years (up to 11%), and January, February, March, August, and October of critically dry water years (up to 17%) (Table O-203). It is not anticipated that changes in exports under Alternative 2 Without TUCP Without VA would have an effect on white sturgeon juveniles compared to the No Action Alternative.

During all months, CalSim 3 estimates of mean monthly flows in the Sacramento River at Rio Vista under Alternative 2 Without TUCP with Delta VA range from about 3,421 cfs for August of critically dry water years to about 104,538 cfs for February of wet water years (Table O-216). For all water year types, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 5%) under Alternative 2 Without TUCP with Delta VA compared to the No Action Alternative, with a few exceptions. Flows under Alternative 2 Without TUCP with Delta VA in above normal water years would moderately increase in September (7%), while flows in dry water years would moderately decrease in June (6%), and flows in critically dry water years would increase in March through July (up to 48%) (Table O-216).

CalSim 3 estimates of mean monthly total exports of SWP and CVP under Alternative 2 Without TUCP with Delta VA range from 1,752 cfs for August of critically dry water years to about 10,928 cfs for November of wet water years (Table O-204). In most months for all water year types, CalSim 3 results indicate that differences in exports from January through December would be minimal (up to 4%) under Alternative 2 Without TUCP with Delta VA compared to the No Action Alternative with a few exceptions. Exports would moderately increase in May of all water year types (up to 27%), March of wet water years (5%), September of above normal water years (15%), August of below normal and dry water years (up to 18%), and April, May, July, August, September, and December of critically dry water years (up to 55%). Exports would moderately decrease in March, April, and June of above normal water years (up to 20%), March and June of below normal water years (up to 32%), January through April and June of dry water years (up to 21%), and January, March, and November of critically dry water years (up to 16%) (Table O-204). It is not anticipated that changes in exports under Alternative 2 Without TUCP with Delta VA would have an effect on white sturgeon juveniles compared to the No Action Alternative and may benefit juveniles in critically dry water years.

During all months, CalSim 3 estimates of mean monthly flows in the Sacramento River at Rio Vista under Alternative 2 Without TUCP with Systemwide VA range from about 3,500 cfs for August of critically dry water years to about 104,609 cfs for February of wet water years (Table O-217). For all water year types, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 4%) under Alternative 2 Without TUCP with Systemwide VA compared to the No Action Alternative, with a few exceptions. Flows under Alternative 2 Without TUCP with Systemwide VA in above normal water years would increase in April, May, and September (up to 7%). Flows in below normal water years would increase in April (up to 13%). Flows in dry water years would moderately decrease in June (7%) and increase in April, May, and August (up to 10%). Flows in critically dry water years would increase March through July (up to 55%) (Table O-217).

CalSim 3 estimates of mean monthly total exports of SWP and CVP under Alternative 2 Without TUCP with Systemwide VA range from 1,809 cfs for August of critically dry water years to about 10,926 cfs for November of wet water years (Table O-205). In most months for all water year types, CalSim 3 results indicate that differences in exports from January through December would be minimal (up to 5%) under Alternative 2 Without TUCP with Systemwide VA compared to the No Action Alternative with a few exceptions. Exports would moderately increase in May of all water year types (up to 27%), September of above normal water years (14%) and below normal water years (5%), August of below normal and dry water years (up to 19%), and April, May, July, August, and September of critically dry water years (up to 51%). Exports would decrease in March, April, and June of above normal water years (up to 19%), March and June of below normal water years (up to 32%), January, February, March, April, and June of dry water years (up to 21%), and January, February, March and November of critically dry water years (up to 20%) (Table O-205). It is not anticipated that changes in exports under Alternative 2 Without TUCP with Systemwide VA would have an effect on white sturgeon juveniles compared to the No Action Alternative and may benefit juveniles in critically dry water years.

Overall, the four phases of Alternative 2 would have negligible negative effects or minor beneficial effects on flow relative to the No Action Alternative for white sturgeon rearing and emigration in the Bay Delta.

Delta Outflow vs Sturgeon YCI

Differences in year class strength between the four phases of Alternative 2 and the No Action Alternative are expected to be negligible. For additional effects of spring Delta outflow vs white sturgeon YCI under the four phases of Alternative 2, refer to the analysis in Section O.5.11.3.1, *[Green Sturgeon] Larval and Juvenile Rearing and Emigration* and Attachment J.2, *Sturgeon Year Class Index and Delta Outflow*, for additional details.

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts or possible beneficial impacts on larval and juvenile white sturgeon, depending on phase due to differences in flow.

Potential Changes to Entrainment of White Sturgeon

Alternative 2 relative to the No Action Alternative is expected to have effects on white sturgeon entrainment at the Delta Fish Collection Facilities due to differences in exports. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for white surgeon include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of white sturgeon under Alternative 2 With TUCP Without VA compared to the No Action Alternative at the CVP Jones Pumping Plant were similar for all water year types, whereas at SWP Banks Pumping Plant there was greater loss in wet, above normal, and dry water year types; however, no loss is anticipated in critically dry water year types at either facility (Tables O-100 and O-101). At the SWP Banks Pumping Plant predicted average monthly loss was up to 25% greater for January and May of dry water year types and as low as -2% for March, April, June, November, and December of below normal water year types (Table O-100). Historical loss of white sturgeon at both facilities is rare and infrequent; this is a driver of low values of predicted loss.
- **Alternative 2 Without TUCP Without VA**
    - Predictions from the salvage density model for white sturgeon include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - At the CVP Jones Pumping Plant predicted loss was similar for all water year types, whereas predicted average monthly loss of white sturgeon of Alternative 2 Without TUCP Without VA compared to the No Action Alternative at SWP Banks Pumping Plant was greater in wet and dry water year types; however, no loss is

anticipated in critically dry water year types at either facility (Tables O-100 and O-101). At the SWP Banks Pumping Plant predicted average monthly loss was up to 25% greater for January and May of dry water year types and as low as -1% of below normal water year types (Table O-100).

- **Alternative 2 Without TUCP Delta VA**
    - Predictions from the salvage density model for white sturgeon include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - At the CVP Jones Pumping Plant predicted loss was similar for all water year types, whereas predicted average monthly loss of white sturgeon of Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at SWP Banks Pumping Plant was greater in wet and dry water year types; however, no loss is anticipated in critically dry water year types at either facility (Tables O-100 and O-101). At the SWP Banks Pumping Plant predicted average monthly loss was up to 16% greater for January and May of dry water year types and as low as -4% for March, April, June, November, and December of below normal water year types (Table O-100).
- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for white sturgeon include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - At the CVP Jones Pumping Plant predicted loss was similar for all water year types, whereas predicted average monthly loss of white sturgeon of Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at SWP Banks Pumping Plant was greater in wet and dry water year types and lower in below normal water years; however, no loss is anticipated in critically dry year types at either facility (Tables O-100 and O-101). At the SWP Banks Pumping Plant predicted average monthly loss was up to 12% greater for January and May of dry water year types and as low as -5% for March, April, June, November, and December of below normal water year types (Table O-100).

<u>Summary</u>

Differences in exports between the four phases of Alternative 2 and the No Action Alternative are expected to have negligible impacts on the entrainment of juvenile white sturgeon at both facilities. Modeled results from the quantitative model show possible beneficial and adverse impacts in various phases, months, and water year types, but since white sturgeon are salvaged so rarely, the numbers may not be representative.

Subadult and Adult Residency

White sturgeon are believed to be most abundant within the Bay-Delta region. Non spawning adults can be found throughout the Delta year-round. When not undergoing spawning or ocean migrations, adults and subadults are usually most abundant in brackish portions of the Bay-Delta (Section O.1.9.1.6, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

Juveniles, subadults and non-spawning adults are in the Bay Delta year-round, refer to the CalSim 3 flow analysis in the juvenile life stage (Section O.5.15.5.1, *Juvenile Rearing and Emigration*) for changes in flow under all four phases of Alternative 2 compared to the No Action Alternative.

For effects of spring Delta outflow vs white sturgeon YCI under the four phases of Alternative 2, refer to the analysis in Section O.5.11.3.1, *[Green Sturgeon] Larval and Juvenile Rearing and Emigration* and Attachment J.2, *Sturgeon Year Class Index and Delta Outflow*, for additional details.

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts to possible beneficial impacts on white sturgeon, depending on phase due to differences in flow.

O.5.16 Native Minnows

O.5.16.1 Sacramento River

Sacramento Splittail, Hardhead, and Sacramento Hitch

- **Sacramento Splittail:** Historically, Sacramento splittail was widespread in the Sacramento River from Redding to the Delta (Rutter 1908, as cited in Moyle et al. 2004). This distribution has become somewhat reduced in recent years (Sommer et al. 1997, 2007b). During drier years there is evidence that spawning occurs farther upstream (Feyrer et al. 2005). Adult splittail migrate upstream in the lower Sacramento River to above the mouth of the Feather River and into the Sutter and Yolo Bypasses (Sommer et al. 1997; Feyrer et al. 2005; Sommer et al. 2007b). Each year, mainly during the spring spawning season, a small number of individuals have been documented at the Red Bluff Pumping Plant and the entrance to the GCID intake (Moyle et al. 2004). Most juvenile Sacramento splittail move from upstream areas downstream into the Delta from April through August (Meng and Moyle 1995; Sommer et al. 2007b). The production and recruitment of YOY Sacramento splittail is largely influenced by extent and duration of inundation of floodplain spawning habitats, with abundance spiking following wet years and declining after dry years (Sommer et al. 1997; Moyle et al. 2004; Feyrer et al. 2006).
- **Hardhead:** Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986). They migrate upstream and into tributary streams as far as 45 miles (72.4 km) to spawning sites. Spawning behavior has not been documented, but it is assumed to be similar to that of the

pikeminnow, which deposit their eggs over gravel-bottomed riffles, runs, and at the head of pools (Moyle et al. 1995). Hardhead larvae and juveniles likely inhabit stream margins with abundant cover and move into deeper habitats as they grow larger. Juvenile and adult hardhead are present in the Sacramento River year-round.

- **Sacramento Hitch:** Sacramento hitch historically occurred in low-elevation streams throughout the Sacramento and San Joaquin Valleys and in the Delta (Moyle et al. 2015). Sacramento hitch were not known to occur in high abundance in the Sacramento watershed, but they are known to prefer shallow backwater areas and historically were observed in the upper and lower Sacramento River and North Delta (Brown & May, 2006; Robinson & Safran, 2014).
- Moyle et al. (2015) summarized habitat and distribution: Spawning takes place mainly in riffles of streams tributary to lakes, river, and sloughs after flows increase in response to spring rains, but spawning requirements are in need of further documentation. Moyle et al. (2015) indicate that YOY hitch spend the next two months after hatching shoaling in shallow water or staying close to aquatic plants before moving out into more open water at around 50-mm fork length.

Potential Changes to Sacramento Splittail, Hardhead, and Sacramento Hitch from Seasonal Operations

CalSim 3 Flows

The greatest factor in determining native minnow spawning success and recruitment is the amount and duration that crucial floodplain spawning areas are inundated during the period of native minnow migration and spawning. In wet years, flows over 22,500 cfs at Tisdale, the first flood control gate, would cause the Tisdale weir to begin spilling into the Sutter Bypass (DWR 2010). Adult migration generally occurs during the late winter with juvenile outmigration into the Delta occurring in spring/early summer. Exact migration, spawning and outmigration timing are not well understood for native minnows, so flows were examined for the months of December through May.

CalSim 3 modeling indicates that average flow released at Keswick Dam under Alternative 2 would generally be similar to flows under No Action Alternative December through May, the range of average flows for the full simulation period are from 6,250 cfs (April with TUCP Without VAs) to 11,918 cfs (February without TUCP systemwide VAs) (Table O-182 through Table O-185). Differences in average flows at Keswick Dam under Alternative 2 are from a 3% reduction (May without TUCP Without VAs) to a 6% increase (April without TUCP systemwide VAs) (Table O-182 through Table O-185). Native minnows need adequate flows to allow access to upstream spawning/rearing habitat, with minimal differences in flows under Alternative 2 the effect on flow to native minnow is likely negligible as compared to the No Action Alternative.

For the full simulation period, and the months of December through May, the difference in average CalSim 3 flow estimates under Alternative 2 compared to the No Action Alternative at Wilkins are minimal, with a range of 1% decrease in flows for May (Alternative 2 With TUCP Without VAs) to a 4% increase in April (Alternative 2 Without TUCP and systemwide VAs) (Table O-190 through Table O-193). Under Alternative 2 CalSim 3 flow estimates at Wilkins

would have a negligible effect on native minnow spawning and migration as compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 75°F observed range of suitable water temperatures for Sacramento splittail during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 307 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 84.2°F range of preferred temperatures in lab and field observations for Sacramento hitch non-spawning adults year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Tables 308 for Keswick Dam, 309 for Red Bluff Diversion Dam, and 310 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 64°F optimal water temperature range for hardhead spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Tables 311 for Keswick Dam and 312 for Red Bluff Diversion Dam. Full results of the analysis assessing the percent of months with water temperature outside the 57.2°F to 78.8°F commonly observed range of temperatures for non-spawning adult hardhead year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Tables 314 for Keswick Dam and 315 for Red Bluff Diversion Dam.

Results for the four analyses are summarized in Table O-102. Table O-102, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 45°F to 75°F observed range for suitable Sacramento splittail spawning, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at Hamilton City (Table O-102). For the 77-84.2°F preferred range for non-spawning Sacramento hitch, there were no combinations (0%) with favorable or unfavorable results at any location analyzed. For the 59-64°F optimal hardhead spawning range, there were zero and one combination (0% and 6.7%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were zero and six combinations (0% and 40.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59-64°F commonly observed range for non-spawning adult hardhead. For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there were one and zero combinations (1.7% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were zero and three combinations (0% and 5.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be negative water temperature-related effects of Alternative 2 With TUCP Without VA on native minnows in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 45°F to 75°F observed range for suitable Sacramento splittail spawning, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at Hamilton City (Table O-102). For the 77°F to 84.2°F preferred range for non-

spawning Sacramento hitch, there were no combinations (0%) with favorable or unfavorable results at any location analyzed. For the 59°F to 64°F optimal hardhead spawning range, there were zero and one combinations (0% and 6.7%, respectively) with favorable results at Keswick Dam and RBDD. There were zero and five combinations (0% and 33.3%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there were no combinations (0%) with favorable results at either Keswick Dam and RBDD, there were two and three combinations (0% and 6.7%, respectively) with unfavorable results at either Keswick Dam and RBDD, respectively. These results suggest that there would be negative water temperature-related effects of Alternative 2 Without TUCP Without VA on native minnows in the Sacramento River.

- Under **Alternative 2 Without TUCP Delta VA** for the 45°F to 75°F observed range for suitable Sacramento splittail spawning, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at Hamilton City (Table O-102). For the 77°F to 84.2°F preferred range for non-spawning Sacramento hitch, there were no combinations (0%) with favorable or unfavorable results at any location analyzed. For the 59°F to 64°F optimal hardhead spawning range, there were no combinations (0%) with favorable results at both locations analyzed. There were zero and five combinations (0% and 33.3%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there were one and zero combinations (1.7% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were zero and four combinations (0% and 6.7%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be negative water temperature-related effects of Alternative 2 Without TUCP Delta VA on native minnows in the Sacramento River.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 45°F to 75°F observed range for suitable Sacramento splittail spawning, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at Hamilton City (Table O-102). For the 77°F to 84.2°F preferred range for non-spawning Sacramento hitch, there were no combinations (0%) with favorable or unfavorable results at any location analyzed. For the 59°F to 64°F optimal hardhead spawning range, there were no combinations (0%) with favorable results at both locations analyzed. There were zero and four combinations (0% and 26.7%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there was one and zero combinations (1.7% and 0%, respectively) with favorable results at both Keswick Dam and RBDD, respectively. There were zero and five combinations (0% and 8.3%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be negative water temperature-related effects of Alternative 2 Without TUCP Systemwide VAs on native minnows in the Sacramento River.

Overall, the four phases of Alternative 2 would have similar negative effects on water temperature conditions for native minnows in the Sacramento River (Table O-102).

Summary

Seasonal operations impact on native minnows would be likely be negligible or slightly adverse based on the CalSim 3 and temperature analysis with a few exceptions. Differences in flow under Alternative 2 are minimal so impacts to native minnow would only be temperature related. Under the four phases of Alternative 2 compared to the No Action Alternative, water temperatures in the Sacramento River at RBDD would likely have an adverse impact on spawning and non-spawning hardhead. Water temperature related impacts on Sacramento splittail and hitch are likely negligible below Keswick Dam and at RBDD.

O.5.16.2 Clear Creek

Hardhead

According to Moyle et al. 2015, hardhead mainly occupy canyon reaches and deep pools in Clear Creek. Hardhead are one of the non-target species regularly caught in the RSTs in lower Clear Creek (Schraml and Chamberlain 2019a, 2019b, 2020, and 2021). Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986). They migrate upstream and into tributary streams as far as 45 miles (72.4 km) to spawning sites.

Potential Changes to Hardhead from Seasonal Operations

CalSim 3 Flows

During the December through May period for adult migration and spawning flows in Clear Creek the CalSim 3 modeling results show that throughout the full simulation period average flows in Clear Creek are higher under Alternative 2 with the exception of a 10% reduction in February. Under Alternative 2 average flows in Clear Creek ranged from 220 cfs (April) to 301 cfs (January and February)(Table O-218 through Table O-221). Even with a 10% reduction in February, flows would remain generally high during the period of hardhead spawning and migration so the effect of seasonal operations under Alternative 2 compared to the No Action Alternative would likely be negligible.

Hardhead are present in Clear Creek all months of the year. During the full simulation period and for all months utilizing the CalSim 3 modeling results, average flows under Alternative 2 had a range from 112 cfs (July, without TUCP systemwide VAs) to 301 cfs (January and February, with TUCP Without VAs) (Table O-218 through Table O-221). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from 31% lower (June, with TUCP Without VAs) to 36% higher (May, without TUCP with Delta VAs) (Table O-218 through Table O-221). With the decrease in flows in February flows would still remain relatively high in the winter, but during the fall a substantial reduction in flows would likely have a negative effect on hardhead occupying Clear Creek by limiting available habitat, and prey availability.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 64°F optimal water temperature range for hardhead spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 304 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of

months with water temperature outside the 57.2°F to 78.8°F commonly observed range of temperatures for hardhead spawning year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 307 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-103. Table O-103, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 59-64°F optimal hardhead spawning range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results (Table O-103). For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there was one combination (1.7%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on native minnows in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-103).

Overall, the four phases of Alternative 2 would have similar negligible effects on water temperature conditions for native minnows in Clear Creek (Table O-103).

Summary

There are likely negligible impacts of seasonal operations on Hardhead in Clear Creek based on temperature and simulated flow analysis for the four phases of Alternative 2 as compared to the No Action Alternative. Both the flow and temperature analysis show that Alternative 2 would have little to no difference in habitat suitability for all stages of hardhead as compared to the No Action Alternative.

O.5.16.3 Lower American River

Hardhead and Sacramento Splittail

- **Hardhead:** The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are fairly common in the lower reaches of the lower American River. Hardhead are fairly common year-round in the lower reaches of the lower American River (Moyle 2002). Although migratory behavior of hardhead in the lower American River individuals is unknown, individuals from other large rivers, such as the Sacramento River, migrate into tributary streams during April and May. Hardhead typically spawn between April and May (Moyle 2002). Although hardhead early life history is largely unknown, young individuals likely remain along stream edges with dense cover and move into deeper water as they grow, which allows migrants to move back downstream in the current (Moyle 2002).

- **Sacramento Splittail:** Splittail likely spawn in the lower reaches of the lower American River (Sommer et al. 2008; Moyle et al. 2004). Because upstream migration is more directed and fish tend to swim farther upstream during wet years (Moyle 2002), more individuals are expected to use the lower American River in wet years. Although juvenile splittail are known to rear in upstream areas for a year or more (Baxter 1999), most move to the Delta after only a few weeks of rearing on floodplain habitat (Bureau of Reclamation 2008). Most juveniles move downstream into the Delta from April to August (Meng and Moyle 1995). The primary factor potentially limiting the lower American River population of Sacramento splittail is availability of inundated floodplains for spawning and rearing habitats (Moyle et al. 2004).

Potential Changes to Hardhead and Sacramento Splittail from Seasonal Operations

CalSim 3 Flows

During the December through May period for adult migration and spawning for flows in the lower American River below Nimbus the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are minimal. Under Alternative 2 average flows in the lower American River below Nimbus ranged from 3,587 cfs (May, without TUCP with Delta VAs) to 6,349 cfs (February, with TUCP Without VAs) (Table O-226 through Table O-229). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 2% reduction (January, without TUCP with Delta VAs) to a 6% increase (April, without TUCP Systemwide VAs) (Table O-226 through Table O-229). With minimal differences in flows native minnow migration and spawning would likely have a negligible affect under Alternative 2 compared to the No Action Alternative, with the exception of critically dry water year types where a reduction in flows during the beginning of the migration period may limit migration of native minnows into the lower American River.

For all months of the year, and for the full simulation period, CalSim 3 estimates of mean monthly flows below Nimbus Dam under the four phases of Alternative 2 are from 1,433 cfs (October, without TUCP and Delta VAs) to 6,349 cfs (February, with TUCP Without VAs) (Table O-226 through Table O-229). The difference in average flows under Alternative 2 as compared to the No Action Alternative for the full simulation period range from a 4% reduction (October, without TUCP with Delta VAs) to a 6% increase (April without TUCP systemwide VAs) (Table O-226 through Table O-229). With minimal differences in flows native minnow occupying the lower American River would likely have a negligible affect under Alternative 2 compared to the No Action Alternative. The only exception would be in critically dry water year types where a reduction in flows during the beginning of the migration period may limit migration of native minnows but would likely have little effect on juveniles and non-spawning adults in the lower American River.

During the December through May period for adult migration and spawning for flows in the lower American River at H street, the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are minimal. Under Alternative 2 average flows in the lower American River at H street ranged from 3,462 cfs (April, with TUCP Without VAs) to 6,339 cfs (February, with TUCP Without VAs) (Table O-230 through Table O-233). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 2% reduction (December, without TUCP and Delta VAs) to a 6% increase (April, without TUCP Systemwide VAs) for the full simulation period (Table O-230 through Table O-233). With minimal differences in flows native minnow migration and spawning would likely have a negligible affect under Alternative 2 compared to the No Action Alternative, with the exception of critically dry water year types where adult migration and spawning may be limited during the beginning of the migration period.

During all months, and the full simulation period, CalSim 3 estimates of mean monthly flows at H Street under Alternative 2 range from 1,334 (October, without TUCP with Delta VAs) to 6,339 cfs (February, with TUCP Without VAs) (Table O-230 through Table O-233). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 6% reduction (August, without TUCP and systemwide VAs) to a 6% increase (April, without TUCP systemwide VAs) for the full simulation period (Table O-230 through Table O-233). With minimal differences in flows native minnow occupying the lower American River would likely have a negligible affect under Alternative 2 compared to the No Action Alternative. The only exception would be in critically dry water year types where a reduction in flows during the beginning of the migration period may limit migration of native minnows but would likely have little effect on juveniles and non-spawning adults in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 75°F water temperature range observed for Sacramento splittail suitable spawning during February through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 87 for Hazel Avenue and Table 88 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the outside the 59°F to 64°F water temperature optimal range for hardhead spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 89 for Hazel Avenue and Table 90 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the outside the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 91 for Hazel Avenue and Table 92 for Watt Avenue.

Results for these three analyses are summarized in Table O-104. Table O-104, as described in Section O.4.16.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 45°F to 75°F water temperature range observed for suitable spawning for Sacramento splittail under each phase of Alternative 2, there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-104). There were also zero month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 59°F to 64°F water temperature optimal range for hardhead spawning there were one and one month-water year type combinations (6.7% and 6.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and two month-water year type combinations (13.3% and 13.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were zero and one month-water year type combinations (0% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and two month-water year type combinations (3.3% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Without VA** for the 45°F to 75°F water temperature range observed for suitable spawning for Sacramento splittail under each phase of Alternative 2, there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-104). There were also zero month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 59°F to 64°F water temperature optimal range for hardhead spawning there were zero and one month-water year type combinations (0% and 6.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and zero month-water year type combinations (6.7% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and two month-water year type combinations (1.7% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Delta VA** for the 45°F to 75°F water temperature range observed for suitable spawning for Sacramento splittail under each phase of Alternative 2, there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-104). There were also zero month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 59°F to 64°F water temperature optimal range for hardhead spawning there were zero and two month-water year type combinations (0% and 13.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two month-water year type combinations (13.3%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were zero and one month-water year type combinations (0% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and three month-water year type combinations (3.3% and 5.0% respectively) with unfavorable results at both Hazel Avenue and Watt Avenue, respectively.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 45°F to 75°F water temperature range observed for suitable spawning for Sacramento splittail under each phase of Alternative 2, there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-104). There were also zero month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 59°F to 64°F water temperature optimal range for hardhead spawning there was one month-water year type combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue. There were two and three month-water year type combinations (13.3% and 20.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were two and three month-water year type combinations (3.3% and 5.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, these results suggest all phases of Alternative 2 would small positive and negative water temperature-related effects to native minnow spawning and non-spawning adults in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There are likely beneficial and adverse impacts of seasonal operations on native minnow in the lower American River based on the difference in simulated flows for all phases of Alternative 2 compared to the No Action Alternative. The water temperature analysis for the lower American River at Hazel and Watt Avenue indicates that there would be both beneficial and adverse water temperature-related effects to native minnows in the lower American River. Under the four phases of Alternative 2 differences in flows are minimal, so adult migration and spawning would likely be unaffected, but the proportion of native minnows remaining in the lower American river would be negatively impacted by sub-optimal temperatures as compared to the No Action Alternative.

O.5.16.4 Stanislaus River

Hardhead

The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are a frequent catch in the lower Stanislaus River (Bradbury and Hickey 2019). The Stanislaus River compared to other systems in the San Joaquin River watershed has higher discharge and albeit slightly cooler water for most of the year. Due to the more stream-like conditions the Stanislaus River is occupied by many native fish, including hardhead. The increased discharge has also limited many non-native fishes, concentrating them in the lower reaches. Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986).

Potential Changes to Hardhead from Seasonal Operations

CalSim 3 Flows

During the December through May period for adult migration and spawning for flows in the Stanislaus River at the confluence with the San Joaquin the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are similar under Alternative 2. Under Alternative 2 average flows in the Stanislaus River at the confluence ranged from 531 cfs (December) to 1,160 cfs (May, with TUCP Without VAs) (Table O-238 through Table O-241). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 3% reduction (May) to a 4% increase (December, without TUCP with Delta VAs) (Table O-238 through Table O-241). With little difference in flows hardhead migration and spawning would likely be negligibly impacted under Alternative 2 compared to the No Action Alternative.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the Stanislaus River at the confluence of the San Joaquin under Alternative 2 range from 345 cfs (July, with TUCP Without VAs) to 1,160 cfs (May, with TUCP Without VAs) (Table O-238 through Table O-241).The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 3% reduction (May) to a 10% increase (August, without TUCP Without VAs) (Table O-238 through Table O-241). Hardhead are present in the Stanislaus River all months of the year. With similar flows most of the year and a slight increase during the fall, hardhead occupying the Stanislaus River would likely have a negligible or positive effect under Alternative 2 as compared to the No Action Alternative.

During the December through May period for adult migration and spawning for flows in the Stanislaus River below Goodwin Dam the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are minimal. Under Alternative 2 average flows in the Stanislaus River below Goodwin Dam ranged from 527 cfs (December, with TUCP Without VAs) to 1,048 cfs (February, with TUCP Without VAs) (Table O-234 through Table O-237). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 8% reduction (April) to a 7% increase (February) (Table O-234 through Table O-237). With minimal differences in flows hardhead migration and spawning would likely be negligibly impacted under Alternative 2 compared to the No Action Alternative.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the Stanislaus River below Goodwin Dam under Alternative 2 had a range from 306 cfs (November, without TUCP Without VAs) to 1,048 cfs (February, with TUCP Without VAs) (Table O-234 through Table O-237). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 8% reduction (April) to a 13% increase (August, without TUCP systemwide VAs) for the full simulation period, and all months (Table O-234 through Table O-237). Hardhead are present in the Stanislaus River for all months of the year. With little difference in flows and slightly higher flows in the fall, hardhead would likely have a negligible or positive effect under Alternative 2 as compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the outside the 59°F to 64°F water temperature optimal range for hardhead spawning during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 868 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the outside the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 69 for Orange Blossom Bridge.

Results for these two analyses are summarized in Table O-105. Table O-105, as described in Section O.4.16.4, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 59°F to 64°F water temperature optimal range for hardhead spawning, there was one month-water year type combination (6.7%) with favorable results and zero month-water year type combinations (0%) with unfavorable results at Orange Blossom Bridge (O-105). For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were two month-water year type combinations (3.3%) with favorable results and four month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-105).

Overall, the four phases of Alternative 2 would have negligible water temperature-related effects on native minnows in the Stanislaus River at Orange Blossom Bridge.

Summary

The difference in simulated flows under the four phases of Alternative 2 as compared to the No Action Alternative are minimal, so flow-related impacts to hardhead would likely be negligible. However, based off the temperature analysis for the Stanislaus River at Orange Blossom Bridge, the frequency of sub-optimal temperatures for both spawning adults and non-spawning adults/juveniles would be higher under the four phases of Alternative 2 compared to the No Action Alternative. Under the four phases of Alternative 2 differences in flows are minimal, so adult migration and spawning would likely be unaffected, but the proportion of hardhead remaining in the Stanislaus River would be negatively affected by sub-optimal temperatures as compared to the No Action Alternative.

O.5.16.5 San Joaquin River

Sacramento Splittail, Hardhead, and Sacramento Hitch

- **Sacramento Splittail:** Historically, Sacramento splittail were widespread in the San Joaquin River and found upstream to Tulare and Buena Vista lakes, where they were harvested by native peoples (Moyle et al. 2004). Today, Sacramento splittail likely ascend the San Joaquin River to Salt Slough during wet years (Baxter 1999). During dry years, Sacramento splittail are uncommon in the San Joaquin River downstream of the Tuolumne River (Moyle et al. 2004).

  The population of Sacramento splittail is largely influenced by extent and period of inundation of floodplain spawning habitats, with abundance spiking following wet years and declining after dry years (Moyle et al. 2004).

- **Hardhead:** In the San Joaquin drainage, hardhead are present throughout tributary streams but are largely absent from the valley reaches of the San Joaquin River (Moyle et al. 2015, Moyle and Nichols 1973, Saiki 1984). Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986).

- **Sacramento Hitch:** Sacramento hitch historically occurred in low-elevation streams throughout the Sacramento and San Joaquin Valleys and in the Delta, but are now absent from the San Joaquin River and tributaries between Friant Dam and the Merced River (Moyle et al. 2015). Sacramento hitch are occasionally captured in low numbers in the lower San Joaquin River in the Mossdale trawl monitoring program (Interagency Ecological Program et al. 2022).

Potential Changes to Sacramento Splittail, Sacramento Hitch, and Hardhead from Seasonal Operations

During the December through May period for adult migration and spawning for flows in the San Joaquin at Vernalis the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are minimal. Under Alternative 2 average flows in the San Joaquin at Vernalis ranged from 2,884 cfs (December) to 6,391 cfs (February, without TUCP with Delta VAs) (Table O-242 through Table O-245). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 1% reduction (May) to a 1% increase (December) for the full simulation period, and months of December through May (Table O-242 through Table O-245). With minimal differences in flows native minnow migration and spawning would likely have a negligible affect under Alternative 2 compared to the No Action Alternative.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the San Joaquin at Vernalis under Alternative 2 range from 1,425 cfs (August, with TUCP Without VAs) to 6,449 cfs (February, without TUCP and Delta VAs) (Table O-242 through Table O-245). The difference in average flows under Alternative 2 compared to the No Action Alternative had a range from a 1% reduction (May) to a 3% increase (August, without TUCP Without VAs) (Table O-242 through Table O-245). Presence of native minnows in the San Joaquin are not well known, but it is likely that many species are present year-round. With

minimal differences in flow under Alternative 2 compared to the No Action Alternative the effect of flow on native minnows is likely negligible.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on native minnows in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

Summary

Based off the CalSim 3 flow analysis differences in flow under the four phases of Alternative 2 would be minimal. Many native minnows likely use the San Joaquin and its tributaries for spawning and rearing, adequate flow is also necessary for spawning adults to access spawning areas. Without a substantial difference in flow, impacts to native minnow under the four phases of Alternative 2 compared to the No Action Alternative would be likely be negligible. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

O.5.16.6 Bay-Delta

Hardhead, Sacramento Hitch, and Sacramento Splittail

- **Hardhead:** The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are present in low abundance in the San Francisco Estuary and Delta. Brown and Michniuk (2007) electrofished parts of the Bay-Delta in the 1980's and 2000's and captured small numbers of hardhead. Retrieval of hardhead at the SWP/CVP south Delta fish salvage facilities remain relatively low (California Department of Water Resources 2020).

- **Sacramento Hitch:** The species is distributed in the Sacramento River Basin, in low numbers in the San Joaquin River Basin, and occasionally captured during monitoring programs in the Delta (Moyle et al. 2015; Interagency Ecological Program et al. 2022). Monitoring data suggests year round presence in the Delta (Interagency Ecological Program et al. 2022).

- **Sacramento Splittail:** Adult Sacramento splittail typically migrate upstream from brackish areas in January and February and spawn in freshwater, particularly on inundated floodplains when they are available, in March and April (Sommer et al. 1997; Moyle et al. 2004; Sommer et al. 2008). A substantial amount of splittail spawning occurs in the Yolo and Sutter Bypasses and the Cosumnes River area of the Delta (Moyle et al. 2004).

  Although juvenile Sacramento splittail are known to rear in upstream areas for a year or more (Baxter 1999), most move to the Delta after only a few weeks or months of rearing in floodplain habitats along the rivers (Feyrer et al. 2006). Juveniles move downstream into the Delta from April to August (Meng and Moyle 1995; Feyrer et al. 2005). Sacramento splittail recruitment is largely limited by extent and period of inundation of floodplain spawning habitats, with abundance observed to spike following wet years and dip after dry years (Moyle et al. 2004).

Potential Changes to Sacramento Splittail, Sacramento Hitch, and Hardhead from Seasonal Operations

CalSim 3 Flows

For many species of native minnow, it has been shown that changes in export flows can lead to higher levels of entrainment which can potentially influence population dynamics. Certain species such as Sacramento splittail are known to utilize the Delta for many portions of their life history so flows into the Delta will have a strong effect on these fish by limiting habitat, prey availability and access to spawning areas. Since many native minnows occupy the Delta year-round, flows and exports were examined for all months of the year.

During all months and for the full simulation period, CalSim 3 estimates of Delta outflow would be similar under Alternative 2 for most months compared to the No Action Alternative. CalSim 3 estimates of average Delta outflow have a range from about 4,500 cfs (August, without TUCP and Delta VAs) to over 58,000 cfs (February, without TUCP Without VAs) for Alternative 2 and for the full simulation period (Table O-206 through Table O-209). Differences in average outflow under Alternative 2 as compared to the No Action Alternative would be from a 6% reduction (May, with TUCP Without VAs) to a 6% increase (April, without TUCP systemwide VAs) (Table O-206 through Table O-209). With minimal differences in Delta outflow under Alternative 2 the effect on native minnows would likely be negligible as compared to the No Action Alternative.

CalSim 3 estimates of mean monthly average flow for the total exports of SWP and CVP under Alternative 2 range from 4,213 cfs (April, without TUCP and Delta VAs) to 8,313 cfs (July, without TUCP systemwide VAs) (Table O-202 through Table O-205). For the full simulation period, CalSim 3 results indicate that differences in average exports for Alternative 2 would be minimal for most of the year having a slight reduction in March followed by an increase in exports in April/May, with May having a substantial increase for all components of Alternative 2. The range of average export flow difference under Alternative 2 compared to the No Action Alternative for the full simulation period were from a 12% reduction in exports (March, without TUCP with Delta VAs) to a 25% increase in exports (May, with TUCP Without VAs) (Table O-202 through Table O-205). Although differences in export flows under Alternative 2 compared to the No Action Alternative are minimal for most of the year, increased exports during April/May would likely cause an increase in entrainment for many native minnows and for all life stages. Given that higher levels of entrainment would be expected at a crucial time of the year, Alternative 2 would likely have a negative effect on native minnows as compared to the No Action Alternative.

Summary

With minimal differences in Delta outflow under Alternative 2 the impact on native minnows would likely be negligible as compared to the No Action Alternative. Although differences in export flows under Alternative 2 compared to the No Action Alternative are minimal for most of the year, increased exports during April/May would likely cause an increase in entrainment for many native minnows. Given that higher levels of entrainment would be expected at a crucial time of the year, Alternative 2 would likely have a negative impact on native minnows with as compared to the No Action Alternative.

Potential Changes to Entrainment of Sacramento Splittail, Sacramento Hitch, and Hardhead

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on native minnows at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Sacramento Splittail: Alternative 2 With TUCP Without VAs**
    - Predictions from the salvage density model for Sacramento splittail include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of Sacramento splittail at SWP Banks Pumping Plant for all months of the year and all water year types Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative, up to 62% greater for the above normal water year types (Table O-106). Predicted average monthly loss of Sacramento splittail at CVP Jones Pumping Plant for all months of the year and all water year types Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for wet, above normal, and below normal water year types, for dry and critically dry water year types predicted loss was lower under Alternative 2 With TUCP. For all water year types Alternative 2 With TUCP Without VAs as compared to the No Action Alternative at Jones had a range from up to 2% greater for above normal water year types to 14% lower for dry water year types, it should also be noted that in critically dry water year types predicted loss only occurred for 6 months of the year (Table O-107). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.
- **Sacramento Splittail: Alternative 2 Without TUCP Without VAs**
    - Predictions from the salvage density model for Sacramento splittail include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of Sacramento splittail at SWP Banks Pumping Plant for all months of the year and all water year types, Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for all but critically dry water year types, with up to 62% greater for the above normal water year types and 5% lower for critically dry water year types (Table O-106). Predicted average monthly loss of Sacramento splittail at CVP Jones Pumping Plant for all months of the year and all water year types Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for wet, above normal, and critically dry water year types, for below normal, and dry water year types

predicted loss was lower under Alternative 2 Without TUCP Without VAs. For all water year types Alternative 2 With TUCP as compared to the No Action Alternative at Jones had a range from up to 2% greater for above normal water year types to 13% lower for dry water year types, it should also be noted that in critically dry water year types predicted loss only occurred for 6 months of the year (Table O-107). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.

- **Sacramento Splittail: Alternative 2 Without TUCP Delta VAs**
    - Predictions from the salvage density model for Sacramento splittail include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of Sacramento splittail at SWP Banks Pumping Plant for all months of the year and all water year types Alternative 2 Without TUCP Delta VAs was greater than predicted average monthly loss under the No Action Alternative for all but critically dry water year types, with up to 47% greater for wet and above normal water year types and 4% lower for critically dry water year types (Table O-106). Predicted average monthly loss of Sacramento splittail at CVP Jones Pumping Plant for all months of the year and all water year types Alternative 2 Without TUCP Delta VAs was equal or lower than predicted average monthly loss under the No Action Alternative for all water year types except for critically dry water year types. For all water year types Alternative 2 Without TUCP Delta VAs as compared to the No Action Alternative at Jones had a range from up to 13% lower for dry water year types to 4% higher for critically dry water year types, it should also be noted that in critically dry water year types predicted loss only occurred for six months of the year (Table O-107). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.
- **Sacramento Splittail: Alternative 2 Without TUCP Systemwide VAs**
    - Predictions from the salvage density model for Sacramento splittail include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of Sacramento splittail at SWP Banks Pumping Plant for all months of the year and all water year types Alternative 2 Without TUCP Systemwide VAs was greater than predicted average monthly loss under the No Action Alternative for all but critically dry water year types, with up to 48% greater for wet water year types and 4% lower for critically dry water year types (Table O-106). Predicted average monthly loss of Sacramento splittail at CVP Jones Pumping Plant for all months of the year and all water year types Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly loss under the No Action Alternative for above normal, below normal and dry water year types, predicted loss was higher for wet, and critically dry

water year types. For all water year types Alternative 2 Without TUCP Systemwide VAs as compared to the No Action Alternative at Jones had a range from up to 12% lower for dry water year types to 3% higher for critically dry water year types, it should also be noted that in critically dry water year types predicted loss only occurred for 6 months of the year (Table O-107). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.

- **Sacramento Hitch: Alternative 2 With TUCP Without VAs**
    - Predictions from the salvage density model for Sacramento hitch include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of Sacramento hitch at SWP Banks Pumping Plant for all months of the year and all water year types Alternative 2 With TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for all water year types except dry water year types. Predicted average monthly loss at Banks under Alternative 2 With TUCP Without VAs had a range from 5% lower for dry water year types to 178% higher for above normal water year types, there was no predicted loss for critically dry water year types. (Table O-110). Predicted average monthly loss of Sacramento hitch at CVP Jones Pumping Plant for the months of March through April and all water year types Alternative 2 With TUCP Without VAs was greater or equal than predicted average monthly loss under the No Action Alternative. For all water year types Alternative 2 With TUCP Without VAs as compared to the No Action Alternative at Jones had a predicted loss that was equal for all but wet water year types, which had a 10% increase in predicted loss, no fish were predicted to be lost in dry and critically dry water year types. It should be noted that loss of Sacramento hitch at both facilities is rare and infrequent, with such low values of predicted loss, the percent differences may not be representative (Table O-111). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.
- **Sacramento Hitch: Alternative 2 Without TUCP Without VAs**
    - Predictions from the salvage density model for Sacramento hitch include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of Sacramento hitch at SWP Banks Pumping Plant for all months of the year and all water year types Alternative 2 Without TUCP Without VAs was greater than predicted average monthly loss under the No Action Alternative for wet, and above normal water year types, predicted loss was lower for below normal, and dry water year types, there was no predicted loss for critically dry water year types. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Without VAs had a range from 5% lower for dry

water year types to 177% higher for above normal water year types (Table O-110). Predicted average monthly loss of Sacramento hitch at CVP Jones Pumping Plant for the months of March through April and all water year types Alternative 2 Without TUCP Without VAs was greater or equal than predicted average monthly loss under the No Action Alternative. The range of predicted loss for Sacramento hitch at Jones under Alternative 2 Without TUCP Without VAs compared to the No Action Alternative was from 0% in above normal water year types to 11% higher for wet water year types, no fish were predicted to be lost in dry and critically dry water year types. It should be noted that loss of Sacramento hitch at both facilities is rare and infrequent, with such low values of predicted loss, the percent differences may not be representative. (Table O-111). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.

- **Sacramento Hitch: Alternative 2 Without TUCP Delta VAs**
    - Predictions from the salvage density model for Sacramento hitch include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of Sacramento hitch at SWP Banks Pumping Plant for all months of the year and all water year types Alternative 2 Without TUCP Delta VAs was greater than predicted average monthly loss under the No Action Alternative for all water year types, except for dry water year types, there was no predicted loss for critically dry water year types. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Delta VAs had a range from 1% lower for dry water year types to 49% higher for above normal water year types (Table O-110). Predicted average monthly loss of Sacramento hitch at CVP Jones Pumping Plant for the months of March through April and all water year types Alternative 2 Without TUCP Delta VAs was lower than predicted average monthly loss under the No Action Alternative. The range of predicted loss for Sacramento hitch at Jones under Alternative 2 Without TUCP Delta VAs compared to the No Action Alternative was from 10% lower in wet water year types to 33% lower for above and below normal water year types, no fish were predicted to be lost in dry and critically dry water year types. It should be noted that loss of Sacramento hitch at both facilities is rare and infrequent, with such low values of predicted loss, the percent differences may not be representative. (Table O-111). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.
- **Sacramento Hitch: Alternative 2 Without TUCP Systemwide VAs**
    - Predictions from the salvage density model for Sacramento hitch include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.

- Predicted average monthly loss of Sacramento hitch at SWP Banks Pumping Plant for all months of the year and all water year types. Alternative 2 Without TUCP Systemwide VAs was greater than predicted average monthly loss under the No Action Alternative for all water year types, there was no predicted loss for critically dry water year types. Predicted average monthly loss at Banks under Alternative 2 Without TUCP Systemwide VAs had a range from 3% higher for dry water year types to 49% higher for above normal water year types (Table O-110). Predicted average monthly loss of Sacramento hitch at CVP Jones Pumping Plant for the months of March through April and all water year types Alternative 2 Without TUCP Systemwide VAs was lower than predicted average monthly loss under the No Action Alternative. The range of predicted loss for Sacramento hitch at Jones under Alternative 2 Without TUCP Systemwide VAs compared to the No Action Alternative was from 11% lower in wet water year types to 36% lower for below normal water year types, no fish were predicted to be lost in dry and critically dry water year types. It should be noted that loss of Sacramento hitch at both facilities is rare and infrequent, with such low values of predicted loss, the percent differences may not be representative. (Table O-111). For detailed information on average monthly loss by water year type, see Attachment I.2, Salvage Density Model Loss Simulation.

- **Hardhead: Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for hardhead include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Whereas at the CVP Jones Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of hardhead of Alternative 2 With TUCP Without VA compared to the No Action At the SWP Banks Pumping Plant was greater all water year types, except in below normal and dry water year types when no fish are expected (Tables O-108 and O-109). At the SWP Banks Pumping Plant predicted average monthly loss was between 19% and 178% greater in September of critically dry water years and April of above normal water years, respectively (Table O-108).
- **Hardhead: Alternative 2 Without TUCP Without VA**
    - Predictions from the salvage density model for hardhead include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Whereas at the CVP Jones Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of hardhead of Alternative 2 Without TUCP Without VA compared to the No Action Alternative at SWP Banks Pumping Plant was greater all water year types, except in below normal and dry water year types when no fish are expected (Tables O-108 and O-109). At the SWP Banks Pumping Plant predicted average monthly loss was

between 16% and 177% greater in April of wet and above normal water year, respectively (Table O-108).

- **Hardhead: Alternative 2 Without TUCP Delta VA**
    - Predictions from the salvage density model for hardhead include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Whereas at the CVP Jones Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of hardhead for Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at SWP Banks Pumping Plant was greater for all water year types, except in below normal and dry water year types when no fish are expected to be lost (Tables O-108 and O-109). At the SWP Banks Pumping Plant predicted average monthly loss was between 7% and 49% greater in April of wet and above normal water year, respectively (Table O-108).
- **Hardhead: Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for hardhead include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Whereas at the CVP Jones Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of hardhead of Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at the SWP Banks Pumping Plant was greater all water year types, except in below normal and dry water year types when no fish are expected (Tables O-108 and O-109). At the SWP Banks Pumping Plant predicted average monthly loss was between 7% and 49% greater in April of wet and above normal water year, respectively (Table O-108).

<u>Summary</u>

Utilizing the salvage density modeling results, predicted average monthly loss for native minnows was higher for all four components of Alternative 2 for most months and water year types. In most instances higher levels of predicted salvage would occur for all species of native minnow for all four components of Alternative 2 as compared to the No Action Alternative.

O.5.17 Pacific Lamprey

O.5.17.1 Trinity River

Spawning and Egg Incubation

Pacific lamprey typically spawn from March through June, when daily mean water temperatures range from 50–64°F, with peak spawning occurring typically occurring in April and May and when water temperatures are approximately 57–59°F (Stone 2006; Brumo et al. 2009). Redds are typically constructed in gravel and cobble substrates within pool and run tailouts and low gradient riffles (Stone 2006, Brumo et al. 2009). Eggs are deposited in the redd and hatch after approximately 15 days, depending on water temperatures (Meeuwig et al. 2005, Brumo 2006). Egg-sac larvae spend another 15 days in redds before emergence. Water temperatures in excess of 65°F during incubation have been shown to reduce embryo survival (Meeuwig et al. 2005). The effects analysis period for spawning and egg incubation in the Trinity River is March through July.

Potential Changes to Pacific Lamprey Spawning and Egg Incubation from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 2 to flows under the No Action Alternative. Minor differences in monthly average flows between Alternative 2 and the No Action Alternative would occur in November through April of some water year types, with most differences less than 5%. Flows under each phase of Alternative 2 would be very similar, with minor differences among the phases occurring in November through April of some water year types and most differences less than 5%.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be more than 5% lower than the No Action Alternative during the spawning period in March in wet water years (Table O-174). The March flow decreases would occur during Pacific lamprey spawning and egg incubation period. The reduction in flows in wet years would likely be minor in the reduction of spawning habitat and detrimental impacts on egg incubation as flows would still be above 1,876 cfs. Average water temperature in the Trinity River below Lewiston Dam in February and March of wet water years may increase slightly under Alternative 2 With TUCP Without VA compared to the No Action Alternative but would remain below the 50°F upper optimum limit recommended by USEPA (2001, as cited in Carter 2005) from Lewiston Dam to North Fork Trinity River in all water year types to support salmonids. Upper temperature thresholds for Pacific lamprey spawning initiation would not be exceeded and the impacts of Alternative 2 With TUCP Without VA are likely negligible to both Pacific lamprey spawning, and egg incubation.
- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be more than 5% lower than the No Action Alternative during the spawning period in March in wet water years (Table O-175). The March flow decreases would occur during Pacific lamprey spawning and egg incubation period, but flows would still be at or above 1,874 cfs. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey spawning and egg incubation as those described for Alternative 2 With TUCP Without VA.

- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be more than 5% lower than the No Action Alternative during the spawning period in March in wet water years (Table O-176). The March flow decreases would occur during Pacific lamprey spawning and egg incubation period. The reduction in flows in wet years would likely be negligible for spawning habitat and egg incubation as flows would still be above 1,872 cfs. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey spawning and egg incubation as those described for Alternative 2 With TUCP Without VA.
- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative during the spawning period in March in wet water years (Table O-177). The March flow decreases would occur during Pacific lamprey spawning and egg incubation period. The reduction in flows in wet years would likely be negligible for spawning habitat and egg incubation as flows would still be above 1,872 cfs. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey spawning and egg incubation as those described for Alternative 2 With TUCP Without VA.

Ammocoete Rearing and Emigration

After emergence from redds, eyeless Pacific lamprey larvae, known as ammocoetes, settle out of the water column and burrow into fine silt and sand substrates, often containing organic matter. Ammocoetes rear in these habitats for four to 10 years. Water temperature requirements for the life stage are not well described. Ammocoetes have been observed burrowed in substrates in streams with water temperatures up to 80°F (Claire 2004), and upper water temperature tolerances are estimated to be around 83°F (Whitesel and Uh 2023). After Pacific lamprey metamorphose to the macropthalmia stage, individuals migrate to the ocean typically in conjunction with high flow events between fall and spring, but can occur year-round. The effects analysis period for ammocoete rearing is year-round and emigration is primarily fall through spring in the Trinity River

Potential Changes to Pacific Lamprey Ammocoete Rearing and Emigration from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 2 to flows under the No Action Alternative. Minor differences in monthly average flows between Alternative 2 and the No Action Alternative would occur in November through April of some water year types, with most differences less than 5%. Flows under each phase of Alternative 2 would be very similar, with minor differences among the phases occurring in November through April of some water year types and nearly all differences less than 5%.

Average water temperature in the Trinity River below Lewiston Dam in February and March of wet water years may increase slightly under Alternative 2 With TUCP Without VA compared to the No Action Alternative but would remain below the 50°F upper optimum limit recommended by USEPA (2001, as cited in Carter 2005) from Lewiston Dam to North Fork Trinity River in all water year types to support salmonids. Upper temperature thresholds for Pacific lamprey ammocoete rearing and emigration would not be exceeded and the impacts of Alternative 2 With

TUCP Without VA are likely negligible to both Pacific lamprey ammocoete growth rates, and emigration.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (TableO.Trin_Atl2_1). The reduction in flows could have minor impacts in the reduction of rearing habitat, and reduced flows during peak emigration periods in December of below normal years as flows decrease from 931 to 819 cfs. Alternative 2 With TUCP Without VA monthly average flows will have negligible to minor impacts on ammocoete rearing and emigration of Pacific lamprey when compared to the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey ammocoete rearing and emigration as those described for Alternative 2 With TUCP Without VA.
- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (TableO.Trin_Atl2_2). A greater than 5% increase in flow is expected only in February in above normal years. The reduction in flows could have minor impacts in the reduction of rearing habitat, and reduced flows during peak emigration periods in December of below normal years as flows decrease from 931 to 818 cfs. Increases in flow in February are likely to have negligible impacts on ammocoete rearing and emigration, as flows would only increase from 1,194 to 1,257 cfs. Alternative 2 Without TUCP Without VA monthly average flows will have negligible to minor impacts on ammocoete rearing and emigration of Pacific lamprey when compared to the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey ammocoete rearing and emigration as those described for Alternative 2 With TUCP Without VA.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (TableO.Trin_Atl2_3). The reduction in flows could have minor adverse impacts in the reduction of rearing habitat, and reduced flows during peak emigration periods in December of below normal years, as flows decrease from 931 to 788 cfs. Alternative 2 Without TUCP With Delta VA monthly average flows will have negligible to minor adverse impacts on ammocoete rearing and emigration of Pacific lamprey when compared to the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey ammocoete rearing and emigration as those described for Alternative 2 With TUCP Without VA.

- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (TableO.Trin_Atl2_4). A greater than 5% increase in flow is expected only in February in above normal years. The reduction in flows could have minor adverse impacts in the reduction of rearing habitat, and reduced flows during peak emigration periods in December of below normal years as flows decrease from 931 to 819 cfs. Increases in flow in February are likely to have negligible impacts ammocoete rearing and emigration, as flows would only increase from 1,194 to 1,325 cfs. Alternative 2 Without TUCP With Systemwide VA monthly average flows will have negligible to minor impacts on ammocoete rearing and emigration of Pacific lamprey when compared to the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey ammocoete rearing and emigration as those described for Alternative 2 With TUCP Without VA.

Adult Upstream Migration and Holding

Adult Pacific lamprey typically enter freshwater from winter to early summer, but in the Klamath River adults have been reported to enter year-round (Petersen-Lewis 2009, Parker 2018). In general, adult Pacific lampreys have two life history types: ocean maturing where individuals likely spawn several weeks after entering freshwater, and stream maturing where individuals spend one year in freshwater prior to spawning (Clemens et al. 2013, Parker et al. 2019). In general, adult Pacific lamprey hold in interstitial spaces within large cobble and boulders and also in glides, runs, and riffles (Lampman 2011). Water temperature requirements for holding adult Pacific lampreys have not been fully evaluated, but adults have been observed in temperatures ranging from 60 to 84°F (Starcevich et al. 2014). The effects analysis period for adult upstream migration and holding in the Trinity River is year-round.

Potential Changes to Pacific Lamprey Adult Upstream Migration and Holding from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 2 to flows under the No Action Alternative. Differences in monthly average flows between Alternative 2 and the No Action Alternative with greater than 5% reduction would occur in February and March of wet years, November in above normal years, and December in below normal years.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (TableO.Trin_Atl2_1). The reduction in flows in winter would likely have minor adverse impacts on the adult upstream migration as flows would remain above 1,684 cfs in wet years in February and March, and 819 cfs in below normal years in December. Alternative 2 With TUCP Without VA monthly average flows will have minor adverse to negligible impacts on adult upstream migration and holding of Pacific lamprey when

compared to the No Action Alternative. Average water temperature in the Trinity River below Lewiston Dam in February and March of wet water years may increase slightly under Alternative 2 With TUCP Without VA compared to the No Action Alternative but would remain below the 50°F upper optimum limit recommended by USEPA (2001, as cited in Carter 2005) from Lewiston Dam to North Fork Trinity River in all water year types to support salmonids. Upper water temperature thresholds for Pacific lamprey upstream migration and holding would not be exceeded and the impacts of Alternative 2 With TUCP Without VA are likely negligible to both Pacific lamprey upstream migration and holding.

- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (TableO.Trin_Atl2_2). A greater then 5% increase in flow is expected only in February in above normal years. The reduction in flows could have minor adverse impacts on upstream migration, but flows would remain above 1,696 cfs. Increases in flow in February are likely to have negligible impacts on upstream migration and holding, as flows would only increase from 1,194 to 1,257 cfs. Alternative 2 Without TUCP Without VA monthly average flows will have negligible to minor impacts on adult upstream migration and holding of Pacific lamprey when compared to the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey upstream migration and holding as those described for Alternative 2 With TUCP Without VA.

- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (TableO.Trin_Atl2_3). The reduction in flows could have minor adverse impacts on upstream migration and holding habitat, but flows would remain above 1,673 cfs. Alternative 2 Without TUCP With Delta VA monthly average flows will have negligible to minor impacts on adult upstream migration and holding of Pacific lamprey when compared to the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey upstream migration and holding as those described for Alternative 2 With TUCP Without VA.

- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (TableO.Trin_Atl2_4). A greater then 5% increase in flow is expected only in February in above normal years. The reduction in flows could have minor adverse impacts on upstream migration, but flows would remain above 1,693 cfs. Increases in flow in February are likely to have negligible impacts on adult upstream migration and holding, as flows would only increase from 1,194 to 1,325 cfs. Alternative 2 Without TUCP With Systemwide VA monthly average flows will have negligible to minor impacts

on adult upstream migration and holding of Pacific lamprey when compared to the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on Pacific lamprey upstream migration and holding as those described for Alternative 2 With TUCP Without VA.

O.5.17.2 Sacramento River

Spawning and Egg Incubation

Pacific lamprey construct redds in shallow water (about 0.5 to 3.5 feet or 0.15 to 1 meter) gravel habitats in the upper river and spawning occurs from March through July with peak spawning typically occurring in early April (Gunckel et al. 2009; Schultz et al. 2014; Moyle et al. 2015). The eggs and pro-larvae incubate for about 1 to 1.5 months. Water flows and temperature impacts on eggs are March-August but are largely April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam for Alternative 2 compared to the No Action Alternative are a mix of increases and decreases (Table O-182 through Table O-189). Impacts on Pacific lamprey spawning are likely to be similarly mixed. Below Red Bluff Diversion Dam would see generally smaller changes in flow values compared to Keswick Dam, with greater increases largely from September through January, and larger decreases found May through August. Flows are expected to generally stay similar to those under the No Action Alternative for most water-year types and months. Below Keswick Dam, flows see more significant increases and decreases compared to the No Action Alternative relative to RBDD. Flow increases below Keswick Dam are generally October through March, while more decreases are found May through September. Overall flow changes at both locations are fairly small compared to the No Action Alternative except for Alternative 2 Without TUCP with systemwide VA, which is expected to increase flows in some water-year types for March and April, during peak spawning, while decreasing flows for many water year types May through August. Pacific lamprey spawning is likely to see mixed and minimal impacts from these flow changes. Compared to the No Action Alternative, most phases of Alternative 2 see very little flow change, and spawning would likely see no impact. Alternative 2 Without TUCP with systemwide VA sees the greatest flow changes compared to the No Action Alternative, but even under this regime flows at both locations are high enough in all months and water-year types that spawning and egg incubation should not see any adverse impacts, while flow increases are likely to have minimal benefits at best.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities for Pacific lamprey during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 295 for Keswick Dam and Table 296 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-112. Table O-112, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were zero month-water year type combinations (0% total combinations during the period, respectively) with favorable results at both Keswick Dam and RBDD (Table O-112). There were zero and one month-water year type combinations (0% and 4.0%, respectively) with unfavorable results at both Keswick Dam and RBDD, respectively. These results suggest that there would be negligible impacts of Alternative 2 With TUCP Without VA on Pacific lamprey spawning and egg incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results at both Keswick Dam and RBDD (Table O-112). These results suggest that there would be negligible water temperature-related impacts of Alternative 2 Without TUCP Without VA on Pacific lamprey spawning and egg incubation in the Sacramento River.
- Results for **Alternative 2 Without TUCP Delta VA** and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-112).

Overall, the four phases of Alternative 2 would have similar negligible impacts on water temperature conditions for Pacific lamprey spawning and egg incubation in the Sacramento River (Table O-112).

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have a negligible impact on spawning and egg incubation in the Sacramento River due to differences in water temperature.

Ammocoete Rearing and Emigration

Pacific lamprey larvae (ammocoetes), after emerging, drift downstream and burrow into fine sediments to rear. Ammocoetes select habitats that are often off-channel, with low flow velocity and shallow depths; therefore, they are vulnerable to stranding by reductions in water level. After 3 or more years, the ammocoetes metamorphose to the macropthalmia (juvenile) stage and migrate downstream to the Delta and ocean. Data from rotary screw trapping at sites on the mainstem Sacramento River indicate that emigration of Pacific lamprey peaks from early winter through early summer, but some emigration is observed year-round at both the RBDD and the GCID diversion dam (Hanni et al. 2006).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam for Alternative 2 are a largely unchanged compared to the No Action Alternative, with some small increases and decreases, except for Alternative 2 Without TUCP with systemwide VA (Table O-182 through Table O-189). Impacts on Pacific lamprey ammocoete rearing and emigration are likely to be mixed and slight. Flows under all forms of Alternative 2 are expected to remain high enough that ammocoete rearing, taking place in shallow sediments, should be largely unaffected. Flow increases could have slight benefits, and flow decreases could have slight adverse impacts, but these are expected to be minimal. Juvenile emigration is likely to see similar minimal impacts. Flows are expected to remain high enough during the outmigration period that survival should be unaffected. Overall impacts from Alternative 2 on ammocoete rearing and emigration are expected to be mixed but minimal.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific Lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 298 for Keswick Dam and Table 299 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-113. Table O-113, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results at both Keswick Dam and RBDD (Table O-113). These results suggest that there would be negligible water temperature-related impacts of Alternative 2 With TUCP Without VA on Pacific lamprey ammocoete rearing and emigration in the Sacramento River.
- Results for **Alternative 2 Without TUCP with VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VA** were identical to those for Alternative 2 With TUCP Without VA (Table O-113).

Overall, the four phases of Alternative 2 would have similar negligible impacts on water temperature conditions for Pacific lamprey ammocoete rearing and emigration in the Sacramento River (Table O-113).

Summary

Alternative 2 relative to the No Action Alternative is expected to have a minor beneficial to minor adverse impact on Pacific lamprey spawning and egg incubation in the Sacramento River due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have a negligible impact on Pacific lamprey spawning and egg incubation in the Sacramento River due to differences in water temperature.

O.5.17.3 Clear Creek

Spawning and Egg Incubation

Pacific lamprey usually spawn in Clear Creek from March through July, depending on water temperatures and local conditions such as seasonal flow regimes. The adults construct redds similar to steelhead redds, and eggs incubate for 11 to 30 days, depending on the water temperature, prior to hatching. Although the extent of spawning is unknown, the species spawns in Clear Creek as evidenced by ammocoetes routinely collected in the screw trap at RM 1.7. Impacts from water flows and temperature on eggs are likely felt March-August, and they likely peak in accordance with peak spawning April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in Clear Creek below Whiskeytown Dam under Alternative 2 would see a mix of increases and decreases compared to the No Action Alternative (Table O-218 through Table O-221). Impacts on Pacific lamprey spawning would likely be mostly beneficial across all versions of Alternative 2, as flows are increased for the peak spawning period. However, some adverse impacts could be felt in wet, above normal, and below normal years in February, since flows are projected to decrease compared to the No Action Alternative, which could affect the beginning of the spawning period; a similar adverse impact might be felt at the tail end of the spawning period in June and lasting through the summer months, which are all projected to see flow decreases.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities for Pacific lamprey during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 288 for Clear Creek below Whiskeytown Dam.

Results for the analysis are summarized in Table O-114. Table O-114, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were three month-water year type combinations (12.5% of total combinations during the

period) with favorable results and no combinations (0%) with unfavorable results below Whiskeytown Dam (Table O-114). These results suggest that there would be positive water temperature-related impacts of Alternative 2 With TUCP Without VA on Pacific lamprey spawning and egg incubation in Clear Creek.

- Under **Alternative 2 Without TUCP Without VA** for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were three month-water year type combinations (12.5% of total combinations during the period) with favorable results and no combination (0%) with unfavorable results below Whiskeytown Dam (Table O-114). These results suggest that there would be positive water temperature-related impacts of Alternative 2 Without TUCP Without VA on Pacific lamprey spawning and egg incubation in Clear Creek.
- Under **Alternative 2 Without TUCP Delta VA** for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were four month-water year type combinations (16.7% of total combinations during the period) with favorable results and one combination (4.0%) with unfavorable results below Whiskeytown Dam (Table O-114). These results suggest that there would be positive water temperature-related impacts of Alternative 2 Without TUCP Delta VA on Pacific lamprey spawning and egg incubation in Clear Creek.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were four month-water year type combinations (16.7% of total combinations during the period) with favorable results and no combinations (0%) with unfavorable results below Whiskeytown Dam (Table O-114). These results suggest that there would be positive water temperature-related impacts of Alternative 2 Without TUCP Systemwide VAs on Pacific lamprey spawning and egg incubation in Clear Creek.

Overall, the four phases of Alternative 2 would have similar positive impacts on water temperature conditions for Pacific lamprey spawning and egg incubation in Clear Creek (Table O-114).

<u>Summary</u>

Alternative 2 relative to the No Action Alternative is expected to have moderate beneficial to minor adverse impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have beneficial impacts on Pacific lamprey spawning and egg incubation in Clear creek due to differences in water temperature.

Ammocoete Rearing and Emigration

Pacific lamprey rearing takes place over a matter of years. Hatched embryos remain in the gravel for up to one more month as gill slits develop. The ammocoetes then spend three to seven years in soft sediments as filter feeders (USFWS 2019). Once ammocoetes have become juveniles, they begin to migrate towards the ocean in spring and possibly early summer. Impacts from water temperature and flow on larval and juveniles are year-round due to their prolonged rearing in their home waters, with spring and summer flows during migratory periods being important as well.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in Clear Creek below Whiskeytown Dam under Alternative 2 would see a mix of increases and decreases compared to the No Action Alternative (Table O-218 through Table O-221). Impacts on ammocoete rearing would likely be mixed, as ammocoetes spend a period of years maturing in sediments. Thus they would be subject to both positive and adverse impacts from the flow increases and decreases that are expected to come with all versions of Alternative 2. Juvenile emigration might see a slight overall positive impact from Alternative 2, as flows are expected to increase during the peak outmigration period over the winter and spring months, with the exception of February for wet, above normal and below normal water years.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific Lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 291 for Clear Creek below Whiskeytown Dam.

Results for the analysis are summarized in Table O-115. Table O-115, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-115). These results suggest that there would be negligible impacts of Alternative 2 With TUCP Without VA on Pacific lamprey ammocoete rearing and emigration in Clear Creek.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those of Alternative 2 With TUCP Without VA (Table O-115).

Overall, the four phases of Alternative 2 would have similar negligible impacts on water temperature conditions for Pacific lamprey ammocoete rearing and emigration in Clear Creek (Table O-115).

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey ammocoete rearing, and minor beneficial impacts on juvenile emigration due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration in Clear Creek due to differences in water temperature.

O.5.17.4 Lower American River

Spawning and Egg Incubation

Hannon and Deason (2008) documented Pacific lamprey spawning in the lower American River from early January to late May, with peak spawning typically occurring in early April. Redds are built in shallow water environments and eggs incubate for several weeks before larvae emerge. Water temperature and flow impacts on eggs are likely January-June, with peak impacts April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the lower American River at H Street and below Nimbus Dam under Alternative 2 will see a mixture of increases and decreases compared to the No Action Alternative (Table O-226 through Table O-233). Impacts on Pacific lamprey spawning would likely be mixed, with some months and water year types seeing flow increases and accompanying positive impacts, and others with flow decreases and accompanying negative impacts. Flow decreases in certain months of critically dry years could have a negative impact on spawning, while flow increases in certain months of dry and critically dry years would likely benefit Pacific lamprey spawning. Impacts during the peak months of April and May are likely to be more positive than negative but depend on water year type.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities during March through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 79 for Hazel Avenue and Table 80 for Watt Avenue.

Results for the analysis are summarized in Table O-116. Table O-116, as described in Section O.4.17.4.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities for Pacific lamprey spawning and egg incubation, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-116). There were three and one month-water year type combinations (12.0% and 4.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Without VA** for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities for Pacific lamprey spawning and egg incubation, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-116). There were two and zero month-water year type combinations (8.0% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

- Under **Alternative 2 Without TUCP Delta VA** for the for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities for Pacific lamprey spawning and egg incubation, there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-116). There were three and zero month-water year type combinations (12.0% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities for Pacific lamprey spawning and egg incubation, there were zero and one month-water year type combinations (0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-116). There were three and zero month-water year type combinations (12.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, the four phases of Alternative 2 would have mostly negative water temperature-related impacts to Pacific lamprey spawning and egg incubation in the lower American River.

Summary

Alternative 2 relative to the No Action Alternative is expected to have beneficial and negative impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have mostly negative impacts on Pacific lamprey spawning and egg incubation in the lower American River due to differences in water temperature.

Ammocoete Rearing and Emigration

Pacific lamprey ammocoetes rear in the lower American River for all or part of their three to seven freshwater residence. Larvae spend a month maturing to ammocoetes before leaving spawning areas to find suitable rearing habitat, usually shallow, off-channel areas with low flow velocity where they will spend the next several years filter-feeding and maturing to juvenile stage. Once juveniles, they will begin migrating towards the ocean. Data from rotary screw trapping in the nearby Feather River suggest that out-migration of Pacific lamprey generally occurs from early winter through early summer (Hanni et al. 2006), although some out-migration likely occurs year-round, as observed at sites on the mainstem Sacramento River (Hanni et al. 2006) and in other river systems (Moyle 2002).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the lower American River at H Street and below Nimbus Dam under Alternative 2 will see a mixture of increases and decreases compared to the No Action Alternative (Table O-226 through Table O-233). Impacts on Pacific lamprey ammocoete rearing would likely be mixed, as ammocoetes spend a period of several years maturing in sediment and would be present for both flow increases and decreases as months and water years change. Flow decreases in many months of critically dry years are likely to have adverse impacts on ammocoete rearing. Impacts on juvenile emigration would likely be similarly mixed, with

flow increases and decreases forecast for the outmigration period over winter and spring months. Flow decreases in winter months of critically dry years are likely to have adverse impacts on emigration, while increases in some spring months of the same years would likely have benefits.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 48 for Hazel Avenue and Table 50 for Watt Avenue.

Results for the analysis are summarized in Table O-117. Table O-117, as described in Section O.4.17.4.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 72°F upper limit for high survival and low occurrence of developmental abnormalities there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-117). There were zero and one month-water year type combinations (0% and 1.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Without VA** for the 72°F upper limit for high survival and low occurrence of developmental abnormalities there were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-117). There were one and zero month-water year type combinations (1.7% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Delta VA** for the 72°F upper limit for high survival and low occurrence of developmental abnormalities there were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-117). There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 72°F upper limit for high survival and low occurrence of developmental abnormalities there were zero and two month-water year type combinations (0.0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-117). There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

These results suggest that there would be negligible water temperature-related impacts to Pacific lamprey ammocoete rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to negative impacts on Pacific lamprey ammocoete rearing and emigration due to differences in flow. Alternative 2 relative to the No Action alternative is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration in the lower American River due to differences in water temperature.

O.5.17.5 Stanislaus River

Spawning and Egg Incubation

Hannon and Deason (2008) have documented Pacific lampreys spawning in the lower American River from early January to late May, with peak spawning typically in early April. Spawning time is presumably similar in the Stanislaus River. Eggs are laid in redds constructed in shallow water, and incubation takes several weeks. Effects from water flows and temperature on eggs are present February-June, likely with a peak April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Stanislaus River at the mouth and below Goodwin Dam under Alternative 2 will see a mix of increases and decreases depending on month and water year type (Table O-234 through Table O-241). The greatest impacts on Pacific lamprey spawning might be felt below Goodwin Dam, where flows see decreases for most water year types during the period of peak spawning in April and May, which could have an adverse impact. However, some flow increases in February could have a slight benefit to the beginning of the spawning period. Impacts would likely not be as strong on spawning near the mouth, where changes in flow are predicted to be smaller in scale than the changes below Goodwin Dam. Overall impacts of flow changes on Pacific lamprey spawning and egg incubation are likely to be mixed, but slightly more adverse than beneficial.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities during April through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 62 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-118. Table O-118, as described in Section O.4.17.5, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities of Pacific lamprey, there were no month-water year type combinations (0.0%) with favorable or unfavorable results at both Orange Blossom Bridge (Table O-118).

- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-118).

Overall, the four phases of Alternative 2 would have negligible water temperature related impacts on Pacific lamprey spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor adverse to minor beneficial impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey spawning and egg incubation in the Stanislaus River due to differences in water temperature.

Ammocoete Rearing and Emigration

Pacific lamprey ammocoetes are expected to rear in the Stanislaus River for all or part of their 3- to 7-year freshwater residence. Larvae usually spend a month in their spawning areas before becoming ammocoetes and moving to rearing habitat in shallow, off-channel areas. After several years, they become juveniles and migrate out to the ocean. Data from rotary screw trapping in the nearby Mokelumne and Tuolumne Rivers suggest that out-migration of Pacific lamprey generally occurs from early winter through early summer (Hanni et al. 2006). Catches of juvenile Pacific lampreys in trawl surveys of the mainstem San Joaquin River, near the mouth of the Stanislaus River at Mossdale, occurred during winter and spring. Some out-migration likely occurs year-round, as observed at sites on the mainstem Sacramento River (Hanni et al. 2006).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Stanislaus River at the mouth and below Goodwin Dam under Alternative 2 will see a mix of increases and decreases depending on month and water year type (Table O-234 through Table O-241). Impacts on Pacific lamprey ammocoete rearing are likely to be mixed, as flow decreases in wetter years might be balanced by flow increases in some months of drier years. As ammocoete rearing takes place over several years, ammocoetes would experience both flow increases and decreases under Alternative 2. Impacts on juvenile outmigration are likely to be similarly mixed, with some months during the winter-early summer outmigration period having flow increases and likely beneficial impacts, and others having flow decreases and accompanying adverse impacts.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 63 for Orange Blossom Bridge and Table 64 for the Stanislaus River above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-119. Table O-119, as described in Section O.4.17.5, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific lamprey, there were no month-water year type combinations (0.0%) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-119). There were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-119).

Overall, the four phases of Alternative 2 would have negligible water temperature related impacts on Pacific lamprey ammocoete rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey ammocoete rearing and emigration due to differences in flow. Alternative 2 and the No Action Alternative are expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration in the Stanislaus River due to differences in water temperature.

O.5.17.6 San Joaquin River

Ammocoete Rearing and Emigration

Pacific lamprey larvae, once emerged, spend roughly a month in spawning areas before becoming ammocoetes and moving to rearing habitat in shallow, off-channel waters with low flow velocity, where they will spend the following several years (roughly three to seven) maturing to the juvenile stage. Once individuals mature to juveniles, they begin a migration towards the ocean. Midwater trawl surveys in the San Joaquin River suggest that peak ammocoete out-migration occurs in January and February (Hanni et al. 2006). Ammocoetes are vulnerable to habitat loss due to the nature of their rearing habitat.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 models predict that flows for the San Joaquin River at Vernalis under Alternative 2 would see small changes, both positive and negative depending on month and water year type, compared to the No Action Alternative (Table O-242 through Table O-245). These flow changes are expected to be rather small, so impacts on ammocoete rearing in Pacific lamprey, which lasts for a period of several years, are likely to be minimal. Increased flows during summer months of critically dry years would likely be beneficial, but overall Alternative 2 is not likely to have

much impact on ammocoete rearing. Flow changes for winter and spring months are small to negligible, so impacts on juvenile emigration would likely be the same.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on Pacific lamprey in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

Summary

Alternative 2 relative to the No Action Alternative are expected to have minor beneficial impacts on Pacific lamprey ammocoete rearing and negligible impacts on juvenile emigration in the San Joaquin River due to differences in flow. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

O.5.17.7 Bay-Delta

Some Pacific lamprey ammocoetes likely spend part of their extended (3 to 7 years) freshwater residence rearing in the Delta, particularly in the upstream, freshwater portions (California Department of Water Resources et al. 2013). Ammocoetes are present year-round in all of the regions (California Department of Water Resources et al. 2013). Data from the Fall Midwater Trawl Survey in the lower Sacramento and San Joaquin Rivers and Suisun Bay suggest that peak out-migration of Pacific lamprey through the Delta coincides with high-flow events from fall through spring (Hanni et al. 2006).Water temperature and flows affect resident ammocoetes year round and migrating juveniles fall-spring. Duration of estuarine adult migration and holding in the San Francisco Estuary is poorly understood, but some evidence suggests they may migrate as early as the fall and throughout the spawning season until late June (Moyle et al. 2015).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Sacramento River at Rio Vista under Alternative 2 would see a mix of increases and decreases compared to the No Action Alternative (Table O-214 through Table O-217). For impacts in the southern Delta, see the San Joaquin River section above, which discusses flow at Vernalis. Under Alternative 2, flows at Rio Vista are expected to be a mixture of increases and decreases compared to the No Action Alternative. Alternative 2 Without TUCP with systemwide VA is the exception, with flows mostly increasing in April and May. Impacts on Pacific lamprey ammocoete rearing are expected to be negligible, as flows are likely adequate for rearing in the sandy substrates. Changes in flows under the four phases of Alternative 2 are likely to have minor beneficial impact on juvenile emigration and adult migration in critically dry water year types, as flows are expected to increase in the spring and summer.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial impacts on Pacific lamprey adult migration and juvenile emigration in critically dry water year types due to differences in flow. Impacts on ammocoete rearing are expected to be negligible.

Potential Changes to Entrainment of Pacific Lamprey

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have impacts on Pacific lamprey entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for Pacific lamprey include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of Pacific lamprey of Alternative 2 With TUCP Without VA compared to the No Action Alternative at CVP Jones Pumping Plant were similar all water year types (Tables O-120 and O-121). At the CVP Jones Pumping Plant predicted average monthly loss was up to 2% greater for December through September of critically dry water year types and as low as -2% March through August of dry water years (Table O-121). Historical loss of Pacific lamprey is infrequent; this is a driver of low values of predicted loss.
- **Alternative 2 Without TUCP Without VA**
    - Predictions from the salvage density model for Pacific lamprey include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of Pacific lamprey of Alternative 2 Without TUCP Without VA compared to the No Action Alternative at CVP Jones Pumping Plant were similar all water year types, except December through September of critically dry water years when it was greater (Tables O-120 and O-121). At the CVP Jones Pumping Plant predicted average monthly loss was up to 11% greater for December through September of critically dry water year types and as low as -2% March through August of dry water years (Table O-121). Historical loss of Pacific lamprey is infrequent; this is a driver of low values of predicted loss.

- **Alternative 2 Without TUCP Delta VA**
    - Predictions from the salvage density model for Pacific lamprey include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of Pacific lamprey of Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at CVP Jones Pumping Plant were lower below normal, above normal, and dry water year types (August through , except December through September of critically dry water years when it was greater (Tables O-120 and O-121). At the CVP Jones Pumping Plant predicted average monthly loss was up to 11% greater for December through September of critically dry water year types and as low as -2% March through August of dry water years (Table O-121). Historical loss of Pacific lamprey is infrequent; this is a driver of low values of predicted loss.
- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for Pacific lamprey include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of Pacific lamprey of Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at the CVP Jones Pumping Plant were greater critically dry year types and similar or lower all other water year types (Tables O-120 and O-121). At the CVP Jones Pumping Plant predicted average monthly loss was up to 9% greater for December through August of critically dry water year types and as low as -18 % for January through October of below normal water year types (Table O-121). Historical loss of Pacific lamprey is infrequent; this is a driver of low values of predicted loss.

Summary

Differences in exports between the four phases of Alternative 2 and the No Action Alternative are expected to have generally beneficial impacts on the entrainment of Pacific lamprey at CVP Jones Pumping Plant, but the species is infrequent at the facility. No impacts at the SWP Banks Pumping Plant are expected.

O.5.18 Western River Lamprey

O.5.18.1 Sacramento River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April-May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam for Alternative 2 compared to the No Action Alternative are a mix of increases and decreases (Table O-182 through Table O-189). Impacts on western river lamprey spawning are likely to be similarly mixed. Below Red Bluff Diversion Dam would see generally smaller changes in flow values compared to Keswick Dam, with greater increases largely from October through April, and larger decreases found May through September. Flows are expected to generally stay similar to those under the No Action Alternative for most water-year types and months. Below Keswick Dam, flows see more significant increases and decreases compared to the No Action Alternative relative to RBDD. Flow increases below Keswick Dam are generally October through April, while more decreases are found May through September. Overall flow changes at both locations are fairly small compared to the No Action Alternative except for Alternative 2 Without TUCP with systemwide VA, which is expected to increase flows in some water-year types for March and April, during peak spawning, while decreasing flows for many water-year types May through September. Western river lamprey spawning is likely to see mixed minimal impacts from these flow changes. Compared to the No Action Alternative, most increments of Alternative 2 see very little flow change, and spawning would likely see no impact. Alternative 2 Without TUCP with systemwide VA sees the greatest flow changes compared to the No Action Alternative, but even under this regime flows at both locations are high enough in all months and water-year types that spawning and egg incubation should not see any adverse impacts, while flow increases are likely to have minimal benefits at best.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 301 for Keswick Dam and Table 302 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-122. Table O-122, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities, there were three and zero month-water year type combinations (10.0% and 0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-122). There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. These results suggest that there would be positive water temperature-related impacts of Alternative 2 With TUCP Without VA on western river lamprey spawning and egg incubation in the Sacramento River.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA, and Alternative 2 without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP without VA (Table O-122).

Overall, the four phases of Alternative 2 would have similar positive impacts on water temperature conditions for western river lamprey spawning and egg incubation in the Sacramento River (Table O-122).

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on western river lamprey spawning and egg incubation due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have beneficial impacts on western river lamprey spawning and egg incubation in the Sacramento River due to differences in water temperature.

Ammocoete Rearing and Emigration

Western river lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam for Alternative 2 are a largely unchanged compared to the No Action Alternative, with some small increases and decreases, except for Alternative 2 Without TUCP with systemwide VA (Table O-182 through Table O-189). Impacts on western river lamprey ammocoete rearing and emigration are likely to be mixed and slight. Flows under all forms of Alternative 2 are expected to remain high enough that ammocoete rearing, taking place in

shallow sediments, should be largely unaffected. Flow increases could have slight benefits, and flow decreases could have slight adverse impacts, but these are expected to be minimal due to robust flow values and to the fact that changes relative to the No Action Alternative are minor. Juvenile emigration is likely to see similar minimal impacts. Flows are expected to remain high enough during the outmigration period that survival should be unaffected. Overall impacts from Alternative 2 on western river lamprey ammocoete rearing and emigration are expected to be mixed but minimal.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities for western river lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 304 for Keswick Dam and Table 305 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-123. Table O-123, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results at both Keswick Dam and RBDD (Table O-123). These results suggest that there would be negligible water temperature-related impacts of Alternative 2 With TUCP Without VA on western river lamprey ammocoete rearing and emigration in the Sacramento River.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-123).

Overall, the four phases of Alternative 2 would have similar negligible impacts on water temperature conditions for western river lamprey ammocoete rearing and emigration in the Sacramento River (Table O-123).

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on western river lamprey ammocoete rearing and emigration due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on western river lamprey ammocoete rearing and emigration in the Sacramento River due to differences in water temperature.

O.5.18.2 Lower American River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April–May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the lower American River at H Street and below Nimbus Dam for Alternative 2 are a mix of increases and decreases compared to the No Action Alternative (Table O-226 through Table O-233). Impacts on western river lamprey spawning are likely mixed as well. The greatest impacts on spawning might be in critically dry years, which see flow increases in March, April, and June for all versions of Alternative 2 except with TUCP Without VA. Increased flows during these months in critically dry years would likely be beneficial to lamprey spawning, which takes place March through August. However, these increases would come with flow decreases in May, which could have an adverse impact on spawning in a peak month for western river lamprey. Flows also decrease in some summer months (depending on water year type), which could have an adverse impact on spawning towards the end of the spawning season. Overall impacts on spawning are likely to be mixed, with flow increases providing benefits in some months and negative impacts from flow decreases in others.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in western river lamprey during February through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 83 for Hazel Avenue and Table 84 for Watt Avenue.

Results for the analysis are summarized in Table O-124. Table O-124, as described in Section O.4.18.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in western river lamprey spawning and egg incubation, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-124). There were four and one month-water year type combinations (13.3% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

- Under **Alternative 2 Without TUCP Without VA** for the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in western river lamprey spawning and egg incubation, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-124). There were two and zero month-water year type combinations (6.7% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Delta VA** for the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in western river lamprey spawning and egg incubation, there were zero and one month-water year type combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-124). There were four and zero month-water year type combinations (13.3% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in western river lamprey spawning and egg incubation, there were zero and one month-water year type combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-124). There were three and one month-water year type combinations (10.0% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, the four phases of Alternative 2 would have mostly negative water temperature-related impacts to western river lamprey spawning and egg incubation lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on western river lamprey spawning and egg incubation due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have adverse impacts on western river lamprey spawning and egg incubation in the lower American River due to differences in water temperature.

Ammocoete Rearing and Emigration

Western River lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and water temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the lower American River at H Street and below Nimbus Dam for Alternative 2 are a mix of increases and decreases compared to the No Action Alternative (Table O-226 through Table O-233). Impacts on western river lamprey ammocoete rearing are likely to be mixed as well. As rearing takes place over a period of several years, ammocoetes would experience the range of impacts from changes in flow, likely over multiple water year types. The greatest impacts on rearing would likely be in critically dry years, which see increases in a handful of months but decreases during some of the driest months, which could have an adverse impact on ammocoete success and survival. Effects of flow changes on western river lamprey juvenile emigration are likely to be mixed. Flows during the winter-early summer emigration period are largely unchanged compared to the No Action Alternative, with the exception of critically dry years which see a range of increases and decreases during this time. Flows are higher in these years later in the emigration window, and lower in the first few months. Overall impacts on emigration are likely to be mixed.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities in western river lamprey year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 85 for Hazel Avenue and Table 86 for Watt Avenue.

Results for the analysis are summarized in Table O-125. Table O-125, as described in Section O.4.18.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 72°F upper limit for high survival and low occurrence of developmental abnormalities in western river lamprey ammocoete rearing and emigration, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-125). There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those presented for Alternative 2 With TUCP Without VA (Table O-125).

These results suggest that the Alternative 2 combinations would have negligible water temperature-related impacts to western river lamprey ammocoete rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on western river lamprey ammocoete rearing and emigration due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on western river lamprey ammocoete rearing and emigration in the lower American River due to differences in water temperature.

O.5.18.3 Stanislaus River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April-May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Stanislaus River at the mouth and below Goodwin Dam for Alternative 2 are a mix of increases and decreases compared to the No Action Alternative (Table O-234 through Table O-241). Effects on western river lamprey spawning are likely to be mixed as well. Flow decreases in April for most water year types would likely have as adverse impact on spawning, as this would be during the peak spawning period. Wet, above normal, and below normal years see flow decreases in June, which would also have an adverse impact; these are mostly smaller than the decreases in April. Increases in flows during June, July, and August in critically dry years would be beneficial to spawning, as this would likely increase spawning success and egg survival in months where flows are among the lowest under the No Action Alternative. Overall impacts on spawning are mixed depending on water year type, but outside of critically dry years these impacts are likely more negative than positive.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in western river lamprey during February through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 65 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-126. Table O-126, as described in Section O.4.18.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities of western river lamprey, there were zero month-water year type combinations (0.0%) with favorable results and one combination (3.3%) with unfavorable results at both Orange Blossom Bridge (Table O-126).
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-126).

Overall, the four phases of Alternative 2 would have negligible water temperature related impacts on western river lamprey spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to moderate adverse impacts on western river lamprey spawning and egg incubation due to differences in flow. Alternative 2 and the No Action Alternative is expected to have negligible impacts on western river lamprey spawning and egg incubation in the Stanislaus River due to differences in water temperature.

Ammocoete Rearing and Emigration

Western river lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Stanislaus River at the mouth and below Goodwin Dam for Alternative 2 are a mix of increases and decreases compared to the No Action Alternative (Table O-234 through Table O-241). Effects on western river lamprey ammocoete rearing are likely to be mixed as well. Flow increases in summer months of critically dry would likely have a positive impact on rearing, increasing ammocoete survival, but decreases in some water year types for spring months would likely have an adverse impact. Effects overall are likely to be mixed positive and negative, as rearing takes place over several years and ammococtes would experience the impacts of flow increases and decreases. Effects of flow changes on western river lamprey juvenile emigration are also likely mixed. Flows mostly increase in February, which is within the primary outmigration period, but decreases in some water year types March-June could have negative impacts on the second half of this period.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities in western river lamprey year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 66 for Orange Blossom Bridge and Table 67 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-127. Table O-127, as described in Section O.4.18.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 72°F upper limit for high survival and low occurrence of developmental abnormalities for western river lamprey, there were no month-water year type combinations (0.0%) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-127). There were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-127).

Overall, the four phases of Alternative 2 would have negligible water temperature related impacts on western river lamprey ammocoete rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Alternative 2 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on western river lamprey ammocoete rearing and emigration due to differences in flow. Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on western River lamprey ammocoete rearing and emigration in the Stanislaus River due to differences in water temperature.

O.5.18.4 San Joaquin River

Ammocoete Rearing and Emigration

Western river lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 estimates for monthly flows in the San Joaquin River at Vernalis for Alternative 2 are largely unchanged compared to the No Action Alternative (Table O-242 through Table O-245). Impacts on western river lamprey ammocoete rearing are likely to be slight, but beneficial. The greatest change in flows is during summer months in critically dry years, which would be beneficial to ammocoete rearing and survival when conditions are at their most unfavorable. Otherwise, flows are almost unchanged compared to the No Action Alternative, and are expected to have little impact on ammocoete rearing. Impacts on juvenile emigration are also negligible, as flows are basically unchanged for all water year types during the outmigration period of winter through early summer.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on western river lamprey in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 2 relative to the No Action Alternative is expected to have negligible to minor beneficial impacts on western river lamprey ammocoete rearing and emigration in the San Joaquin River due to differences in flow. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.5.18.5 Bay-Delta

The Sacramento and San Joaquin River basins are at the southern edge of the range for western river lamprey (Moyle et al. 2009). While their population abundance is poorly understood, they are frequently caught in the Delta Juvenile Fish Monitoring Program in the winter months through trawls at Sherwood Harbor, Mossdale, and Chipps Island (Interagency Ecological Program et al. 2022). Ammocoetes spend an unknown amount of time as ammocoetes (likely 3-5 years) in silt-sand backwater eddies and have been documented during dredging studies in the Delta (Lamprey Technical Workgroup 2021; Moyle et al. 2015). Adults typically start their migration back into their natal habitats in the fall.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Bay-Delta under the four phases of Alternative 2 would see a mix of increases and decreases compared to the No Action Alternative (Table O-214 through Table O-217). For impacts in the southern Delta, see the San Joaquin River section above, which discusses flow at Vernalis. Under the four phases of Alternative 2, flows at Rio Vista are expected to be a mixture of increases and decreases compared to the No Action Alternative. Alternative 2 Without TUCP with systemwide VA is the exception, with flows mostly increasing in April and May. Similar to Pacific lamprey, impacts on western river lamprey ammocoete rearing are expected to be negligible. Increased flow at Rio Vista in spring and summer of critically dry years could have a minor beneficial impact on juvenile emigration.

Impacts on adult migration are likely to be negligible, with no larger trend in flows during the fall of critically dry water years.

Summary

Alternative 2 relative to the No Action Alternative are expected to have minor beneficial impacts on western river lamprey juvenile emigration in critically dry water year types and negligible impacts on adult migration due to differences in flow. Impacts on ammocoete rearing are expected to be negligible.

Potential Changes to Entrainment of Western River Lamprey

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have impacts on western river lamprey entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for western river lamprey include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of western river lamprey of Alternative 2 With TUCP Without VA compared to the No Action Alternative at CVP Jones Pumping Plant were similar most water year types, except in dry water year types when no fish are expected and February through March of critically dry water years when it would decrease up to 5% (Table O-128 and Table O-129). Historic loss of western river lamprey is infrequent; this is a driver of low values of predicted loss.
- **Alternative 2 Without TUCP Without VA**
    - Predictions from the salvage density model for western river lamprey include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of western river lamprey of Alternative 2 Without TUCP Without VA compared to the No Action Alternative at CVP Jones Pumping Plant were similar most water year types, except in dry water year types when no fish are expected and February through March of critically dry water years when it would decrease up to 6% (Table O-128 and Table O-129).

- **Alternative 2 Without TUCP Delta VA**
    - Predictions from the salvage density model for western river lamprey include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of western river lamprey of Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at CVP Jones Pumping Plant were similar most water year types, except in dry water year types when no fish are expected and February through March of critically dry water years when it would decrease up to 9% (Table O-128 and Table O-129).
- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for western river lamprey include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of western river lamprey of Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at the CVP Jones Pumping Plant were similar most water year types, except in dry water year types when no fish are expected and February through March of critically dry water years when it would decrease up to 9% (Table O-128 and Table O-129).

Summary

Differences in exports between the four phases of Alternative 2 and the No Action Alternative are expected to have generally beneficial impacts on the entrainment of Western river lamprey at CVP Jones Pumping Plant during critically dry water years, but the species is infrequent at the facility. No impacts at the SWP Banks Pumping Plant are expected.

O.5.19 Striped Bass

O.5.19.1 Sacramento River

Spawning and Egg Incubation

It is believed that striped bass do not spawn or rear in the Sacramento River upstream of RBDD (Tehama-Colusa Canal Authority 2008). Most spawning in the Sacramento River occurs in the lower river between Colusa and the confluence of the Sacramento and Feather Rivers (Moyle 2002). About one-half to two-thirds of adults spawn in the Sacramento River and the remainder spawn in the Delta (Leet et al. 2001). After spawning, most adult striped bass move downstream into brackish and salt water for summer and fall (Moyle 2002).

Eggs are free-floating and negatively buoyant and hatch as they drift downstream, with larvae occurring in shallow and open waters of the lower reaches of the Sacramento and San Joaquin rivers, the Delta, Suisun Bay, Montezuma Slough, and Carquinez Strait. According to Hassler (1988), the distribution of larvae in the estuary depends on river flow. In low-flow years, all eggs and larvae are found in the Delta, while in high-flow years, the majority of eggs and larvae are transported downstream into Suisun Bay.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows at Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤6%) increase or decrease is estimated April through June (Alternative 2 With TUCP with Systemwide VA at Red Bluff Diversion Dam). Generally, increases are expected to occur in April and decreases June. However, changes are expected to be minor and suggests habitat will largely remain similar to the No Action Alternative (Table O-186 through Table O-189, Table O-190 through Table O-193, and Table O-194 through Table O-197).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 68°F optimal water temperature range for spawning, embryo incubation and initial rearing for striped bass during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 317 for Butte City.

Results for the analysis are summarized in Table O-130. Table O-130, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 59°F to 68°F optimal water temperature range, there were two month-water year type combinations (13.3% of total combinations during the period) with favorable results at Butte City (Table O-130). There were no combinations (0%) with unfavorable results at Butte City. These results suggest that there would be positive impacts from Alternative 2 With TUCP Without VA on striped bass spawning and egg incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 59°F to 68°F optimal water temperature range, there were three month-water year type combinations (20.0% of total combinations during the period) with favorable results at Butte City (Table O-130). There were no combinations (0%) with unfavorable results at Butte City. These results suggest that there would be positive impacts from Alternative 2 Without TUCP Without VA on striped bass spawning and egg incubation in the Sacramento River.
- Under **Alternative 2 Without TUCP Delta VA** for the 59°F to 68°F optimal water temperature range, there was one month-water year type combination (6.7% of total combinations during the period) with favorable results at Butte City (Table O-130). These results suggest that there would be positive impacts from Alternative 2 Without TUCP Delta VA on striped bass spawning and egg incubation in the Sacramento River.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 59°F to 68°F optimal water temperature range, there were two month-water year type combinations (13.3% of total combinations during the period) with favorable results at Butte City (Table O-130). There was one combination (6.7%) with unfavorable results at Butte City. These results suggest that there would be positive water temperature-related impacts and negligible negative impacts from Alternative 2 Without TUCP Systemwide VA on striped bass spawning and egg incubation in the Sacramento River.

Overall, the four phases of Alternative 2 would have similar positive impacts on water temperature conditions for striped bass spawning and egg incubation in the Sacramento River (Table O-130).

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative for CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will largely remain similar with adverse impacts in June. The water temperature analysis indicates that there would be beneficial effects of all phases of Alternative 2 on striped bass spawning and egg incubation. Overall, these results suggest that there would be minor adverse impacts from flow on spawning habitat and generally beneficial water temperature-related impacts on striped bass spawning and egg incubation in the Sacramento River under Alternative 2.

Larval and Juvenile Rearing and Emigration

During this early period the embryos and larvae in the Sacramento River are carried into the Delta and Suisun Bay (Moyle 2002). YOY striped bass distribute themselves in accordance with the estuarine salinity gradient (Kimmerer 2002a; Feyrer et al. 2007), indicating that salinity is a major factor affecting their habitat use and geographic distributions. Kimmerer (2002a) found that distributions of fish species, including striped bass, substantially overlapped with the low-salinity zone. Older individuals are increasingly flexible about their distribution relative to salinity (Moyle 2002). Statistically significant correlations between indices of age-0 abundance or survival in the San Francisco Estuary and Delta have been found with Delta outflow (which can be approximated by X2, the distance in km from the Golden Gate Bridge at which bottom salinity is 2 psu) (e.g., Kimmerer et al. 2009; Mac Nally et al. 2010), with evidence for greater extent of habitat as the mechanism (Kimmerer et al. 2009). However, subsequent density-dependent survival after the first summer dampens the effects of flow on subsequent recruitment (Kimmerer et al. 2000).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows at Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤5%) increase and/or decrease is estimated most months except June (Alternative 2 With TUCP with Systemwide VA at Red Bluff Diversion Dam) when a slight (5%) decrease occurs. This suggests habitat will largely remain similar to the No Action Alternative (Table O-186 through Table O-189, Table O-190 through Table O-193, and Table O-194 through Table O-197).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F range of optimal temperatures for larvae, fry, and juvenile rearing and emigration year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 318 for Butte City.

Results for the analysis are summarized in Table O-131. Table O-131, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 61°F to 71°F optimal water temperature range for larvae, fry, and juvenile rearing and emigration, there were zero month-water year type combination (0% of total combinations during the period) with favorable results and two combinations (3.3%) with unfavorable results at Butte City (Table O-131). These results suggest that there would be negligible negative water temperature-related impacts from Alternative 2 With TUCP Without VA on striped bass larvae, fry, and juvenile rearing and emigration in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 61°F to 71°F optimal water temperature range for larvae, fry, and juvenile rearing and emigration, there were no month-water year type combinations (0.0% of total combinations during the period) with favorable results at Butte City (Table O-131). There was one combination (1.7%) with unfavorable results at Butte City. These results suggest that there would be negligible negative water temperature-related effects of Alternative 2 Without TUCP Without VA on striped bass larvae, fry, and juvenile rearing and emigration in the Sacramento River.
- Results for **Alternative 2 without TUCP Delta TUCP VA** and **Alternative 2 without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-131).

Overall, the four phases of Alternative 2 would have negligible negative impacts on water temperature conditions for striped bass larvae, fry, and juvenile rearing and emigration in the Sacramento River (Table O-131).

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative for CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will largely remain similar, except June under Alternative 2 With TUCP with Systemwide VA which had slight adverse impact. The water temperature analysis indicates that all phases of Alternative 2 would cause negligible negative impacts to striped bass larvae, fry, and juvenile rearing and emigration. Overall, these results suggest that there would be minor adverse flow impacts and minor adverse water temperature impacts on striped bass larvae, fry, and juvenile rearing and emigration in the Sacramento River under Alternative 2.

O.5.19.2 Lower American River

Adults

Striped bass are present in the lower American River throughout the year, with the greatest abundance in summer (Surface Water Resources 2001). Striped bass are distributed from the confluence with the Sacramento River to Nimbus Dam (Moyle 2002), and they provide a locally important sportfishing resource.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam, and at H Street indicate that minor (≤ 5%) increase and/or decrease is estimated for most months except April (Nimbus Dam and H street) under Alternative 2 With TUCP with Systemwide VA when a slight (6-7%) increase occurs (Table O-226 through Table O-229 and Table O-230 through Table O-233). These results suggest flows will remain similar most months of the year, except April which would have slight increase in flow.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 77°F stress initiation value for adult striped bass year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 93 for Hazel Avenue and Table 94 for Watt Avenue.

Results for the analysis are summarized in Table O-132. Table O-132, as described in Section O.4.19.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- For the 77°F stress initiation water temperature value for adult striped bass under **Alternative 2 With TUCP Without VA**, there were zero month-water combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-132). There were also zero month-water combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those presented with Alternative 2 With TUCP Without VA (Table O-132).

These results suggest that the Alternative 2 combinations would have negligible water temperature-related impacts on adult striped bass in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will remain largely similar, except one to two months out of the year when slight beneficial and/or adverse impacts are expected. The optimal water temperature range modeling estimates indicate there are no combinations with beneficial or adverse impacts at Butte City. These results suggest that there would be negligible impacts from flow on adult habitat extent and negligible water temperature-related impacts on adult striped bass in the lower American River at Hazel Avenue and Watt Avenue under Alternative 2.

Juvenile Rearing

Although the occurrence of spawning in the lower American River is uncertain, the river is believed to serve as a nursery area for YOY and subadult striped bass (Surface Water Resources 2001). Striped bass are distributed from the confluence with the Sacramento River to Nimbus Dam (Moyle 2002), and they provide a locally important sportfishing resource.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam, and at H Street indicate that a minor (≤ 5%) increase and/or decrease is estimated for most months except April (Nimbus Dam and H street) under Alternative 2 With TUCP with Systemwide VA when a slight (6-7%) increase occurs(Table O-226 through Table O-229 and Table O-230 through Table O-233). These results suggest flows will remain similar most months of the year, except April which would have slight increases in flow.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 95 for Hazel Avenue and Table 96 for Watt Avenue.

Results for the analysis are summarized in Table O-133. Table O-133, as described in Section O.4.19.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 61°F to 71°F optimal range for juvenile striped bass, there were zero month-water combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-133). There were one and five month-water combinations (1.7% and 8.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

- Under **Alternative 2 Without TUCP Without VA** for the 61°F to 71°F optimal range for juvenile striped bass, there were zero and two month-water combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-133). There were three and four month-water combinations (5.0% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Delta VA** for the 61°F to 71°F optimal range for juvenile striped bass, there were zero and two month-water combinations (0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-133). There were two month-water combinations (3.3%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 61°F to 71°F optimal range for juvenile striped bass, there were 0 month-water combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-133). There were one and four month-water combinations (1.7% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP Delta VA would have similar negligible negative water temperature-related impacts on striped bass juvenile rearing in the lower American River. Effects of Alternative 2 Without TUCP Systemwide VAs would be more negative than the other phases.

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will largely remain similar, except one to two months out of the year with slight beneficial and/or adverse impacts. The optimal water temperature range modeling estimates indicate adverse effects at Hazel Avenue and Watt Avenue in the lower American River under most phases of Alternative 2. Overall, these results suggest negligible impacts from flow, as they would be generally similar to the No Action Alternative, and minor adverse water temperature impacts on striped bass juvenile rearing in the lower American River at Hazel Avenue and Watt Avenue under Alternative 2.

O.5.19.3 Stanislaus River

Spawning and Egg Incubation

Striped bass have been observed at Lovers Leap and at Knights Ferry from May through the end of June. These adult fish were observed in all habitats (U.S. Fish and Wildlife Service 2002; Kennedy and Cannon 2005). The distribution of striped bass in the Stanislaus River is thought to be limited to downstream of the historic Knights Ferry Bridge due to a set of falls about three feet tall in the area (U.S. Fish and Wildlife Service 2002).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows vary between minor (≤ 1%) to slight (≤ 8%) decreases estimated at the Stanislaus River April through June (Table O-234 through Table O-237 and Table O-238 through Table O-241). At Goodwin Dam, slight (up to 8%) decreases are expected. At the mouth, on average minor (up to 3%) decreases are expected. These results suggest averaged flows may be anticipated to have minor adverse impacts on striped bass.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 59°F- 68°F optimal range of water temperature for spawning, embryo incubation, and initial rearing of striped bass for April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 70 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-134. Table O-134, as described in Section O.4.19.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 59°F- 68°F optimal range of water temperature for spawning, embryo incubation, and initial rearing of striped bass, there was one month-water year type combination (6.7%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-134).
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-134).

Overall, the four phases of Alternative 2 would have minor positive water temperature-related impacts on striped bass spawning, embryo incubation, and initial rearing in the Stanislaus River at Orange Blossom Bridge.

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests flows may have minor adverse impacts on striped bass. The optimal water temperature range modeling estimates indicate a 6.7% month-water year type combination with beneficial results and no combinations with adverse results at Orange Blossom Bridge. Overall, these results suggest minor adverse flow and minor beneficial water temperature-related impacts to striped bass spawning and egg incubation in the Stanislaus River at Goodwin Dam and the mouth under all phases of Alternative 2.

Larval and Juvenile Rearing and Emigration

Striped bass have been observed at Lovers Leap and at Knights Ferry from May through the end of June. The distribution of striped bass in the Stanislaus River is thought to be limited to downstream of the historic Knights Ferry Bridge due to a set of falls about 3 feet tall in the area (U.S. Fish and Wildlife Service 2002).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows vary between minor (≤1%) to slight (≤ 13%) increases and minor (≤ 1%) to slight (≤ 8%) decreases estimated at Goodwin Dam and mouth of the Stanislaus River; increases above 5% in averaged flow are expected four and two of the months at Goodwin Dam and the mouth (respectively) and decreases above 5% one month out of the year at Goodwin Dam (Table O-234 through Table O-237 and Table O-238 through Table O-241). At Goodwin Dam, slight (≤ 13%) increases are expected an average of 4 months (December, February, July, and August) and a slight (8%) decrease in April; the remaining five months would generally have minor (≤ 5%) increases and decreases in flow. At the mouth, on average slight (≤ 10%) increases are expected in August and September; the remaining 10 months, increases and decreases are minor (≤ 4%). These results suggest averaged flows may be anticipated to have generally beneficial impacts on striped bass.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 71 for Orange Blossom Bridge and Table 72 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-135. Table O-135, as described in Section O.4.19.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing there were zero and two month-water year type combinations (0.0% and 3.3%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-135). There were zero and three month-water year type combinations (0.0% and 5.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.
- Under **Alternative 2 Without TUCP Without VA** for the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing there were zero and two month-water year type combinations (0.0% and 3.3%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-135). There were zero and four month-water year type combinations (0.0% and 6.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

- Under **Alternative 2 Without TUCP Delta VA** and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-135).

Overall, the four phases of Alternative 2 would have minor negative water temperature-related impacts on striped bass juvenile rearing in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests flows may have generally beneficial impacts on striped bass. The optimal water temperature range modeling estimated that Alternative 2 would likely have minor water temperature-related effects on juvenile striped bass, with Alternative 2 without TUCP without VA having slightly more adverse impacts than other phases of Alternative 2. Overall, these results suggest that there would be minor beneficial flow impacts and minor adverse water temperature-related impacts on striped bass juvenile rearing and emigration in the Stanislaus River above the confluence with the San Joaquin River.

O.5.19.4 San Joaquin River

Striped bass are regularly found in San Joaquin River tributaries, including in lower mainstem deep pools of the Stanislaus and Tuolumne Rivers (e.g., Anderson et al. 2007). Ainsley et al. (2013) reported that striped bass were collected at two locations between the Head of the Old River and the mouth of the Stanislaus River on the mainstem San Joaquin River in May. In the San Joaquin River outflow is balanced by tidal currents, so that embryos and larvae stay suspended in the same general area in which spawning took place. Essentially, larval bass from both rivers are most abundant where salt and fresh water meet. Thus, when they begin to feed, they are concentrated in the most productive portions of the entire estuary. Larval growth and survival rates are also highest in areas of brackish water, presumably because of reduced energy costs for osmoregulation (Moyle 2002).

Potential Changes to Striped Bass from Seasonal Operations

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows vary between minor (≤ 3%) increases and/or decreases are estimated at Vernalis most months; however, minor (6%) to substantial (≤ 34%) increases are generally expected June through September of critically dry water years (Table O-242 through Table O-245). These differences suggest averaged flows estimates will largely be similar to the No Action Alternative under all phases of Alternative 2, except in June through September of dry water years when flow increases occur.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on striped bass in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 suggest mean monthly flow will largely be similar; however, there may be beneficial impacts on striped bass expected during June through September of dry water years. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.5.19.5 Bay-Delta

Striped bass use the Delta as a migratory route and for rearing and seasonal foraging. Striped bass spend the majority of their lives in salt water, returning to freshwater to spawn. Adult striped bass spend about six to nine months of the year in San Francisco and San Pablo Bays (Hassler 1988). Striped bass also use deeper areas of many of the larger channels in the Delta, in addition to large embayments such as Suisun Bay.

Spawning occurs in spring, primarily in the Sacramento River between Sacramento and Colusa and in the San Joaquin River between Antioch and Venice Island (Farley 1966). Eggs are free-floating and negatively buoyant and hatch as they drift downstream, with larvae occurring in shallow and open waters of the lower reaches of the Sacramento and San Joaquin Rivers, the Delta, Suisun Bay, Montezuma Slough, and Carquinez Strait. According to Hassler (1988), the distribution of larvae in the estuary depends on river flow. In low-flow years, all striped bass eggs and larvae are found in the Delta, while in high-flow years, the majority of eggs and larvae are transported downstream into Suisun Bay.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows vary between minor (≤5%) to substantial (≤ 54%) increases and minor (≤ 5%) to substantial (≤ 29%) decreases estimated in the Bay-Delta; increases and/or decreases at/or above 5% in averaged flows are expected between 8% to 42% of the months (Table O-202, Table O-206, and Table O-210). At SWP and CVP exports, moderate (≤ 25%) flow increases are expected an average of 2 months (generally April and May) and slight (≤ 13%) flow decreases in March and June; the remaining months (generally July through February) have minor (≤ 4%) projected increases and decreases in flow. For Delta outflow, slight (≤ 6%) decreases are generally expected in May; the remaining months (generally June through April) have minor (≤ 5%) projected increases and decreases under most phases of Alternative 2. At the confluence of Old and Middle River in the Delta, substantial (≤54%) increases are expected an average of 2 months (generally April and May) and a slight (≤ 8%) to moderate (29%) decreases an average of 3 months (generally January, March, and June); the remaining months are projected to have minor (≤ 4%) decreases and/or increases. These results suggest averaged flows may have beneficial and adverse impacts on striped bass.

Delta Outflow vs. Bay-Delta Species Abundance

- **Alternative 2 With TUCP Without VA**
    - Differences in Delta outflow between April and June, due to seasonal operations under Alternative 2 With TUCP Without VA compared with the No Action Alternative, may have effects on striped bass annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 there were then used as input to the relationship between outflow and abundance for the striped bass.
    - Predictions from the Delta outflow model for the striped bass indicated that the overall average abundance index for Alternative 2 With TUCP Without VA would essentially be similar when compared to the No Action Alternative across all water year types except for in critically dry years (-4% to -1%, +2% in critically dry years).
- **Alternative 2 Without TUCP Without VA**
    - Differences in Delta outflow between April and June due to seasonal operations under Alternative 2 Without TUCP Without VA compared with the No Action Alternative may have effects on striped bass annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 there were then used as input to the relationship between outflow and abundance for the striped bass.
    - Predictions from the Delta outflow model for the striped bass indicated that the overall average abundance index for Alternative 2 Without TUCP Without VA would essentially be similar to the No Action Alternative across all water year types except during critical water year types (-1% to -4%, +12% in critically dry years).
- **Alternative 2 Without TUCP Delta VA**
    - Predictions from the Delta outflow model for the striped bass indicated that the overall average abundance index for Alternative 2 Without TUCP Delta VA would essentially be similar to the No Action Alternative across all water year types except in critically dry years (-1%, +12% in critically dry years).
- **Alternative 2 Without TUCP Systemwide VA**
    - Differences in Delta outflow between April and June due to seasonal operations under Alternative 2 Without TUCP Systemwide VA compared with the No Action Alternative may have effects on striped bass annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 there were then used as input to the relationship between outflow and abundance for the striped bass.
    - Predictions from the Delta outflow model for the striped bass indicated that the overall average abundance index for Alternative 2 Without TUCP Systemwide VA would essentially be similar to the No Action Alternative across all water year types except in critically dry years (-1% to +4%, +15% in critically dry years).

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 flow and Delta Outflow species abundance modeling had some differences. The differences determined by CalSim 3 modeling suggests flows may have both beneficial and adverse impacts on striped bass. Predictions from the Delta Outflow species abundance model for striped bass indicated that the overall average abundance index for Alternative 2 would essentially be similar to the No Action Alternative during all water year types except in critically dry years when striped bass abundances may increase 2% (Alternative 2 With TUCP Without VA), 12% (Alternative 2 Without TUCP without VA and Alternative 2 without TUCP Delta VA), and 15% (Alternative 2 Without TUCP with Systemwide VA). Overall, these results suggest adverse and beneficial flow impacts on striped bass most water years and primarily beneficial impacts during critically dry water years.

Potential Changes to Entrainment of Striped Bass

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on striped bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for striped bass include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of striped bass under Alternative 2 With TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant was similar all water year types and CVP Jones Pumping Plant was similar or lower all water year types (Table O-136). At CVP Jones Pumping Plant predicted average monthly loss of striped bass was up to 12% lower on dry water years; largemouth bass generally had lower loss rates than striped bass (Table O-137). It should be noted that loss of striped bass at both facilities is common; however, the percentage differences may not imply significance at a population level.
- **Alternative 2 Without TUCP Without VA**
    - Predictions from the salvage density model for striped bass include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of striped bass under Alternative 2 Without TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant was generally similar or greater and CVP Jones Pumping Plant was similar or lower all water year types (Table O-136). At the SWP Banks Pumping Plant

predicted average monthly loss was up to 5% greater for below normal water year types and was similar all other water year types (Table O-137). At CVP Jones Pumping Plant predicted average monthly loss of striped bass was up to 6% and 12% lower on below normal and dry water years, respectively (Table O-137).

- **Alternative 2 Without TUCP Delta VA**
    - Predictions from the salvage density model for striped bass include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of striped bass under Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at the SWP Banks Pumping Plant were generally similar or greater and CVP Jones Pumping Plant were similar or lower all water year types (Table O-136). At the SWP Banks Pumping Plant predicted average monthly loss was up to 5% greater for below normal water years, and similar all other water year types (Table O-137). At CVP Jones Pumping Plant predicted average monthly loss of striped bass was up to 8% and 12% lower on below normal and dry water years, respectively; loss was similar all other water year types (Table O-137).
- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for striped bass include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of striped bass under Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at the SWP Banks Pumping Plant were generally similar or greater and CVP Jones Pumping Plant were similar or lower all water year types (Table O-136). At the SWP Banks Pumping Plant predicted average monthly loss was up to 5% greater for below normal water years; loss was similar all other water year types (Table O-137). At CVP Jones Pumping Plant predicted average monthly loss of striped bass was up to 11% lower on below normal and dry water years (Table O-137.

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative, salvage density modeling had some differences. The salvage density modeling predicted monthly loss under Alternative 2 at SWP Banks Pumping Plant are similar during all water year types except during below normal water years, when loss would generally have minor increases; at CVP Jones Pumping Plant loss would generally be slightly lower during most water year types, except during above normal and critical water years, which would be similar. Overall, these results suggest that loss would decrease at CVP Jones Pumping Plant from entrainment under most phases of Alternative 2 during most water years.

O.5.20 American Shad

O.5.20.1 Sacramento River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento River. Migrating adults generally take 2 to 3 months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the February to April adult American shad migration into the Delta, CalSim 3 estimates of mean monthly flows below Keswick Dam under Alternative 2 range from about 3,400 cfs (with TUCP Without VA) for March during critically dry years to 24,000 cfs for February during wet water years (Table O-183). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. This increase in flows could result in more eggs and larval fish to be washed further downstream earlier than expected but Alternative 2 cannot be determined to have adverse impacts. Alternative 2 relative to the No Action Alternative is expected to have small effects these months, but flows are higher (up to 30%) for Alternative 2 (without TUCP with Delta and Systemwide VA) in April of critically dry water years (Table O-183). Therefore, Alternative 2 would likely have negligible flow impacts on American shad eggs and embryos relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 319 for Butte City.

Results for the analysis are summarized in Table O-138. Table O-138, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 62°F to 75°F optimal range, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at Butte City (Table O-138). These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on American shad spawning and larval rearing in the Sacramento River.
- Results for **Alternative 2 Without TUCP Without VA** are identical to those for Alternative 2 With TUCP Without VA (Table O-138).

- Under **Alternative 2 Without TUCP Delta VA** for the 62°F to 75°F optimal range, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at Butte City (Table O-138). There was one month-water year type combination (6.7%) with unfavorable results.). These results suggest that there would be negligible water temperature-related effects of Alternative 2 Without TUCP Delta VA on American shad spawning and larval rearing in the Sacramento River.
- Results for **Alternative 2 Without TUCP Systemwide VAs** are identical to those for Alternative 2 without TUCP Delta VA (Table O-138).

Overall, the four phases of Alternative 2 would have similar negligible effects on water temperature conditions for American shad spawning and larval rearing in the Sacramento River (Table O-138).

Summary

Alternative 2 relative to the No Action Alternative is largely expected to have negligible impacts on American shad spawning and larval rearing below Keswick Dam as flow for spawning is not a limiting factor for American shad due to differences in flow. Alternative 2 relative to the No Action Alternative will have negligible impacts on American shad spawning and larval rearing in the Sacramento River due to differences in water temperature. Therefore, the differences in flow and temperature for all phases of Alternative 2 compared to the No Action Alternative in the Sacramento River are expected to have negligible impacts on American shad spawning and larval rearing.

Juvenile Rearing and Emigration

In the Sacramento River, summer rearing habitat occurs in the main river from Colusa to the north Delta (Stevens et al. 1987). As the season progresses, juvenile shad move downstream and enter salt water primarily during September through November (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the September to November juvenile American shad emigration back into the Delta, CalSim 3 estimates of mean monthly flows below Keswick Dam under Alternative 2 range from about 4,300 cfs during October in critically dry years to 9,000 cfs for September during wet water years (Table O-183). Because American shad are anadromous fish that migrate great lengths to reach their spawning grounds, these flow levels are likely to be adequate for juvenile rearing and emigration, therefore no adverse impacts are expected to result. Alternative 2 relative to the No Action Alternative are higher (18%) for Alternative 2 in November of below normal water years due to differences in flow (Table O-183). Therefore, Alternative 2 would likely have negligible flow impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F range optimal range for juvenile rearing and emigration during July through

November are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 320 for Butte City.

Results for the analysis are summarized in Table O-139. Table O-139, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 62°F to 75°F optimal range, there was one month-water year type combinations (4.0% of total combinations during the period) with favorable results and no combinations (0%) with unfavorable results at Butte City (Table O-139). These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on American shad juvenile rearing and emigration in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 62°F to 75°F optimal range, there no month-water year type combinations (0%) with favorable or unfavorable results. These results suggest that there would be negligible water temperature-related effects of Alternative 2 Without TUCP Without VA on American shad juvenile rearing and emigration in the Sacramento River.
- Results for **Alternative 2 Without TUCP Delta VA** are identical to those for Alternative 2 without TUCP without VA.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 62°F to 75°F optimal range, there was one month-water year type combinations (4.0% of total combinations during the period) with favorable results and one combination with unfavorable results at Butte City (Table O-139).These results suggest that there would be negligible water temperature-related impact of Alternative 2 Without TUCP Systemwide VAs on American shad juvenile rearing and emigration in the Sacramento River.

Overall, Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP Delta VA would have similar negligible impacts on water temperature conditions for American shad juvenile rearing and emigration in the Sacramento River (Table O-139).

<u>Summary</u>

Alternative 2 relative to the No Action Alternative is largely expected to have negligible impacts on American shad juvenile rearing and emigration in the Sacramento River due to differences in flow. Flow for rearing and emigration is not a limiting factor for American shad. Alternative 2 relative to the No Action Alternative is also expected to have negligible impacts on American shad juvenile rearing and emigration in the Sacramento River due to differences in water temperature. Therefore, the differences in flow and temperature for Alternative 2 compared to the No Action Alternative are expected to have a negligible impacts on American shad spawning and larval rearing.

O.5.20.2 Lower American River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento River. Migrating adults generally take 2 to3 months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962). Adult American shad migrate into the lower American River to spawn during the late spring, typically during April through early July (California Department of Fish and Wildlife 1986).

Potential Changes to American Shad from Seasonal Operations

<u>CalSim 3 Flows</u>

During the February to April adult American shad migration into Delta, CalSim 3 estimates of mean monthly flows below Nimbus Dam and H street under Alternative 2 range from about 785 cfs for April in critically dry years with TUCP Without VA to 12,316 cfs for February of wet water years without TUCP systemwide VAs (Table O-230 and Table O-231Table O-233). Alternative 2 relative to the No Action Alternative is expected to have generally minimal effects in these months, but flows is moderately higher (100-111%) for Alternative 2 in April of critically dry water years without TUCP without VA due to differences in flow (Table AR_ND_A2 and Table O-231). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. This increase in flows could result in more eggs and larval fish to be washed further downstream earlier than expected but Alternative 2 cannot be determined to have adverse effects. Therefore, Alternative 2 would likely have negligible flow impacts on American shad eggs and embryos relative to the No Action Alternative.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range for American shad spawning and larval rearing during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 97 for Hazel Avenue and Table 98 for Watt Avenue.

Results for the analysis are summarized in Table O-140. Table O-140, as described in Section O.4.20.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 62°F to 75°F optimal range for American shad spawning and larval rearing, there were zero month-water combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-140). There were zero and one month-water combinations (0.0% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

- Under **Alternative 2 Without TUCP Without VA** for the 62°F to 75°F optimal range for American shad spawning and larval rearing, there were zero month-water combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-140). There were two and zero month-water combinations (13.3% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Delta VA** for the 62°F to 75°F optimal range for American shad spawning and larval rearing, there were zero month-water combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-140). There were zero month-water combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 62°F to 75°F optimal range for American shad spawning and larval rearing, there were two and zero month-water combinations (13.3% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-140). There were zero and one month-water combinations (0.0% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP Delta VA would have positive and negative water temperature-related effects to American shad spawning and larval rearing in the lower American River. Effects of Alternative 2 Without TUCP Systemwide VAs would be more positive than the other phases.

<u>Summary</u>

Alternative 2 relative to the No Action Alternative is expected to have negligible impacts on American shad spawning and larval rearing below Nimbus Dam and at H Street due to differences in flow. Flow for spawning is not a limiting factor for American shad. Water temperatures for spawning initiation from Hazel Avenue and Watt Avenue under all phases of Alternative 2 compared to the No Action Alternative will have beneficial and adverse impacts on American shad spawning and larval rearing in the lower American River. Therefore, the differences in flow and temperature for all phases of Alternative 2 compared to the No Action Alternative in the lower American River are expected to have some beneficial and adverse impacts on American shad spawning and larval rearing.

Juvenile Rearing and Emigration

American shad rearing and emigration in the lower American River is dependent on water temperatures. August through September, but before November, are optimal months for juvenile American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the September to November juvenile American shad emigration back into Delta, CalSim 3 estimates of mean monthly flows below Nimbus Dam and H street under Alternative 2 range from about 574 cfs (w/o TUCP w/ Delta VA) for October in critically dry years to 4,111 cfs (w/o TUCP w/ Delta VA) for November of wet water years (Tables O-226 through O-233). Alternative 2 relative to the No Action Alternative is consistently lower (up to 23%, without TUCP without VA) for Alternative 2 below Nimbus Dam and H street in November during critically dry years due to differences in flow(Tables O-226 through O-233). Because American shad are anadromous fish that migrate great lengths to reach their spawning grounds, these flow levels are likely to be adequate for juvenile rearing and emigration, so no adverse impacts are expected to result. Therefore, Alternative 2 would likely have negligible flow impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for American shad juvenile rearing and emigration during July through November are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 99 for Hazel Avenue and Table 100 for Watt Avenue.

Results for the analysis are summarized in Table O-141. Table O-141, as described in Section O.4.20.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 63°F to 77°F optimal range for American shad spawning and larval rearing, there were two and zero month-water combinations (8.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-141). There were one and zero month-water combinations (4.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Without VA** for the 63°F to 77°F optimal range for American shad spawning and larval rearing, there was one month-water combinations (4.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-141). There were one and zero month-water combinations (4.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Delta VA** for the 63°F to 77°F optimal range for American shad spawning and larval rearing, there was one month-water combinations (4.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-141). There were two and zero month-water combinations (8.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

- Under **Alternative 2 Without TUCP Systemwide VAs** for the 63°F to 77°F optimal range for American shad spawning and larval rearing, there were two month-water combinations (8.0%) with favorable results at both Hazel Avenue and Watt Avenue, respectively (Table O-141). There were three and zero month-water combinations (12.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, the four phases of Alternative 2 would have positive and negative water temperature-related effects to American shad juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Alternative 2 relative to the No Action Alternative is largely expected to have negligible impacts on American shad juvenile rearing and emigration due to differences in flow. Flow for rearing and emigration is not a limiting factor for American shad. Water temperatures for larval rearing and emigration at Hazel Avenue and Watt Avenue under all phases of Alternative 2 compared to the No Action Alternative would have beneficial and adverse impacts on American shad juvenile rearing and emigration in the lower American River. Therefore, the differences in flow and temperature for all phases of Alternative 2 compared to the No Action Alternative are expected to have beneficial and adverse impacts on American shad juvenile rearing and emigration.

O.5.20.3 Stanislaus River

Spawning and Larval Rearing

American shad migrate up the Stanislaus River to spawn in the late spring and support a sport fishery during that period. American shad have been observed on occasion from June through July at Lovers Leap (U.S. Fish and Wildlife Service 2002; Kennedy and Cannon 2005). American shad were found primarily in the faster habitats and were observed in schools of 20 or more (U.S. Fish and Wildlife Service 2002).

Potential Changes to American Shad from Seasonal Operations

<u>CalSim 3 Flows</u>

During the February to April adult American shad migration into Delta, CalSim 3 estimates of mean monthly flows below Goodwin Dam and Stanislaus River mouth under Alternative 2 range from about 200 cfs for March in critically dry years to about 2200 cfs for February below Goodwin Dam and Stanislaus River Mouth in wet water years with and without TUCP and VAs (Tables O-234 though O-241). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. Alternative 2 relative to the No Action Alternative is moderately higher (43%) for Alternative 2 in February of dry water years below Goodwin Dam and 10% higher at Stanislaus River Mouth with and without TUCP and VAs due to differences in flow(Tables O-234 through O-241) This increase in flows could result in more eggs and larval fish to be washed further downstream earlier than expected, but Alternative 2 cannot be determined to have adverse effects. Therefore, Alternative 2 would likely have negligible impacts on American shad eggs and embryos relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range for American shad spawning and larval rearing during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 73 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-142. Table O-142, as described in Section O.4.20.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 59°F to 68°F 62°F to 75°F optimal range for American shad spawning and larval rearing, there were one month-water year type combinations (6.7%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-142).
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-142).

Overall, the four phases of Alternative 2 would have negligible water temperature-related effects on American shad spawning and larval rearing in the Stanislaus River at Orange Blossom Bridge.

Alternative 2 relative to the No Action Alternative is largely expected to have negligible impacts on American shad spawning and larval rearing. Flow for spawning is not a limiting factor for American shad due to differences in flow. Water temperatures for spawning initiation at Orange Bridge Dam and above the confluence under Alternative 2 compared to the No Action Alternative will have negligible water-temperature related impacts on American shad spawning and larval rearing at Orange Blossom Bridge in the Stanislaus River. Therefore, the differences in flow and temperature for Alternative 2 compared to the No Action Alternative in the lower American River are expected to have negligible impacts on American shad spawning and larval rearing.

Juvenile Rearing and Emigration

American shad rearing and emigration in the Stanislaus River is dependent on water temperatures. From Orange Blossom Bridge to just above the confluence, juvenile rearing and emigration generally occur in July for American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the September to November juvenile American shad emigration back into Delta, CalSim 3 estimates of mean monthly flows below Goodwin Dam and Stanislaus River Mouth under Alternative 2 range from about 200 cfs for November in critically dry years to 870 cfs in October

during wet water years below Goodwin Dam and Stanislaus River mouth with and without TUCP and VAs (Tables O-234 through O-241). Alternative 2 relative to the No Action Alternative is unchanged for Alternative 2 below Goodwin Dam with and without TUCP and VAs and 28% to 42% higher at Stanislaus River Mouth with and without TUCP and VAs in September during critically dry years due to differences in flow (Tables O-234 through O-241). With no change below Goodwin Dam and an increase in flows at Stanislaus River Mouth, there should be no adverse impacts to American shad from Alternative 2. Therefore, Alternative 2 would likely have negligible flow impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for American shad juvenile rearing and emigration during July through November are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 74 for Orange Blossom Bridge and Table 75 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-143. Table O-143, as described in Section O.4.20.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 63°F to 77°F optimal range for American shad juvenile rearing and emigration there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-143). There were zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-143).

Overall, the four phases of Alternative 2 would have negligible water temperature-related effects on American shad juvenile rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Alternative 2 relative to the No Action Alternative is largely expected to have negligible impact on American shad juvenile rearing and emigration. Flow for rearing and emigration is not a limiting factor for American shad due to differences in flow. Water temperatures for larval rearing and emigration at Orange Blossom Bridge and above the confluence under Alternative 2 compared to the No Action Alternative are suggested to have negligible water temperature-related impacts on American shad juvenile rearing and emigration in the Stanislaus River. Therefore, the differences in flow and temperature for Alternative 2 compared to the No Action Alternative are expected to have negligible impacts on American shad juvenile rearing and emigration.

O.5.20.4 San Joaquin River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas. Migrating adults generally take 2 to3 months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962).

Little is known about American shad populations inhabiting the San Joaquin River. American shad may spawn in the San Joaquin River system, but their abundance is unknown.

Potential Changes to American Shad from Seasonal Operations

<u>CalSim 3 Flows</u>

During the February to April adult American shad migration into the Delta, CalSim 3 estimates of mean monthly flows in the San Joaquin River at Vernalis under Alternative 2 range from about 2,000 cfs for March critically dry years to 13,000 cfs for February of wet water years with and without TUCP and VAs (Table O-243). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. Alternative 2 relative to the No Action Alternative is slightly higher (~5%) for Alternative 2 Without TUCP Delta VAs and systemwide VAs in March of critically dry water years due to differences in flow (Table O-243) This increase in flows could result in more eggs and larval fish to be washed further downstream earlier than expected but Alternative 2 cannot be determined to have adverse impacts. Therefore, Alternative 2 would likely have negligible impacts on American shad eggs and embryos relative to the No Action Alternative.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on American shad in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

<u>Summary</u>

There may be negligible impacts from seasonal operations on American shad spawning and larval rearing based on analyses of simulated flows under Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are unlikely to have an impact on American shad juvenile rearing and non-spawning adult. Changes in water temperature from seasonal operations under Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on American shad spawning and larval rearing in the San Joaquin River. Under Alternative 2, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the American shad spawning and larval rearing period.

Juvenile Rearing and Emigration

American shad rearing and emigration is dependent on water temperatures. Generally, juvenile rearing and emigration generally occur in July for American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the September to November juvenile American shad emigration back into the Delta, CalSim 3 estimates of mean monthly flows in the San Joaquin River at Vernalis under Alternative 2 range from about 800 cfs for September in critically dry years to 2,900 cfs for November in the San Joaquin River at Vernalis with and without TUCPs and VAs of wet water years (Table O-243). Alternative 2 relative to the No Action Alternative is slightly higher (up to 12%) for Alternative 2 in September in the San Joaquin River at Vernalis with and without TUCPs and VAs during critically dry years due to differences in flow (Table O-243). With these flows, American Shad may not be affected by Alternative 2. Therefore, Alternative 2 would likely have negligible impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on American shad in the San Joaquin River. Under Alternative 2, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile rearing and emigration period (Figure O-15).

Summary

There may be negligible impacts from seasonal operations on American shad juvenile rearing and non-spawning adults based on analyses of simulated flows under Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are unlikely to have a substantial impact on American shad juvenile rearing and non-spawning adult. Under Alternative 2, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile rearing and emigration period.

O.5.20.5 Bay-Delta

American shad spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento, Feather, American, and Yuba Rivers. Some spawning also takes place in the lower San Joaquin, Mokelumne, and Stanislaus Rivers (U.S. Fish and Wildlife Service 1995). The spawning migration may begin as early as February, but most adults migrate into the Delta in March and early April (Skinner 1962). Migrating adults generally take 2 to 3 months to pass through the Sacramento–San Joaquin estuary (Painter et al. 1979).

American shad rearing and emigration in the Bay-Delta is dependent on water temperatures. August through September, but before November, are optimal months for juvenile American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

Delta Outflow vs. Bay-Delta Species Abundance

- **Alternative 2 With TUCP Without VA**
    - Differences in Delta outflow between February and June due to seasonal operations under Alternative 2 With TUCP Without VA compared with the No Action Alternative may have effects on American shad annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the American shad.
    - Predictions from the Delta Outflow model for American shad indicated that the overall average abundance index for Alternative 2 With TUCP Without VA would essentially be similar to mean abundance under the No Action Alternative across all water year types (-2% to 0%).
- **Alternative 2 Without TUCP Without VA**
    - Differences in Delta outflow between February and June due to seasonal operations under Alternative 2 Without TUCP and without VA compared with the No Action Alternative may have effects on American shad annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the American shad.
    - Predictions from the Delta Outflow model for American shad indicated that the overall average abundance index for Alternative 2 Without TUCP and without VA would essentially be similar to the mean abundance under the No Action Alternative across all water year types except during critical water year types (-2% to 0%, +7% during critical water year types).
- **Alternative 2 Without TUCP Delta VA**
    - Differences in Delta outflow between February and June due to seasonal operations under Alternative 2 Without TUCP Delta VA compared with the No Action Alternative may have effects on American shad annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the American shad.
    - Predictions from the Delta Outflow model for American shad indicated that the overall average abundance index for Alternative 2 Without TUCP Delta VA would essentially be similar to the mean abundance under the No Action Alternative across all water year types except in critically dry years (-1% to +2%, +6% during critically water year types).

- **Alternative 2 Without TUCP Systemwide VA**
    - Differences in Delta outflow between February and June due to seasonal operations under Alternative 2 Without TUCP and systemwide VA compared with the No Action Alternative may have effects on American shad annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the American shad.
    - Predictions from the Delta Outflow model for American shad indicated that the overall average abundance index for Alternative 2 Without TUCP Systemwide VA would potentially lead to slightly higher American shad abundances than the No Action Alternative in the driest years (+4% in below normal years, +5% in dry years, and +10% in critically dry years).

Summary

There may be negligible impacts from of seasonal operations on American shad spawning and larval rearing based on analyses of simulated flows under Alternative 2 in comparison to the No Action Alternative. American shad abundance index is similar to the No Action Alternative for all phases of Alternative 2 except for Alternative 2 Without TUCP with systemwide VA where there could potentially be an increase in American shad abundances during critically dry years in the Bay-Delta based from the Delta Outflow model. Therefore, Alternative 2 would not have a substantial change when compared to the No Action Alternative.

Potential Changes to Entrainment of American Shad

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on American shad entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for white surgeon include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of American shad under Alternative 2 With TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant was similar for all water year types and CVP Jones Pumping Plant were similar most water year types (Table O-144). At CVP Jones Pumping Plant predicted average monthly loss was similar water years, except dry water year types when loss decreased up to 5%. It should be noted that loss of American shad at both facilities is common; however, the percentage differences may not imply significance at a population level.

- **Alternative 2 Without TUCP Without VA**
    - Predictions from the salvage density model for American shad include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of American shad under Alternative 2 Without TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant and CVP Jones Pumping Plant were similar most water year types (Table O-144). At the SWP Banks Pumping Plant predicted average monthly loss was similar for all water year types, except during critically dry water year types when it decreased up to 6% (Table O-145). At CVP Jones Pumping Plant predicted average monthly loss was generally similar except during dry water years when loss increased up to 5% (Table O-144).
- **Alternative 2 Without TUCP Delta VA**
    - Predictions from the salvage density model for American shad include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of American shad under Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at the SWP Banks Pumping Plant and CVP Jones Pumping Plant were similar most water year types (Table O-144). At the SWP Banks Pumping Plant predicted average monthly loss was similar for all water year types, except during critically dry water year types when it decreased up to 9% (Table O-145). At CVP Jones Pumping Plant predicted average monthly loss was generally similar except during dry water years when loss increased up to 5% (Table O-144). It should be noted that loss of American shad at both facilities is common; however, the percentage differences may not imply significance at a population level.
- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for American shad include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of American shad under Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at the SWP Banks Pumping Plant was similar for all water year types and CVP Jones Pumping Plant were similar most water year types (Table O-144). At the SWP Banks Pumping Plant predicted average monthly loss was similar for all water year types, except during critically dry water year types when it decreased up to 9% (Table O-145). It should be noted that loss of American shad at both facilities is common; however, the percentage differences may not imply significance at a population level.

Summary

There may be beneficial and adverse changes to American shad entrainment based on analyses of simulated exports under all phases Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, entrainment was similar to the No Action Alternative for most what year types with some exceptions that decreased and increased during certain phases and water year types.

O.5.21 Threadfin Shad

O.5.21.1 Sacramento River

Spawning for threadfin shad takes place in California April through August, peaking in June and July. The embryos hatch in 3 to 6 days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Threadfin shad are occasionally caught at the Red Bluff Diversion Dam RST in the Sacramento River, and occur year-round (Voss 2024).

Potential Changes to Threadfin Shad from Seasonal Operations

Flow Impacts

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 2 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal spawning range during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 321 for Butte City.

Results for the analysis are summarized in Table O-146. Table O-146, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 63°F to 77°F optimal range, there were zero month-water year type combinations (0.0% of total combinations during the period) with favorable results and one combination (4.0%) with unfavorable results at Butte City (Table O-146). These results suggest that there would be negligible negative water temperature-related effects of Alternative 2 With TUCP Without VA on threadfin shad spawning in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA**, **VA** for the 63°F to 77°F optimal range, there were zero month-water year type combinations (0.0% of total combinations during the period) with favorable and unfavorable results at Butte City (Table O-146). These results suggest there would be negligible water temperature-related effects of Alternative 2 without TUCP without VA on threadfin shad spawning in the Sacramento River.
- Results for **Alternative 2 Without TUCP Delta VA** are identical to those of Alternative 2 With TUCP Without VA (Table O-146).
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 63°F to 77°F optimal range, there were zero month-water year type combinations (0.0% of total combinations during the period) with favorable results at Butte City (Table O-146). There were three month-water year type combinations (12.0%) with unfavorable results at Butte City. These results suggest that there would be negative effects of Alternative 2 With TUCP Without VA on threadfin shad spawning in the Sacramento River.

Overall, Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP Delta VA would have similar negligible effects on water temperature conditions for threadfin shad spawning in the Sacramento River (Table O-146). However, Alternative 2 Without TUCP Systemwide VAs would have a negative effect.

Summary

There may be negligible to adverse impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are expected to have a negligible impact on threadfin. Temperature analysis suggests adverse impacts on spawning under Alternative 2 Without TUCP with Systemwide VAs and negligible impacts under all other phases in the Sacramento River.

O.5.21.2 Lower American River

Spawning for threadfin shad takes place in California April through August, peaking in June and July. The embryos hatch in 3 to 6 days and larvae immediately become planktonic. Threadfin shad are occasionally captured as part of the non-salmonid bi-catch in the RSTs in the lower American River (Pacific States Marine Fisheries Commission 2014).

Potential Changes to Threadfin Shad from Seasonal Operations

Flow Impacts

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 2 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for threadfin shad adult spawning during April through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 101 for Hazel Avenue and Table 102 for Watt Avenue.

Results for the analysis are summarized in Table O-147. Table O-147, as described in Section O.4.21.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 63°F to 77°F optimal range for threadfin shad spawning, there were two and zero month-water combinations (8.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-147). There were zero and one month-water combination (0.0% and 4.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Without VA** for the 63°F to 77°F optimal range for threadfin shad spawning, there were one and zero month-water combinations (4.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-147). There was one month-water combination (4.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Delta VA** for the 63°F to 77°F optimal range for threadfin shad spawning, there were one and zero month-water combinations (4.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-147). There were zero month-water combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 63°F to 77°F optimal range for threadfin shad spawning, there were two and one month-water combinations (8.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-147). There were zero month-water combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

Overall, the four phases of Alternative 2 would have positive and negative water temperature related effects to threadfin shad spawning in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There may be negligible, beneficial and adverse impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are expected to have a negligible impact on threadfin shad. Water temperature analysis suggests beneficial and adverse impacts on spawning for the four phases of Alternative 2 in the lower American River.

O.5.21.3 Stanislaus River

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Threadfin shad are occasionally captured in the Caswell RST in the lower Stanislaus River (Bradbury and Hickey 2019).

Potential Changes to Threadfin Shad from Seasonal Operations

Flow Impacts

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 2 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for threadfin shad adult spawning during April through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 76 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-148. Table O-148, as described in Section O.4.21.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for 63°F to 77°F optimal range for threadfin shad adult spawning, there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge (Table O-148).
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-148).

Overall, the four phases of Alternative 2 would have negligible water temperature-related effects on threadfin shad spawning in the Stanislaus River at Orange Blossom Bridge.

Summary

There may be negligible impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are expected to have a negligible impact on threadfin shad. Temperature analysis also suggests negligible impacts for Alternative 2 in the Stanislaus River on threadfin shad spawning.

O.5.21.4 San Joaquin River

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Juveniles can form dense schools and while they are typically abundant in freshwater, they may also be found in varying salinities throughout the estuary. Threadfin shad are fast-growing but short-lived, with an average lifespan of two years.

Potential Changes to Threadfin Shad from Seasonal Operations

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 2 are likely adequate for threadfin shad.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on threadfin shad in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

There may be negligible impacts from seasonal operations on threadfin shad based on analyses of simulated flows under the four phases of Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, changes in flows are expected to have a negligible impacts on threadfin shad. Under Alternative 2, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout year in the San Joaquin River at Vernalis.

O.5.21.5 Bay-Delta

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Juveniles can form dense schools and while they are typically abundant in freshwater, they may also be found in varying salinities throughout the estuary. Threadfin shad are fast-growing but short-lived, with an average lifespan of two years.

Potential Changes to Threadfin Shad from Seasonal Operations

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 2 are likely adequate for threadfin shad.

Summary

There may be negligible impacts from seasonal operations on threadfin shad under the four phases of Alternative 2 in comparison to the No Action Alternative.

Potential Changes to Entrainment of Threadfin Shad

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have impacts on threadfin shad entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation n*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for white surgeon include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at

SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.

- Predicted average monthly loss of threadfin shad under Alternative 2 With TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant was similar for all water year types and CVP Jones Pumping Plant were similar most water year types (Tables O-149 and O-150). At CVP Jones Pumping Plant predicted average monthly loss was similar water years, except dry and critically dry water year types when loss decreased up to 6%.

- **Alternative 2 Without TUCP Without VA**

  - Predictions from the salvage density model for threadfin shad include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.

  - Predicted average monthly loss of threadfin shad under Alternative 2 Without TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant and CVP Jones Pumping Plant was similar most water year types (Tables O-149 and O-150). At the SWP Banks Pumping Plant predicted average monthly loss was similar for all water year types, except during dry water year types when it decreased up to 6% (Table O-149). At CVP Jones Pumping Plant predicted average monthly loss was generally similar except during critically dry water years when loss increased up to 10% and dry water years when loss decreased up to 5% (Table O-150). It should be noted that loss of threadfin shad at both facilities is common; however, the percentage differences may not imply significance at a population level.

- **Alternative 2 Without TUCP Delta VA**

  - Predictions from the salvage density model for threadfin shad include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.

  - Predicted average monthly loss of threadfin shad under Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at the SWP Banks Pumping Plant was similar most water year types and CVP Jones Pumping Plant decreased or increased most water year types (Tables O-149 and O-150). At the SWP Banks Pumping Plant predicted average monthly loss was similar for all water year types, except during dry water year types when it increased up to 6% (Table O-149). At CVP Jones Pumping Plant predicted average monthly decreased up to 5% on below normal and dry water years; loss increased up to 5% on critically dry water years. Table O-150). It should be noted that loss of threadfin shad at both facilities is common; however, the percentage differences may not imply significance at a population level.

- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for threadfin shad include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of threadfin shad under Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at the SWP Banks Pumping Plant and CVP Jones Pumping Plant was similar most water year types (Tables O-149 and O-150). At the SWP Banks Pumping Plant predicted average monthly loss was similar for all water year types, except during dry water year types when it increased up to 8% (Table O-149). At CVP Jones Pumping Plant predicted average monthly loss was generally similar except during critically dry water years when loss increased up to 5% and below normal water years when loss decreased up to 5% (Table O-150). It should be noted that loss of threadfin shad at both facilities is common; however, the percentage differences may not imply significance at a population level.

Summary

There may be beneficial and adverse changes to entrainment on threadfin shad juvenile rearing and non-spawning adults based on analyses of simulated exports under Alternative 2 in comparison to the No Action Alternative. Under Alternative 2, entrainment increased at SWP Banks Pumping Plant across all phases water year types except during the dry and critically dry water year types for the phases without VAs and decreased at CVP Jones Pumping Plant for all water year types and phases except during the critical water year type for the phases without TUCP.

O.5.22 Black Basses

O.5.22.1 Three Micropterus spp.

Three *Micropterus* spp. constitute the group of black basses in California, and include largemouth bass (two species), smallmouth bass, and spotted bass (three sub-species). All three species are introduced but have recreational value in California.

Largemouth Bass

Largemouth bass first spawn during their second or third spring at about 7 inches in length. Spawning is limited to freshwater (Moyle 2002). The males begin building nests when the water temperature reaches about 60°F (15.6°C). Spawning takes place from April through June, at temperatures up to 75°F (23.9°C).

Smallmouth Bass

Smallmouth bass reach maturity in their third or fourth spring, at which point they move into shallower water. Spawning begins in May and can continue into June or July (Moyle 2002). Spawning has been observed at temperatures ranging from 13°C to 26°C (55.4°F to 78.8°F), with optimal water temperatures ranging from 16°C to 18°C (60.8°F to 64.4°F) (Wang 2010).

Spotted Bass

Maturity is reached in the second or third year and spawning occurs in freshwater when temperatures reach 15°C to 18°C (59°F to 64.4°F), continuing until temperatures reach 22°C to 23°C (71.6°F to 73.4°F) in early June. Males move to shallow water in March and early April, where they construct nests 40 to 80 cm (31.5 inches) in diameter, generally in shallow areas less than or equal to 6 m deep (University of California, Agriculture and Natural Resources 2019b; Wang 2010).

O.5.22.2 Sacramento River

Spawning

Spawning occurs in freshwater for all three taxa. This means all spawning occurs upstream of the brackish estuary. See details in Section O.4.22.1 above for spawning timing for each species.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative mean monthly flows at Keswick Dam, Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤6%) increases and decreases are estimated most months April through July; March would remain the same as the No Action Alternative. Minor increases would generally occur in April. Minor decreases would typically occur in June and July. This suggests largemouth, smallmouth, and spotted habitat will largely remain similar to the No Action Alternative under Alternative 2 (Table O-186 through Table O-189, Table O-190 through Table O-193, and Table O-194 through Table O-197).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 323 for Butte City. Full results of the analysis assessing the percent of months with water temperature outside the 55°F to 70°F optimal range for smallmouth bass spawning during May through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 325 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 331 for Butte City.

Results for the three analyses are summarized in Table O-151. Table O-151, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results at Butte City (Table O-151). For the 55°F to 70°F optimal range for smallmouth bass spawning, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Hamilton City. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Butte City. These results suggest that there would be negligible water temperature-related effects of Alternative 2 With TUCP Without VA on black bass spawning in the Sacramento River.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** were identical to those of Alternative 2 With TUCP Without VA (Table O-151).

Overall, all four phases of Alternative 2 would have similar negligible effects on water temperature conditions for black bass spawning in the Sacramento River (Table O-151).

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative for CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will remain largely similar, except April, June, and July when minor beneficial and adverse (respectively) impacts on largemouth, smallmouth, and spotted bass may be expected. The optimal water temperature range modeling estimates indicate neither beneficial nor adverse impacts on largemouth, smallmouth, and spotted bass under Alternative 2 compared to the No Action Alternative. Overall, these results suggest there would be generally minor adverse flow impacts on largemouth, smallmouth, and spotted bass spawning habitat in June and negligible water temperature-related impacts compared to the No Action Alternative for all three species in the Sacramento River under Alternative 2.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters. However, they require large quantities of food; they are likely to remain in slower moving waters of the stream or move vertically within the lake to accommodate preferences.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative mean monthly flows at Keswick Dam, Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤5%) increase and/or decrease is estimated most months except April (Keswick Dam) and June (Red Bluff Diversion Dam) under Alternative 2 With TUCP with Systemwide VA when a 6% increase and a 5% decrease, respectively, occur. This suggests largemouth, smallmouth, and spotted habitat will largely remain similar to the No Action Alternative under Alternative 2 (Table O-186 through Table O-189, Table O-190 through Table O-193, and Table O-194 through Table O-197).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for non-spawning adult largemouth bass growth year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 324 at Butte City. Full results of the analysis assessing the percent of months with water temperature above the 66°F lower end of observed summer-time range for non-spawning adult smallmouth bass during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 327 for the Sacramento River at Hamilton. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F optimal range for non-spawning adult smallmouth bass growth year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 320 for the Sacramento River at Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 75°F to 87°F preferred summer-time range for non-spawning adult spotted bass during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 332 for the Sacramento River at Butte City.

Results for the four analyses are summarized in Table O-152. Table O-152, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 77°F to 86°F optimal range for non-spawning adult largemouth bass growth, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results at Butte City (Table O-152). For the 66°F lower end of observed summer-time range for non-spawning adult smallmouth bass, there were no month-water year type combinations (0%) with favorable results and two combinations (13.3%) with unfavorable results at Hamilton City. For the 77°F to 80°F optimal range for non-spawning adult smallmouth bass growth, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Hamilton City. For the 75°F to 87°F preferred summer-time range for non-spawning adult spotted bass, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Butte City. These results suggest that there would be negative water temperature-related effects of Alternative 2 With TUCP Without VA on black bass non-spawning adults in the Sacramento River.
- Under **Alternative 2 Without TUCP Without VA** for the 77°F to 86°F optimal range for non-spawning adult largemouth bass growth, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results at Butte City (Table O-152). For the 66°F lower end of observed summer-time range for non-spawning adult smallmouth bass, there were no month-water year type combinations (0%) with favorable results and three combinations (20.0%) with unfavorable results at Hamilton City. For the 77°F to 80°F optimal range for non-spawning adult smallmouth bass growth, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Hamilton City. For the 75°F to 87°F preferred summer-time range for non-spawning adult spotted bass, there were no month-water year type combinations (0%) with either favorable or unfavorable

results at Butte City. These results suggest that there would be negative water temperature-related effects of Alternative 2 Without TUCP Without VA on black bass non-spawning adults in the Sacramento River.

- Results for **Alternative 2 Without TUCP Delta VA** and **Alternative 2 Without TUCP Systemwide VAs** were identical to those for Alternative 2 With TUCP Without VA (Table O-152).

Overall, all four phases of Alternative 2 would have similar negative effects on water temperature conditions for black bass spawning in the Sacramento River (Table O-152).

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative for CalSim 3 flow and water temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will largely remain similar, except April (Keswick Dam) and June (Red Bluff Diversion Dam) under Alternative 2 With TUCP with Systemwide VA which had slight beneficial and adverse (respectively) impacts on largemouth, smallmouth, and spotted bass. The optimal summer water temperature range modeling estimates indicate were neither beneficial nor adverse conditions for largemouth and spotted bass compared to the No Action Alternative at Butte and Hamilton cities. The optimal summer water temperature range modeling estimates indicate two to three month-water year type combinations) with adverse results for smallmouth bass at lower end of optimal range at Hamilton City. Overall, these Alternative 2 results suggest that there would be minor adverse impacts from flow for largemouth, smallmouth, and spotted bass. There would be no water temperature-related impacts on largemouth and spotted bass, but there would be adverse temperature-related effects on smallmouth bass in the Sacramento River.

O.5.22.3 Lower American River

Spawning

Spawning for all three taxa occurs in cooler, shallow waters with flow. See details in Section O.4.22.1 above for spawning timing for each species.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam, and at H Street indicate that minor (≤ 5%) increase and decrease is estimated for March through July, except April under Alternative 2 With TUCP with Systemwide VA when a slight increase would occur (6% below Nimbus Dam, 7% at H street) (Table O-222 through Table O-225, Table O-226 through Table O-229, and Table O-230 through Table O-233). These results suggest flows will remain largely similar, except April a minor increase in flow. Flow effects on largemouth, smallmouth, and spotted bass would be generally similar to the No Action Alternative under Alternative 2, except in April when minor beneficial impacts may occur.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 105 for Hazel Avenue and Table 106 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 55°F to 70°F optimal range for smallmouth bass spawning during May through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 109 for Hazel Avenue and Table 110 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 115 for Hazel Avenue and Table 116 for Watt Avenue.

Results for the three analyses are summarized in Table O-153. Table O-153, as described in Section O.4.22.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-153). There were also zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 55°F to 70°F optimal range for smallmouth bass spawning, there were 0 month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero and one month-water year type combinations (0.0% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were one and zero month-water year type combinations (6.7% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were also zero and two month-water year type combinations (0.0% and 13.2%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Without VA** for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-153). There were zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 55°F to 70°F optimal range for smallmouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero and one month-water year type combinations (0.0% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero month-water year type combinations (0.0%) with unfavorable results at Hazel Avenue and Watt Avenue.

- Under **Alternative 2 Without TUCP Delta VA** for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-153). There were zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 55°F to 70°F optimal range for smallmouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there was one month-water year type combination (6.7%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero and two month-water year type combinations (0.0% and 13.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-153). There were one and zero month-water year type combinations (6.7% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 55°F to 70°F optimal range for smallmouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were three and zero month-water year type combinations (20.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero and two month-water year type combinations (0.0% and 13.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, the four phases of Alternative 2 would have similar positive and negative effects on water temperature conditions for spawning black basses in the lower American River.

<u>Summary</u>

Overall, under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 flow modeling had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will remain largely similar to the No Action Alternative, except April when minor beneficial impacts on largemouth, smallmouth, and spotted bass may occur. Temperature modeling suggests that the four phases of Alternative 2 would have both beneficial and adverse effects.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters. However, they require large quantities of food; they are likely to remain in slower moving waters of the stream or move vertically within the lake to accommodate preferences.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam and at H Street indicate that minor (≤ 5%) increase and/or decrease is estimated for most months except April under Alternative 2 With TUCP with Systemwide VA when a slight increase occurs (6% below Nimbus dam and 7% at H street) (Table O-226 through Table O-229 and Table O-230 through Table O-233). These results suggest flows will remain largely similar, except April which would have a slight increase in flow. Flow effects on largemouth, smallmouth, and spotted bass would be generally similar to the No Action Alternative under Alternative 2.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for growth for largemouth bass during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 107 for Hazel Avenue and Table 108 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 111 for Hazel Avenue and Table 112 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F optimal range for growth in smallmouth bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 113 for Hazel Avenue and 114 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 75°F to 87°F preferred summer-time range for spotted bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 117 for Hazel Avenue and Table 118 for Watt Avenue.

Results for the four analyses are summarized in Table O-154. Table O-154, as described in Section O.4.22.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0% with favorable results at both Hazel Avenue and Watt Avenue (Table O-154). There were also zero month-water year type combinations (0%,) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass, there were one and zero month-water year type combinations (6.7% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and zero month-water year type combinations (6.7% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were 0 month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were also zero month-

water year type combinations (0%,) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 75°F to 87°F preferred summer-time range for spotted bass, there were zero and one month-water year type combinations (0.0% and 6.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0%,) with unfavorable results at both Hazel Avenue and Watt Avenue.

- Under **Alternative 2 Without TUCP Without VA** for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0% with favorable results at both Hazel Avenue and Watt Avenue (Table O-154). There were also zero month-water year type combinations (0%,) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass, there were one and zero month-water year type combinations (6.7% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and zero month-water year type combinations (6.7% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were 0 month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were also 0 month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 75°F to 87°F preferred summer-time range for spotted bass, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were also zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Delta VA** for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-154). There were also zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass, there were three and zero month-water year type combinations (20.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and zero month-water year type combinations (6.7% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were 0 month-water year type combinations (0.0% with favorable results at both Hazel Avenue and Watt Avenue. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 75°F to 87°F preferred summer-time range for spotted bass, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.
- Under **Alternative 2 Without TUCP Systemwide VAs** for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-154). There were also zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 66°F water temperature lower end

of observed summer-time range of non-spawning adult smallmouth bass, there were two and zero month-water year type combinations (13.3% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were three and zero month-water year type combinations (20.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were also zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 75°F to 87°F preferred summer-time range for spotted bass, there were zero and one month-water year type combinations (0.0% and 6.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

Overall, the four phases of Alternative 2 would have positive and negative effects on water temperature conditions for non-spawning adult black bass species in the lower American River.

Summary

Overall, there were differences between all phases of Alternative 2 and the No Action Alternative in CalSim 3 flow and temperature modeling. The differences determined by CalSim 3 modeling suggests spawning habitat extent will remain largely similar, except one to two months out of the year with slight beneficial and/or adverse impacts on largemouth, smallmouth, and spotted bass. The water temperature analysis indicates beneficial and adverse impacts on non-spawning largemouth, smallmouth, and spotted bass in the lower American River.

O.5.22.4 Stanislaus River

Spawning

Spawning for all three taxa occurs in cooler, shallow waters with flow. See details in Section O.4.22.1 above for spawning timing for each species. The Stanislaus River supports spawning for largemouth bass and spotted bass.

Potential Changes to Largemouth and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 simulated averaged water year type flows fluctuates between minor (≤ 1%) to slight (≤ 13%) increases and minor (≤ 1%) to slight (≤ 8%) decreases are estimated at Goodwin Dam and mouth of the Stanislaus River (Table O-234 through Table O-237 and Table O-238 through Table O-241). At Goodwin Dam, slight (≤ 12%) increases are expected in July and a slight (8%) decrease in April. At the mouth of the Stanislaus River, flow is expected to remain similar (<5%) to the No Action Alternative April through July. These results suggest flows may be anticipated to have generally negligible impacts on largemouth, smallmouth, and spotted bass.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 78 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 82 for Orange Blossom Bridge.

Results for the two analyses are summarized in Table O-155. Table O-155, as described in Section O.4.22.4, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there was one month-water year type combinations (6.7%) with favorable and 0 month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-155). For the 58.1°F to 73.4°F observed range for spotted bass spawning, there was two month-water year type combinations (13.3%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-155).

Overall, the four phases of Alternative 2 would have positive effects on water temperature conditions for spawning black basses in the Stanislaus River.

Summary

CalSim 3 modeling suggests that projected flows in the Stanislaus River under Alternative 2 are expected to have negligible impacts on spawning for largemouth, smallmouth, and spotted bass. Analysis of projected water temperature changes suggests that Alternative 2 would likely have positive impacts on spawning behavior for these species in the Stanislaus River.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters. However, they require large quantities of food; they are likely to remain in slower moving waters of the stream or move vertically within the reservoirs to accommodate preferences.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 simulated averaged water year type flows fluctuates between minor (≤ 1%) to slight (≤ 13%) increases and minor (≤ 1%) to slight (≤ 8%) decreases are estimated at Goodwin Dam and mouth of the Stanislaus River (Table O-234 through Table O-237 and Table O-238 through Table O-241). At Goodwin Dam,

slight (≤ 13%) increases are expected an average of 4 months (December, February, July, and August) and a slight (8%) decrease in April; other increases and decreases in flow are minor (≤ 5%). At the mouth, on average slight (≤ 10%) increases are expected in August and September; the remaining increases and decreases in flow are minor (≤ 4%). These results suggest flows may be anticipated to have generally beneficial on largemouth, smallmouth, and spotted bass.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for growth for largemouth bass during year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 79 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass during June through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 80 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F optimal range for growth in smallmouth bass during year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 81 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 75°F to 87°F preferred summer-time range for spotted bass during June through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 83 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-156. Table O-156, as described in Section O.4.22.4, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

- Under **Alternative 2 With TUCP Without VA** for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Road (Table O-156). For the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Road. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Road For the 75°F to 87°F preferred summer-time range for spotted bass, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Road.
- Results for **Alternative 2 Without TUCP Without VA**, **Alternative 2 Without TUCP Delta VA**, and **Alternative 2 Without TUCP Systemwide VAs** are identical to those of Alternative 2 With TUCP Without VA (Table O-156).

Overall, the four phases of Alternative 2 would have a negligible effect on water temperature conditions for non-spawning adult black bass species in the Stanislaus River at Orange Blossom Road.

Summary

CalSim 3 modeling suggests flows may have generally beneficial impacts on largemouth, smallmouth, and spotted bass. The optimal water temperature range modeling estimates were neither beneficial nor adverse for largemouth, smallmouth, and spotted bass. Overall, these results suggest generally beneficial flow impacts and negligible water temperature-related impacts on non-spawning largemouth, smallmouth, and spotted bass in the Stanislaus River under Alternative 2 compared to the No Action Alternative.

O.5.22.5 San Joaquin River

Spawning occurs in freshwater for all three taxa. This means all spawning occurs upstream of the brackish estuary. Non-spawning adults are generally more tolerant of various water quality parameters and may be found from the tributaries of the San Joaquin to the brackish estuary. As all three taxa require large quantities of food, they are more likely to be concentrated in areas with plentiful food and instream cover.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows vary between minor (≤ 3%) increases and/or decreases are estimated at Vernalis most months; however, minor (6%) to substantial (≤ 34%) increases are generally expected June through September of critically dry water years (Table O-242 through Table O-245). These results suggest flows will largely be similar to the No Action Alternative under all phases of Alternative 2, except in June through September of dry water years beneficial effects on largemouth, smallmouth, and spotted bass are expected.

Changes in water temperature from seasonal operations under the four phases of Alternative 2 compared to the No Action Alternative are likely to have a negligible impact on black basses in the San Joaquin River. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 flow modeling suggest flows will be largely similar; beneficial impacts on largemouth, smallmouth, and spotted bass may be expected June through September of dry water years. Under the four phases of Alternative 2, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.5.22.6 Bay-Delta

Non- spawning adults are present year-round predominantly in the brackish water interface where food is abundant. Larvae and Juveniles are likely to remain upstream of the brackish water interface, where plant beds and slower waters occur.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flows

All phases of Alternative 2 compared to the No Action Alternative CalSim 3 mean monthly flows vary between minor (≤5%) to substantial (≤ 52%) increases and minor (≤ 5%) to substantial (≤ 29%) decreases are estimated in the Bay-Delta (Table O-202, Table O-206, and Table O-210). For SWP and CVP exports, moderate (≤ 25%) flow increases are expected generally in April and May, and slight (≤ 13%) decreases in March and June. For Delta outflow, slight (≤ 6%) decreases are generally expected in May; all other differences in flow are minor (≤ 5%). At the confluence of Old and Middle River in the Delta, substantial (≤54%) increases are generally expected in April and May, and a slight (≤ 6%) to moderate (≤ 29%) decreases are generally expected January, March, and June; all other flow differences minor (≤ 4%). These results suggest averaged flows may be anticipated to have beneficial and adverse impacts on largemouth, smallmouth, and spotted bass.

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative CalSim 3 flow and salvage density modeling had some differences. The differences determined by CalSim 3 modeling suggests flows may have both beneficial and adverse impacts on largemouth, smallmouth, and spotted bass.

Potential Changes to Entrainment of Largemouth Bass

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on largemouth bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for largemouth bass include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of largemouth bass under Alternative 2 With TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant was generally similar and CVP Jones Pumping Plant was lower all water year types, except wet water years (Tables O-157 and O-158). At the SWP Banks Pumping Plant predicted average monthly loss was up to 20% greater for below normal water years; on critically dry water years, largemouth bass loss was up to 5% lower (Table O-157). At CVP Jones Pumping Plant predicted average monthly loss of largemouth bass was up to 12% lower on dry water years (Table O-158).

- **Alternative 2 Without TUCP Without VA**
    - Predictions from the salvage density model for largemouth bass include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of largemouth bass under Alternative 2 Without TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant were generally similar or greater and CVP Jones Pumping Plant were similar or lower all water year types (Tables O-157 and O-158). At the SWP Banks Pumping Plant predicted average monthly loss was up to 21% greater for below normal water year types (Table O-157). At CVP Jones Pumping Plant predicted average monthly loss of largemouth bass was up to 10% and 11% lower on below normal and dry water years; loss was similar to No Action Alternative all other water year types (Table O-158).
- **Alternative 2 Without TUCP Delta VA**
    - Predictions from the salvage density model for largemouth bass include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of largemouth bass under Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at the SWP Banks Pumping Plant was generally similar or greater and CVP Jones Pumping Plant was similar or lower all water year types (Tables O-157 and O-158). At the SWP Banks Pumping Plant predicted average monthly loss was up to 20% and 109%greater for below normal and critically dry water years, respectively (Table O-157). At CVP Jones Pumping Plant predicted average monthly loss of largemouth bass was up to 12% lower on dry water years (Table O-158).
- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for largemouth bass include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of largemouth bass under Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at the SWP Banks Pumping Plant was generally similar or greater and CVP Jones Pumping Plant was similar or lower all water year types (Tables O-157 and O-158). At the SWP Banks Pumping Plant predicted average monthly loss was up to 20% and 113% greater on below normal and critically dry water years (Table O-157). At CVP Jones Pumping Plant predicted average monthly loss of largemouth bass was up to 11% lower on dry water years (Table O-158).

Potential Changes to Entrainment of Smallmouth Bass

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on smallmouth bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for smallmouth bass include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of smallmouth bass of Alternative 2 With TUCP Without VA compared to the No Action at SWP Banks Pumping Plant was similar all water year types, except in dry water years when loss would decrease and critically dry water year types when no fish are expected; at CVP Jones Pumping Plant loss would be similar on below normal and critically dry water year types, all other water year types have no anticipated loss (Tables O-159 and Table O-160). At the SWP Banks Pumping Plant predicted average monthly loss decreased up to 5% in October of dry water years and was similar to the No Action Alternative all other water years loss is expected (Table O-159). Historic loss of smallmouth bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.
- **Alternative 2 Without TUCP Without VA**
    - Predictions from the salvage density model for smallmouth bass include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.
    - Predicted average monthly loss of smallmouth bass of Alternative 2 Without TUCP Without VA compared to the No Action Alternative at SWP Banks Pumping Plant was similar all water year types, except in below normal and dry water years when loss would decrease and critically dry water year types when no fish are expected; at CVP Jones Pumping Plant loss would be similar on below normal and critically dry water year types, all other water year types have no anticipated loss (Table O-159 and Table O-160). At the SWP Banks Pumping Plant predicted average monthly loss decreased up to 5% in October of below normal water years and October and March of dry water years (Table O-159). Historic loss of smallmouth bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.
- **Alternative 2 Without TUCP Delta VA**
    - Predictions from the salvage density model for smallmouth bass include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at

SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.

- Predicted average monthly loss of smallmouth bass of Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at SWP Banks Pumping Plant was similar all water year types, except in below normal water years when loss would decrease and critically dry water year types when no fish are expected; at CVP Jones Pumping Plant loss would decrease on below normal water years and be similar critically dry water years, all other water year types have no anticipated loss (Table O-159 and Table O-160). At the SWP Banks Pumping Plant predicted average monthly loss increased up to 5% in October of dry water years (Table O-159). At the CVP Jones Pumping Plant predicted average monthly loss decreased up to 10% January through March and May of below normal water years (Table O-160). Historic loss of smallmouth bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for smallmouth bass include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of smallmouth bass of Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at SWP Banks Pumping Plant was similar all water year types, except critically dry water year types when no fish are expected; at CVP Jones Pumping Plant loss would decrease on below normal and critically dry water year types, all other water year types have no anticipated loss (Table O-159 and Table O-160). At the CVP Jones Pumping Plant predicted average monthly loss decreased up to 12% January through March and May of below normal water years (Table O-160). Historic loss of smallmouth bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Potential Changes to Entrainment of Spotted Bass

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on spotted bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**
    - Predictions from the salvage density model for spotted bass include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.

- Predicted average monthly loss of spotted bass of Alternative 2 With TUCP Without VA compared to the No Action Alternative at SWP Banks Pumping Plant was similar in below normal water years and no fish are expected all other water year types; at CVP Jones Pumping Plant loss was similar most water year types, except critically dry water years when loss would decrease (Table O-161 and Table O-162). At the CVP Jones Pumping Plant predicted average monthly loss decreased up to 10% in January and August of critically dry water years (Table O-162). Historical loss of spotted bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

- **Alternative 2 Without TUCP Without VA**

  - Predictions from the salvage density model for spotted bass include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.

  - Predicted average monthly loss of spotted bass of Alternative 2 Without TUCP Without VA compared to the No Action Alternative at SWP Banks Pumping Plant decreased below normal water years and no fish are expected all other water year types; at CVP Jones Pumping Plant loss was similar most water year types, except critically dry water years when loss would decrease (Table O-161 and Table O-162). At the SWP Banks Pumping Plant predicted average monthly loss decreased up to 6% in March of below normal water years (Table O-161). At the CVP Jones Pumping Plant predicted average monthly loss decreased up to 7% in January and August of critically dry water years (Table O-162). Historical loss of spotted bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

- **Alternative 2 Without TUCP Delta VA**

  - Predictions from the salvage density model for spotted bass include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.

  - Predicted average monthly loss of spotted bass of Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at SWP Banks Pumping Plant decreased below normal water years and no fish are expected all other water year types; at CVP Jones Pumping Plant loss was similar most water year types, except below normal and critically dry water years when loss would decrease (Table O-161 and Table O-162). At the SWP Banks Pumping Plant predicted average monthly loss decreased up to 29% greater in March of below normal water years (Table O-161). At the CVP Jones Pumping Plant predicted average monthly loss decreased up to 12% in March, April, and December of below normal water years and 11% in January and August of dry water years (Table O-162).

- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for spotted bass include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of spotted bass of Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at SWP Banks Pumping Plant decreased below normal water years and no fish are expected all other water year types; at CVP Jones Pumping Plant loss was similar most water year types, except below normal and critically dry water years when loss would decrease (Table O-161 and Table O-162). At the SWP Banks Pumping Plant predicted average monthly loss decreased up to 27% greater in March of below normal water years (Table O-161). At the CVP Jones Pumping Plant predicted average monthly loss decreased up to 13% in March, April, and December of below normal water years and 12% in January and August of dry water years (Table O-162).

Summary

Overall, under all phases of Alternative 2 compared to the No Action Alternative salvage density modeling had some differences. The salvage density modeling predicted monthly largemouth bass loss to due entrainment under Alternative 2 compared to the No Action Alternative are similar or lower (CVP Jones Pumping Plant) most water year types and generally greater (SWP Banks Pumping Plant) in below normal and critically dry water years. The salvage density modeling predicted monthly loss of smallmouth bass under Alternative 2 compared to the No Action Alternative are similar or slightly to largely lower for smallmouth and spotted bass for nearly all water year types. Overall, these results suggest largemouth bass loss decreases at CVP Jones Pumping Plant most water year types and increases at SWP Banks Pumping Plant during below normal and critically dry water year types due to entrainment; results suggest generally beneficial flow impacts on smallmouth and spotted bass loss decreases from entrainment under Alternative 2.

O.5.23 Starry Flounder

O.5.23.1 Bay-Delta

Adult starry flounder primarily inhabit coastal marine waters (Orcutt 1950; Haertel and Osterberg 1967; Bottom et al. 1984; Hieb and Baxter 1993). Distribution of age-0 juveniles within the San Francisco Estuary and Delta is primarily in Suisun Bay and San Pablo Bay, with lower abundance in the west Delta (Baxter et al. 1999). Starry flounder older than age 1 (age-1+ fish) occur principally in San Pablo Bay, Suisun Bay, and Central Bay (Baxter et al. 1999).

Starry flounder can tolerate a wide range of salinities. In the Sacramento and San Joaquin Rivers, starry flounder have been observed in salinities as low as 0.02–0.06 ppt (i.e., essentially fresh water) (Orcutt 1950). Age-0 and age-1+ starry flounder are a common species in estuarine habitats along the West Coast (see Orcutt 1950; Pearson 1989; Emmett et al. 1991; Baxter et al. 1999; Kimmerer 2002b).

Spawning occurs primarily during the winter months of December and January (Orcutt 1950). By age-2 many starry flounder are nearing reproductive maturity and have migrated to ocean habitats adjacent to their natal estuaries. Adults may move seasonally into shallow coastal waters to spawn, perhaps in proximity to estuaries to take advantage of estuarine circulation which would advect fertilized eggs near the bottom into nursery areas.

Potential Changes to Starry Flounder from Seasonal Operations

Delta Outflow vs. Bay-Delta Species Abundance

- **Alternative 2 With TUCP Without VA**
    - Differences in Delta outflow between March and June due to seasonal operations under Alternative 2 With TUCP Without VA compared with the No Action Alternative may have effects on starry flounder annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the starry flounder.
    - Predictions from the Delta Outflow model for starry flounder indicated that the overall average abundance index for Alternative 2 With TUCP Without VA would essentially be similar to mean abundance under the No Action Alternative across all water year types (ranging from -2% to -3%, +3% in critically dry years).
- **Alternative 2 Without TUCP Without VA**
    - Differences in Delta outflow between March and June due to seasonal operations under Alternative 2 Without TUCP and without VA compared with the No Action Alternative may have effects on starry flounder annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the starry flounder.
    - Predictions from the Delta Outflow model for starry flounder indicated that the overall average abundance index for Alternative 2 Without TUCP and without VA would essentially be similar to mean abundance under the No Action Alternative across all water year types except critically dry water year types (-4% to 0%, +17% during critically dry water year types).
- **Alternative 2 Without TUCP Delta VA**
    - Differences in Delta outflow between March and June due to seasonal operations under Alternative 2 Without TUCP Delta VA compared with the No Action Alternative may have effects on starry flounder annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the starry flounder.

- Predictions from the Delta Outflow model for starry flounder indicated that the overall average abundance index for Alternative 2 Without TUCP Delta VA would essentially be similar to mean abundance under the No Action Alternative across all water year types except in critically dry years (ranging from -1% to +4%, +17% in critically dry years).

- **Alternative 2 Without TUCP Systemwide VA**

  - Differences in Delta outflow between March and June due to seasonal operations under Alternative 2 Without TUCP and systemwide VA compared with the No Action Alternative may have effects on starry flounder annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the starry flounder.

  - Predictions from the Delta Outflow model for starry flounder indicated that the overall average abundance index for Alternative 2 Without TUCP Systemwide VA would potentially lead to slightly higher starry flounder abundances than the No Action Alternative in the driest years (+8% in below normal Years, +9% in dry years, and +24% in critically dry years).

Summary

Alternative 2 relative to the No Action Alternative and their impacts on starry flounder abundance in the Delta generally differ between each phase but would best be explained in three groups due to differences in flow. The first group would be Alternative 2 With TUCP and without VA, and Alternative 2 Without TUCP and Delta VA. Under each of these phases, impacts would generally be negligible, with overall starry flounder abundance predicted to be similar to the No Action Alternative across all water year types with the exception being critically dry years, when abundance would slightly increase. Alternative 2 Without TUCP Without VA would likely have no impacts on starry flounder, as abundance was found to be essentially similar to the No Action Alternative across all water year types. Finally, Alternative 2 Without TUCP Systemwide VA would possibly be the most beneficial phase, potentially leading to higher starry flounder abundances than the No Action Alternative in all types of dry years.

Potential Changes to Entrainment of Starry Flounder

Differences in exports under the four phases of Alternative 2 compared with the No Action Alternative may have effects on starry flounder entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

- **Alternative 2 With TUCP Without VA**

  - Predictions from the salvage density model for starry flounder include mean monthly total exports. Table O-202 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 With TUCP Without VAs and the No Action Alternative.

- Predicted average monthly loss of starry flounder under Alternative 2 With TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant increased most water year types, except critically dry water years when loss was similar; at CVP Jones Pumping Plant loss was similar most water year types, except critically dry water years when loss decreased (Table O-163 and Table O-164). At the SWP Banks Pumping Plant predicted average monthly loss increase ranged from 15% in December through July of wet water years and February through August of below normal water years to 49% in March, April, May, July, August, and November of dry water years (Table O-163). At CVP Jones Pumping Plant predicted average monthly loss was generally similar except during January and September of critically dry water year types when loss decreased up to 8% (Table O-164). Historical loss of starry flounder at both facilities is infrequent, and this is a driver of low values of predicted loss.

- **Alternative 2 Without TUCP Without VA**

  - Predictions from the salvage density model for starry flounder include mean monthly total exports. Table O-203 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP Without VAs and the No Action Alternative.

  - Predicted average monthly loss of starry flounder under Alternative 2 Without TUCP Without VA compared to the No Action Alternative at the SWP Banks Pumping Plant increased or decreased all water year types and CVP Jones Pumping Plant was similar all water year types (Table O-163 and Table O-164). At the SWP Banks Pumping Plant predicted average monthly loss increase ranged from 15% in December through July of wet water years to 49% in March, April, May, July, August, and November of dry water years; loss decreased in October of critically dry water years up to 10% (Table O-163). Historical loss of starry flounder at both facilities is infrequent, and this is a driver of low values of predicted loss.

- **Alternative 2 Without TUCP Delta VA**

  - Predictions from the salvage density model for starry flounder include mean monthly total exports. Table O-204 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.

  - Predicted average monthly loss of starry flounder under Alternative 2 Without TUCP Delta VA compared to the No Action Alternative at the SWP Banks Pumping Plant increased most water year types, except critically dry water years when loss decreased; at CVP Jones Pumping Plant loss decreased most water year types, except above normal and critically dry water years when loss was similar (Table O-163 and Table O-164). At the SWP Banks Pumping Plant predicted average monthly loss increase ranged from 7% in December through July of above normal water years to 49% in March, April, May, July, August, and November of dry water years; loss decreased in October of critically dry water years up to 10% (Table O-163). At CVP Jones Pumping Plant predicted average

monthly loss decrease ranged from 5% in June through October of wet water years and May and November of below normal water years to 11% in March through August of dry water years (Table O-163). Historical loss of starry flounder at both facilities is infrequent, and this is a driver of low values of predicted loss.

- **Alternative 2 Without TUCP Systemwide VA**
    - Predictions from the salvage density model for starry flounder include mean monthly total exports. Table O-205 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 2 Without TUCP with Delta VAs and the No Action Alternative.
    - Predicted average monthly loss of starry flounder under Alternative 2 Without TUCP Systemwide VA compared to the No Action Alternative at the SWP Banks Pumping Plant increased most water year types, except critically dry water years when loss was similar; at CVP Jones Pumping Plant loss decreased in most water year types, except above normal and critically dry water years when loss was similar (Table O-163 and Table O-164). At the SWP Banks Pumping Plant predicted average monthly loss increase ranged from 6% in December through July of above normal water years to 22% in March, April, May, July, August, and November of dry water years (Table O-163). At CVP Jones Pumping Plant predicted average monthly loss decrease ranged from 5% in June through October of wet water years and May and November of below normal water years to 12% in March through August of dry water years (Table O-163). Historical loss of starry flounder at both facilities is infrequent, and this is a driver of low values of predicted loss.

Summary

For salvage density at SWP Banks Pumping Plant, there would be an adverse impact on starry flounder in most water year types, except for critically dry years when loss would be negligible or minorly beneficial. Salvage loss at CVP Jones Pumping Plant was a negligible impact for Alternative 2 With TUCP Without VA and without TUCP Without VA. For Alternative 2 Without TUCP Delta VA and without TUCP Systemwide VA, there would be a beneficial impact on salvage, except during above normal and critically dry years when loss would be negligible.

O.5.24 Coastal Pelagic Species

O.5.24.1 Potential Changes to Northern Anchovy and Pacific Herring from Seasonal Operations

Northern anchovy and Pacific herring could be subject to operational effects of the Proposed Action as it pertains to Delta outflow and its effect on the salinity field. However, the effects on salinity would be small relative to the salinity tolerance of Coastal Pelagic Species EFH such as Northern Anchovy (Baxter et al. 1999). Kimmerer et al. (2009) showed for Northern Anchovy that neither indices of habitat extent nor indices of abundance were related to X2, an index of Delta outflow and its effects.

Kimmerer (2009) found Pacific herring abundance indices were not associated with flow. However, Pacific herring do utilize the San Francisco Bay Estuary as spawning and rearing habitat (Pak et al. 2023, Grimaldo et al. 2020, Watters et al. 2004). Grimaldo et al. (2020) found Pacific herring larvae presence and abundance was lower in landward regions (e.g. Suisun Bay) during a high outflow year, likely due to either increased advection from high flows or reduced net landward movement via gravitational circulation. Juvenile herring abundance in Suisun Bay in the spring is associated with saltier conditions that allow their range to expand landward (Pak et al. 2023).

O.5.24.2 Potential Changes to Entrainment of Northern Anchovy and Pacific Herring

There are no expected impacts to entrainment of Northern anchovy due to operations since the distribution in the San Francisco Estuary has shifted towards higher salinities (> 20) since the introduction of the invasive clam, Potamocorbula amurensis (Kimmerer 2006). Impacts to entrainment of Pacific herring are potentially adverse in drier water year types depending on severity but are likely to be extremely rare. Historical salvage of Pacific herring has only occurred a few times since 2000, primarily in 2014, a critically dry year (during the months of March and April), fish were also salvaged in 2019 and 2020 in much lower numbers (CDFW 2024c).

O.5.25 Upper Klamath-Trinity River Spring-run Chinook Salmon ESU

O.5.25.1 Trinity River

Spawning and Egg/Alevin Incubation

Most spring-run Chinook salmon in the Trinity River spawn from late September to mid-November, with a peak in October (Gough et al. 2021a,b). At optimal intragravel temperatures (41–55°F) the incubation period lasts 40–60 days and alevins may remain in the gravel for another 4–6 weeks (Healey 1991, Moyle 2002). In the Trinity River, spring-run Chinook salmon incubation and emergence typically occurs through February (Leidy and Leidy 1984). The effects of flow and water temperature on spring-run Chinook salmon spawning and egg/alevin incubation may therefore occur from approximately mid-September through February.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

<u>Alternative 2 With TUCP Without VA</u>

Under Alternative 2 With TUCP Without VA, modeled monthly average flows in the Trinity River below Lewiston Dam would be at least 5% lower than the No Action Alternative only in November of above normal water years, in December of below normal water years, and in February of wet water years (Table O-174). Modeled monthly average flows under Alternative 2 With TUCP Without VA would increase by at least 5% in February and March of above normal water years compared with the No Action Alternative. The November flow decrease would occur during the primary spring-run Chinook salmon spawning period and the December and February flow decreases, as well as the February flow increase, would occur during the egg/alevin incubation period. The monthly flow differences would have minor effects on the availability or suitability of spawning and egg/alevin incubation habitat for spring-run Chinook salmon relative to the No Action Alternative. Under Alternative 2 With TUCP Without VA, like the No Action

Alternative, the variable flow regime is expected to maintain spawning habitat quality through periodic scour and redeposition of spawning gravel, which is intended to improve incubation conditions and egg-to-emergence survival by reducing fine sediment.

Modeled monthly average flow in November of above normal water years would decrease from 403 cfs under the No Action Alternative to 363 cfs under Alternative 2 With TUCP Without VA (Table O-174), which may benefit spawning spring-run Chinook salmon by increasing WUA for spawning adults in the primary spawning reach from Lewiston Dam to North Fork Trinity River compared with the No Action Alternative (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999, Rupert et al. 2017a, b). Comparative effects on spawning suitability would vary in downstream reaches, with a decrease in spawning WUA from North Fork Trinity River to South Fork Trinity River and an increase in spawning WUA from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In all reaches of the Trinity River, the effects of flow changes on spawning and incubation suitability are likely to vary spatially with channel confinement and incision (Goodman et al. 2018). Where the channel is naturally unconfined and not overly incised and where channel restoration has removed remnant riparian berms and reduced legacy channel confinement and incision, a stronger positive relationship between flow and salmonid habitat suitability, particularly for flows of approximately 300–1,200 cfs, can be expected than in areas of greater channel confinement (see Section O.4.24.1.1 for a detailed discussion). This is mainly a result of increasing habitat area, which provides more space for redds and reduces the risk of redd superimposition by later-spawning salmonids.

In December of below normal water years modeled monthly average flow in the Trinity River below Lewiston Dam would decrease from 931 cfs under the No Action Alternative to 880 cfs under Alternative 2 With TUCP Without VA (Table O-174). In February of wet water years, modeled monthly average flows would decrease from 1,843 cfs under the No Action Alternative to 1,706 cfs under Alternative 2 With TUCP Without VA. The December and February flow decreases would occur during the spring-run Chinook salmon egg/alevin incubation period. Although WUA for egg/alevin incubation is not available for the Trinity River, the lower monthly average flows in December and February under Alternative 2 With TUCP Without VA would be unlikely to change redd hydraulics or redd substrate conditions relative to the No Action Alternative, especially in areas with a confined channel where relatively minor changes in flow have little influence on water depth or velocity, and no impacts on egg/alevin incubation suitability are expected.

Modeled monthly average flow in the Trinity River below Lewiston Dam would increase in February of above normal water years from 1,194 cfs under the No Action Alternative to 1,390 cfs under Alternative 2 With TUCP Without VA and in March of above normal water years from 1,021 cfs under the No Action Alternative to 1,095 cfs under Alternative 2 With TUCP Without VA (Table O-174). The February flow increase would occur during the spring-run Chinook salmon egg/alevin incubation period but is not expected to change redd hydraulics or other conditions that may affect incubation suitability. No effects on egg/alevin incubation suitability are expected.

Modeled monthly average water temperature in the Trinity River below Lewiston Dam in November of above normal water years and December of below normal water years would not differ from the No Action Alternative (Figure O-18 and Figure O-19, respectively), while in February of wet water years the modeled monthly average water temperature may increase slightly under Alternative 2 With TUCP Without VA compared with the No Action Alternative (Figure O-17). In February of above normal water years, modeled monthly average water temperature in the Trinity River below Lewiston Dam may decrease slightly compared with the No Action Alternative. November water temperatures under Alternative 2 With TUCP Without VA would remain well below the upper water temperature objective of 56°F (Table O-11) to protect spawning spring-run Chinook salmon in the reach from Lewiston Dam to the North Fork Trinity River (Asarian et al. 2023). In December and February, water temperatures from Lewiston Dam to North Fork Trinity River would remain below the 50°F (10°C) upper optimum limit recommended by USEPA (2001, as cited in Carter 2005) in all water year types to support spring-run Chinook salmon incubation and emergence (Asarian et al. 2023). Water temperatures under Alternative 2 With TUCP Without VA would have negligible impacts on spring-run Chinook salmon spawning and incubation suitability compared with the No Action Alternative.

Compared with the No Action Alternative, the impacts of seasonal operations under Alternative 2 With TUCP Without VA would likely have minor impacts on the availability and suitability of spring-run Chinook salmon spawning and incubation habitat in the Trinity River. Overall, the impacts in the reaches most heavily used by spawning spring-run Chinook salmon would likely be negligible or slightly beneficial, with spatial variability related to the impacts of channel geometry on habitat suitability.

Alternative 2 Without TUCP Without VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be very similar to flows under Alternative 2 With TUCP Without VA, except for a smaller increase (greater than 5%) in February of above normal water years (Table O-175) and a slightly smaller decrease (greater than 5%) in February of wet water years. During the spring-run Chinook salmon spawning and incubation period, modeled monthly average flows in November of above normal water years, December of below normal water years, and February of wet water years would be at least 5% less than flows under the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on spring-run Chinook salmon spawning and incubation as those described for Alternative 2 With TUCP Without VA. Compared with the No Action Alternative, the increased average flow in February of above normal water years would is not expected to affect egg/alevin incubation suitability. Overall, the impacts of seasonal operations under Alternative 2 Without TUCP Without VA on the availability and suitability of spring-run Chinook salmon spawning and incubation habitat would likely be negligible or slightly beneficial compared with the No Action Alternative, with spatial variability related to the impacts of channel geometry on habitat suitability.

Alternative 2 Without TUCP With Delta VA

Compared with the No Action Alternative, substantial (greater than 5%) reductions in monthly average flow under Alternative 2 Without TUCP With Delta VA would occur in November of above normal water years and February of wet water years. Effects on spring-run Chinook

salmon spawning and egg/alevin incubation at these times would be nearly identical to those under Alternative 2 With TUCP Without VA. Increased flow (greater than 5%) in February of above normal water years would be unlikely to change redd hydraulics or redd substrate conditions relative to the No Action Alternative is not expected to affect egg/alevin incubation suitability.

Like Alternative 2 With TUCP Without VA, the November flow decrease would not result in changes in average water temperature in the Trinity River below Lewiston Dam (Figure O-18 and Figure O-19). Average water temperature in the Trinity River below Lewiston Dam in February of wet water years may increase slightly under Alternative 2 Without TUCP With Delta VA compared with the No Action Alternative (Figure O-17) but water temperatures from Lewiston Dam to North Fork Trinity River would remain below the 50°F (10°C) upper optimum limit recommended by USEPA (2001, as cited in Carter 2005) in all water year types to support spring-run Chinook salmon incubation and emergence (Asarian et al. 2023). The potential impacts on the availability and suitability of spring-run Chinook salmon spawning and egg/alevin incubation habitat that may result from the small November and February differences in monthly average flow and water temperature relative to the No Action Alternative would be the same as those described for Alternative 2 With TUCP Without VA.

Overall, the impacts in the reaches most heavily used by spawning spring-run Chinook salmon would likely be negligible or slightly beneficial, with spatial variability related to the impacts of channel geometry on habitat suitability.

Alternative 2 Without TUCP With Systemwide VA

Monthly average flows under Alternative 2 Without TUCP With Systemwide VA in November of above normal water years and February of wet water years would be at least 5% less than flows under the No Action Alternative and nearly identical to Alternative 2 Without TUPC With Delta VA as well as associated differences in water temperature and would have the same impacts on spring-run Chinook salmon spawning and incubation as those described for Alternative 2 Without TUCP With Delta VA.

In February of above normal water years, monthly average flow would increase by 132 cfs from 1,194 cfs under the No Action Alternative to 1,326 cfs under Alternative 2 Without TUCP With Systemwide VA (Table O-177). This increase would not be expected to have measurable impacts on depth, velocity, or substrate that could affect suitability for incubating spring-run Chinook salmon eggs/alevins. Similarly, the February flow increase would not result in measurable changes in average water temperature in the Trinity River below Lewiston Dam (Figure O-18) and there would be no change in the water temperature suitability for incubating spring-run Chinook salmon eggs/alevins relative to the No Action Alternative.

Juvenile Rearing and Emigration

In the Trinity River, spring-run Chinook salmon fry emerge from the gravel beginning in December and most emergence is complete by the end of February (Leidy and Leidy 1984). Fry and juvenile Chinook salmon rearing in the Trinity River preferentially use areas of relatively slow water velocity and habitat with woody material, undercut banks, and other complex cover (Hampton 1988, Pinnix et al. 2019). Naturally spawned juvenile spring-run Chinook salmon typically outmigrate as sub-yearlings from the Trinity River and occasionally as yearlings.

Hatchery releases of spring-run Chinook salmon also include mostly sub-yearlings and some yearling releases in spring and fall, respectively. Peak outmigration of natural and hatchery origin juveniles occurs in May, June, and July based on monitoring in the lower Trinity River near the town of Willow Creek (Harris et al. 2016; Petros et al. 2017). The effects of flow and water temperature on rearing and emigrating spring-run Chinook salmon may therefore occur from December through July.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, modeled monthly average flows in the Trinity River below Lewiston Dam would be more than 5% lower than the No Action Alternative in November of above normal water years, in December of below normal water years, and in February of wet water years (Table O-174). In February and March of above normal water years, modeled monthly average flows under Alternative 2 With TUCP Without VA would increase by at least 5% compared with the No Action Alternative.

The December, February, and March differences may have spatially variable effects on the availability and suitability of juvenile rearing and emigration habitat for spring-run Chinook salmon. The decrease in modeled monthly average flow in December of below normal water years from 931 cfs under the No Action Alternative to 880 cfs under Alternative 2 With TUCP Without VA would result in a decrease in fry WUA and an increase in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, an increase in both fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and a decrease in fry WUA and an increase in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The monthly average flow reductions in February of wet water years from 1,843 cfs to 1,706 cfs would result in reductions in WUA for fry and juvenile spring-run Chinook salmon from Lewiston Dam to Dutch Creek, small increases in fry and juvenile WUA from Dutch Creek to North Fork Trinity River, a slight decrease in fry WUA and a small increase in juvenile WUA from North Fork Trinity River to South Fork Trinity River, and little to no change in fry and juvenile WUA from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

The modeled monthly flow increase in February of above normal water years from 1,194 cfs under the No Action Alternative to 1,390 cfs under Alternative 2 With TUCP Without VA would result in an increase in Chinook salmon fry WUA and decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek and a decrease in both fry and juvenile WUA in the reaches from Dutch Creek to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In March of above normal water years, the increase in modeled monthly average flow from 1,021 cfs under the No Action Alternative to 1,095 cfs under Alternative 2 With TUCP Without VA would result in an increase in Chinook salmon fry WUA and decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, a decrease in both fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and an increase in fry WUA and very small decrease in juvenile WUA from South Fork Trinity River to Weitchpec.

Where the channel is naturally unconfined and not overly incised and in locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships and rearing WUA in some restored areas may exhibit a stronger positive relationship to flow up to approximately 3,500 cfs (Cooper-Hertel et al. 2022). Consequently, spring-run Chinook salmon WUA in all reaches is likely to vary spatially with channel confinement and incision and WUA in restored areas may be greater than described in U.S. Fish and Wildlife Service and Hoopa Valley Tribe (1999). See Section O.4.24.1.1 for additional details. The potential changes in WUA for spring-run Chinook salmon fry and juveniles may have minor, short-term effects on the ability of these life stages to access cover and preferred habitat that would occur only in a few months of the eight-month rearing period and in some reaches of the Trinity River.

In December of below normal water years, differences in modeled monthly average flows between Alternative 2 With TUCP Without VA and the No Action Alternative would not result in changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-19). In February of wet water years, reductions in modeled monthly average flows between Alternative 2 With TUCP Without VA and the No Action Alternative may slightly increase modeled monthly average water temperatures below Lewiston Dam compared with the No Action Alternative (Figure O-17). In December and February of the aforementioned water year types, modeled monthly average water temperatures at Trinity River below Lewiston Dam under Alternative 2 With TUCP Without VA would remain well below the 62.6°F water temperature objective for emigrating juvenile spring-run Chinook salmon recommended for normal and wetter water year types and the 68°F objective recommended for dry and critically dry water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the objectives are intended to be measured at Weitchpec and applicable prior to July 9, historical data and model results suggest that water temperatures in December and February would remain below both objectives under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating spring-run Chinook salmon under Alternative 2 With TUCP Without VA relative to the No Action Alternative.

Compared with the No Action Alternative, seasonal operations under Alternative 2 With TUCP Without VA would likely have negligible impacts on the availability and suitability of spring-run Chinook salmon juvenile rearing and emigration habitat in the Trinity River. The impacts would vary spatially due to the impacts of channel geometry on habitat suitability.

<u>Alternative 2 Without TUCP Without VA</u>

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be very similar to flows under Alternative 2 With TUCP Without VA, except for a smaller increase (greater than 5%) in February of above normal water years and a slightly larger decrease (greater than 5%) in February of wet water years (Table O-175). Monthly average flows in November of above normal water years, December of below normal water years, and February of wet water years would be at least 5% less than flows under the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same effects on spring-run Chinook salmon juvenile rearing and emigration as those described for Alternative 2 With TUCP Without VA.

In February of above normal water years, modeled monthly average flow would increase by 145 cfs from 1,194 cfs under the No Action Alternative to 1,339 cfs under Alternative 2 Without TUCP Without VA (Table O-175). This increase may result in a small increase in spring-run Chinook salmon fry WUA and a decrease in juvenile WUA in the Trinity River from Lewiston Dam to Dutch Creek and small decreases in fry and juvenile WUA in downstream reaches (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The flow increase in February of above normal water years would not result in changes in modeled average water temperature in the Trinity River below Lewiston Dam (Figure O-18) and, as described for Alternative 2 With TUCP Without VA, there would be no change in the temperature suitability for rearing and emigrating spring-run Chinook salmon relative to the No Action Alternative.

Alternative 2 Without TUCP With Delta VA

Compared with the No Action Alternative, substantial (greater than 5%) reductions in modeled monthly average flow in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Delta VA would occur in November of above normal water years and February of wet water years (Table O-176). Modeled monthly average flow in February of above normal water years would increase substantially (greater than 5%) under Alternative 2 Without TUCP With Delta VA relative to the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same effects on spring-run Chinook salmon juvenile rearing and emigration as those described for Alternative 2 With TUCP Without VA for November and February.

Alternative 2 Without TUCP With Systemwide VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be similar to flows under Alternative 2 Without TUCP With Delta VA, but with a larger increase in February of above normal water years (Table O-177). Modeled monthly average flows in November of above normal water years and February of wet water years would be at least 5% less than flows under the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on spring-run Chinook salmon juvenile rearing and emigration as those described for Alternative 2 Without TUCP With Delta VA.

In February of above normal water years, modeled monthly average flow would increase by 132 cfs from 1,194 cfs under the No Action Alternative to 1,326 cfs under Alternative 2 Without TUCP With Systemwide VA (Table O-177). This increase may result in a small increase in spring-run Chinook salmon fry WUA and a decrease in juvenile WUA in the Trinity River from Lewiston Dam to Dutch Creek and small decreases in fry and juvenile WUA in downstream reaches (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The flow increase in February of above normal water years would not result in changes in average water temperature in the Trinity River below Lewiston Dam (Figure O-18) and, as described for Alternative 2 With TUCP Without VA, there would be no change in the temperature suitability for rearing and emigrating spring-run Chinook salmon relative to the No Action Alternative.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon typically enter the Trinity River from April through September. By the end of July, most fish have arrived at the primary spawning reach, which extends from Lewiston Dam downstream to the confluence with the North Fork Trinity River. After entering freshwater, spring-run Chinook salmon remain in deep pools until the onset of the spawning season, which typically begins in late September (Leidy and Leidy 1984; Gough et al. 2019, 2021a,b). The effects of flow and water temperature on migrating and holding spring-run Chinook salmon adults may therefore occur from April through September.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, seasonal operations in the Trinity River are expected to provide similar habitat conditions for spring-run Chinook salmon upstream migration and holding to the No Action Alternative. Like the No Action Alternative, Trinity River flow and water temperature below Lewiston Dam would be managed to maintain suitable habitat conditions for anadromous fish. During the April–September spring-run Chinook salmon upstream migration and holding period there would be minor (less than 5%) differences in modeled monthly average flow between the two alternatives in April and no differences in May through September (Table O-174). The minor differences in April are not expected to result in changes in habitat suitability for migrating and holding spring-run Chinook salmon. During the entirety of the adult upstream migration and holding period, monthly average flows would be approximately 500 cfs or greater in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and holding habitat to support pre-spawning spring-run Chinook salmon.

Modeled monthly average flows in July, August and September, when adult spring-run Chinook salmon may be holding and water temperatures are typically at or near seasonal highs (Asarian et al. 2023), would be the same under Alternative 2 With TUCP Without VA as under the No Action Alternative (Table O-174). Under both alternatives, July–September flows would maintain suitable water temperatures for adult upstream migration (60°F from July 1 to September 14 and 56°F from September 15 to September 30 at Douglas City [RM 93.7]; Table O-11) (Asarian et al. 2023). Although downstream warming during the warmest months and driest water year types could result in unsuitable water temperatures for migrating spring-run Chinook salmon at some locations (Buxton 2023), the likelihood of this occurring would be the same under Alternative 2 With TUCP Without VA as under the No Action Alternative because flows would be the same under both alternatives. Under Alternative 2 With TUCP Without VA, suitability for adult spring-run Chinook salmon upstream migration and holding would be the same as under the No Action Alternative.

Alternative 2 Without TUCP Without VA

During the April–September spring-run Chinook salmon upstream migration and holding period, modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to flows under Alternative 2 With TUCP Without VA, with minor (less than 5%) differences in modeled monthly average flow between the two alternatives in April and no differences in May through September (Table O-175). The

monthly average flows and associated monthly average water temperatures would have the same impacts on migrating and holding spring-run Chinook salmon as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Delta VA

During the April–September spring-run Chinook salmon upstream migration and holding period, modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Delta VA would be very similar to flows under Alternative 2 With TUCP Without VA, with minor (less than 5%) differences in modeled monthly average flow between the two alternatives in April and no differences in May through September (Table O-176). The monthly average flows and associated monthly average water temperatures would have the same impacts on migrating and holding spring-run Chinook salmon as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Systemwide VA

During the April–September spring-run Chinook salmon upstream migration and holding period, modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be nearly identical to flows under Alternative 2 With TUCP Without VA, with minor (less than 5%) differences in modeled monthly average flow between the two alternatives in April and no differences in May through September (Table O-177). The monthly average flows and associated monthly average water temperatures would have the same impacts on migrating and holding spring-run Chinook salmon as those described for Alternative 2 With TUCP Without VA.

O.5.26 Southern Oregon/Northern California Coast Coho Salmon ESU

O.5.26.1 Trinity River

Spawning and Egg/Alevin Incubation

Most coho salmon spawning in the mainstem Trinity River occurs in November and December between Lewiston Dam and the North Fork Trinity River (Section O.1.2.5.1, *Coho salmon, Southern Oregon/Northern California Coast ESU*). Coho salmon eggs and alevins in the Trinity and Klamath River Basins may be present in the gravel from November to mid-May (Leidy and Leidy 1984), so effects of flow and water temperature on coho salmon eggs and alevins may occur during this period.

Potential Changes to Coho Salmon from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, modeled monthly average flows in the Trinity River below Lewiston Dam would be at least 5% lower than the No Action Alternative only in November of above normal water years, in December of below normal water years, and in February of wet water years (Table O-174). Like all other phases of Alternative 2, monthly average flows averaged across the full simulation period would be slightly less in November through April than monthly average flows under the No Action Alternative. The November and December flow decreases would occur during the primary coho salmon spawning period.

Reduced modeled monthly average flow in November of above normal water years from 403 cfs under the No Action Alternative to 363 cfs under Alternative 2 With TUCP Without VA may provide minor benefits to spawning coho salmon by slightly increasing WUA for spawning adults in most portions of the Trinity River between Lewiston Dam and Weitchpec, including the most heavily used spawning reach immediately downstream of Lewiston Dam (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999; Rupert et al. 2017a, 2017b). Reduced monthly average flow in December of below normal water years from 931 cfs to 880 cfs may increase spawning WUA for coho salmon in lesser-used downstream portions of the Trinity River but is predicted to slightly reduce spawning WUA in a more heavily used upstream reach compared to the No Action Alternative (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The effect of flow differences on spawning suitability is likely to vary spatially with channel confinement and incision (Goodman et al. 2018). In locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships. The November and December flow decreases would not result in measurable changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (see Appendix F, Figure F.2.11-1-1), and average water temperatures under Alternative 2 With TUCP Without VA would remain well below the upper water temperature objective of 56°F to protect spawning coho salmon in the reach from Lewiston Dam to the North Fork Trinity River (Table O-11; Asarian et al. 2023).

In February of wet water years, modeled monthly average flows in the Trinity River below Lewiston Dam would be reduced from 1,843 cfs under the No Action Alternative to 1,706 cfs under Alternative 2 With TUCP Without VA. These decreases would occur during the coho salmon egg/alevin incubation period. The February flow reduction under Alternative 2 With TUCP Without VA could slightly increase the risk of dewatering of redds constructed in January compared with the No Action Alternative. This is because modeled monthly average flows under Alternative 2 With TUCP Without VA would decrease by 157 cfs from January (1,863 cfs) to February (1,706 cfs), in contrast to the No Action Alternative under which flows would decrease by only 29 cfs from January (1,872 cfs) to February (1,843 cfs) (Table O-174).

Modeled monthly average water temperature in the Trinity River below Lewiston Dam in February of wet water years may increase slightly under Alternative 2 With TUCP Without VA compared with the No Action Alternative (Figure O-17) but would remain below the 50°F upper suitability limit recommended by Washington State Department of Ecology (WDOE) (2002, as cited in Carter 2005) to support coho salmon incubation and emergence.

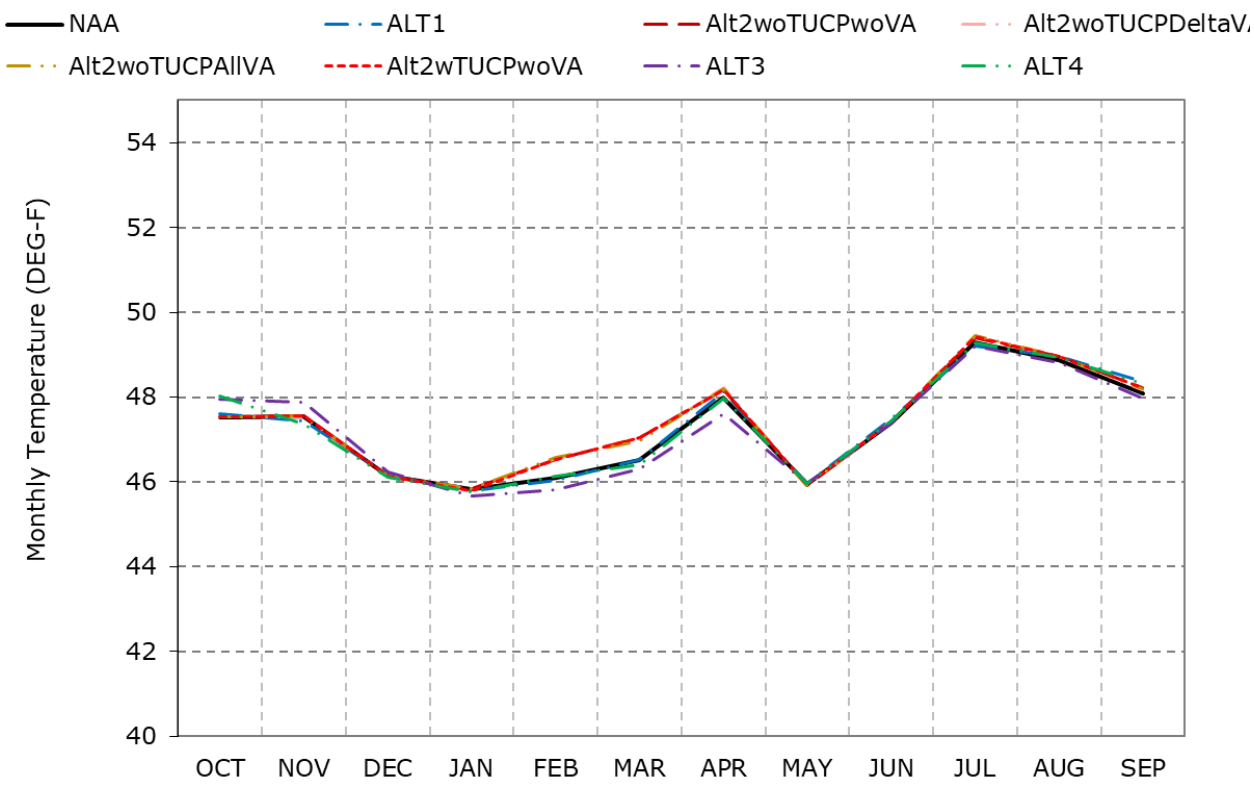

Figure O-17. Modeled Monthly Average Water Temperature in the Trinity River below Lewiston Dam in Wet Water Years

Alternative 2 Without TUCP Without VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to flows under Alternative 2 With TUCP Without VA (Table O-175) so impacts to coho spawning, egg incubation, and fry emergence habitat from flow changes and water temperature would be the same as Alternative 2 With TUCP Without VA.

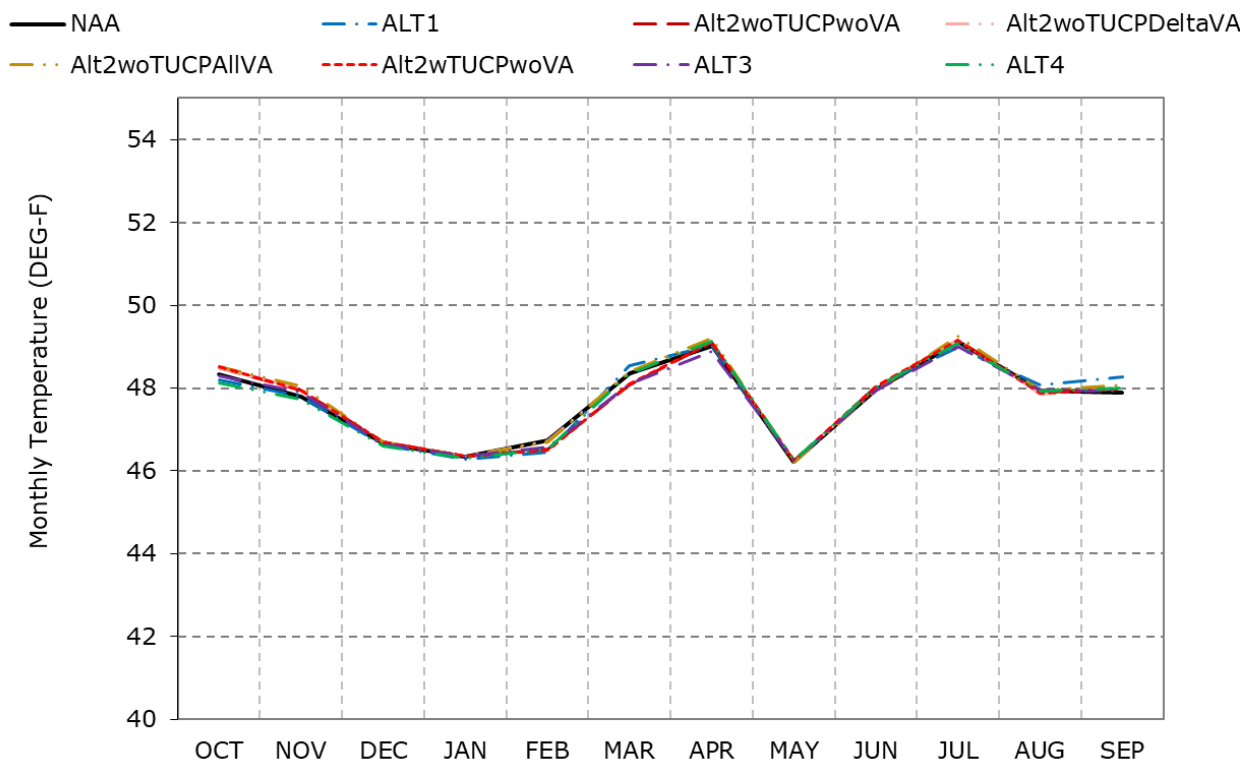

Figure O-18. Modeled Monthly Average Water Temperature in the Trinity River below Lewiston Dam in Above Normal Water Years

<u>Alternative 2 Without TUCP With Delta VA</u>

With regard to spawning, egg incubation, and fry emergence modeled monthly average flows in the Trinity River under Alternative 2 Without TUCP With Delta VA would be nearly identical to flows under Alternative 2 With TUCP Without VA in November and February (Table O-176). Compared with the No Action Alternative, greater than 5% reductions in modeled monthly average flow under Alternative 2 Without TUCP With Delta VA would occur in November of above normal water years and in February of wet water years. Flow increases are predicted to occur in February of above normal water years.

Like Alternative 2 With TUCP Without VA, the November flow decreases under Alternative 2 Without TUCP With Delta VA would not result in changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-18 and Figure O-19). Modeled monthly average water temperature in the Trinity River below Lewiston Dam in February of wet water years may increase slightly under Alternative 2 Without TUCP With Delta VA compared with the No Action Alternative (Figure O-17). The potential impacts on the availability and suitability of coho salmon spawning and egg/alevin incubation habitat that may result from the small differences in monthly average flow and water temperature relative to the No Action Alternative would be the same as those described for Alternative 2 With TUCP Without VA.

A graph of modeled water temperatures in the Trinity River in wet water years.

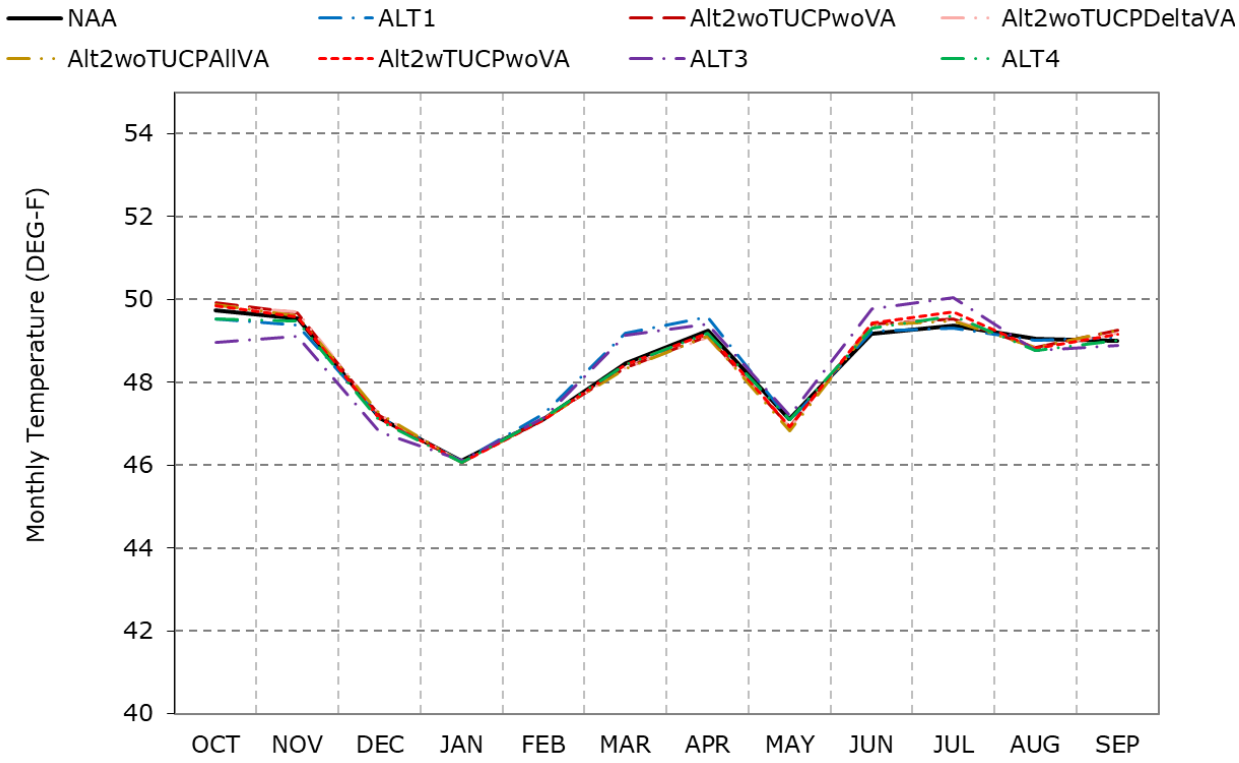

Figure O-19. Modeled Monthly Average Water Temperature in the Trinity River below Lewiston Dam in Below Normal Water Years

Alternative 2 Without TUCP With Systemwide VA

Monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be nearly identical to Alternative 2 Without TUCP With Delta VA and impacts from flow and temperature changes would be the same for coho spawning, egg incubation, and fry emergence habitat as Alternative 2 Without TUCP With Delta VA (Table O-177).

Juvenile Rearing and Emigration

Naturally spawned juvenile coho salmon in the Trinity River emerge from the gravel and begin rearing in winter and early spring, with the first captures of young-of-year (age-0) coho salmon typically occurring in early March (U.S. Fish and Wildlife Service 2023, unpublished; Yurok Tribe 2023, unpublished). Fry, juvenile, and subyearling coho salmon rearing in the Trinity River strongly prefer areas of slow water velocity and habitat with cover from woody material, overhanging vegetation, and clusters of aquatic vegetation (Hampton 1988, 1997; Chase et al. 2009; Pinnix et al. 2019). During high flows, young coho salmon use floodplains and other off-channel habitats (Chase et al. 2009). Rearing occurs year-round, typically over a period of 12–15 months, and the effects of flow and water temperature on rearing coho salmon, therefore, occur throughout the year. Most Trinity River coho salmon outmigrate to the ocean as yearling smolts between January and July (Harris et al. 2016; Petros et al. 2015; Petros et al. 2017).

Potential Changes to Coho Salmon from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, modeled monthly average flows in the Trinity River below Lewiston Dam would be more than 5% lower than the No Action Alternative in November of above normal water years, in December of below normal water years, and in February of wet water years (Table O-174). These differences may have spatially variable impacts on the availability and suitability of juvenile rearing and emigration habitat for coho salmon. The decrease in modeled monthly average flow in November of above normal water years from 403 cfs under the No Action Alternative to 363 cfs under Alternative 2 With TUCP Without VA (Table O-174) would result in minor increases in observed and predicted WUA for juvenile coho salmon in all reaches of the Trinity River from Lewiston Dam to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Similarly, the decrease in monthly average flow in December of below normal water years from 931 cfs under the No Action Alternative to 880 cfs under Alternative 2 With TUCP Without VA would result in minor increases in observed and predicted WUA for juvenile coho salmon from Lewiston Dam to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The reduced monthly average flows in February (from 1,843 cfs to 1,706 cfs) of wet water years would result in reductions in WUA for fry and juvenile coho salmon from Lewiston Dam to Dutch Creek, no change in fry and juvenile WUA from Dutch Creek to North Fork Trinity River, a slight decrease in fry WUA and a slight increase in juvenile WUA from North Fork Trinity River to South Fork Trinity River, and little to no change in fry and juvenile WUA from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The increased monthly average flows in February and March of above normal water years would result in little to no change in WUA for fry and minor reductions in WUA for juvenile coho salmon from Lewiston Dam to Weitchpec. The effect of flow differences on rearing suitability is likely to vary spatially with channel confinement and incision (Cooper-Hertel et al. 2022). In locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships. These changes in WUA for coho salmon fry and juveniles may have minor, short-term impacts on the ability of these life stages to access cover and preferred habitat that would occur only in a few months of the 12–15 month rearing period and in some reaches of the Trinity River.

In November of above normal water years and in December of below normal water years, differences in modeled monthly average flows between Alternative 2 With TUCP Without VA and the No Action Alternative would not result in changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-18 and Figure O-19, respectively). In February of wet water years, differences in monthly average flows between Alternative 2 With TUCP Without VA and the No Action Alternative may slightly increase modeled monthly average water temperatures in the Trinity River below Lewiston Dam compared with the No Action Alternative (Figure O-17). In February of above normal water years, modeled monthly average water temperature in the Trinity River below Lewiston Dam may decrease slightly compared with the No Action Alternative. In November, December, and February, of the aforementioned water year types, modeled monthly average water temperatures at Trinity River below Lewiston Dam under Alternative 2 With TUCP Without VA would remain well below the 59°F water temperature objective for emigrating juvenile coho salmon recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa

Valley Tribe 1999). Although the 59°F objective is intended to be measured at Weitchpec and applicable prior to June 4, historical data and model results suggest that water temperatures in November, December, and February would remain below the 59°F objective under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating coho salmon under Alternative 2 With TUCP Without VA relative to the No Action Alternative. The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 2 With TUCP Without VA through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives in portions of the coho salmon juvenile rearing and emigration period at downstream locations in some water year types under Alternative 2 With TUCP Without VA, water temperatures and the potential impacts on coho salmon would not differ from the No Action Alternative.

Alternative 2 Without TUCP Without VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to flows under Alternative 2 With TUCP Without VA (Table O-175) so impacts to juvenile rearing and emigration from flow changes and water temperature would be the same as Alternative 2 With TUCP Without VA...

Alternative 2 Without TUCP With Delta VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Delta VA would be nearly identical to flows under Alternative 2 With TUCP Without VA except for the changes in December of below normal water years and March of above normal water years. The modeled monthly average flows would be more than 5% lower than the No Action Alternative in November of above normal water years and in February of wet water years (Table O-176). These differences in monthly average flow and associated differences in modeled monthly average water temperature would have the same impacts on coho salmon juvenile rearing and emigration as those described for Alternative 2 With TUCP Without VA for November and February. However, Alternative 2 Without TUCP with Delta VA would not have the decrease in flows in December of below normal water years and associated increase in juvenile rearing habitat predicted under Alternative 2 With TUCP Without VA or the increase in flows in March of above normal water years and associated decrease in WUA.

Alternative 2 Without TUCP With Systemwide VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be nearly identical to flows under Alternative 2 Without TUCP With Delta VA and impacts to juvenile rearing and emigration would be the same as Alternative 2 Without TUCP With Delta VA (Table O-177). Adult Upstream Migration and Holding from August to January, coho salmon return from the ocean through the Klamath River Estuary to the Trinity River, moving upstream toward spawning habitat. Based on recent weir counts, the date of peak abundance of upstream-migrating coho salmon in the Trinity River ranges from late September to mid-November (Kier et al. 2018, 2019, 2020, 2021, 2022). After completing their upstream migration, mature coho salmon may hold for days, weeks, or sometimes months before spawning. Because most spawning occurs in November and

December, the impacts of flow and water temperature on migrating and holding coho salmon would primarily occur from August through December.

Potential Changes to Coho Salmon from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, seasonal operations in the Trinity River are expected to provide similar habitat conditions for coho salmon upstream migration and holding to the No Action Alternative. Like the No Action Alternative, Trinity River flow and water temperature below Lewiston Dam would be managed to maintain suitable habitat conditions for anadromous fish including coho salmon. During the primary coho salmon upstream migration and holding period there would be no differences in modeled monthly average flow between the two alternatives in August, September, or October and minor differences in November and December. Modeled monthly average flows in the Trinity River below Lewiston Dam would be more than 5% lower than the No Action Alternative only in November of above normal water years and in December of below normal water years (Table O-174). These differences may result in minor, short-term changes in habitat conditions but modeled monthly average flows from August through January when adult coho salmon are migrating and holding would be equal to or greater than 300 cfs in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and holding habitat to support pre-spawning coho salmon.

Modeled monthly average flows in August and September, when adult coho salmon begin migrating upstream from the ocean and water temperatures are typically at or near seasonal highs (Asarian et al. 2023), would be the same under Alternative 2 With TUCP Without VA as under the No Action Alternative (Table O-174). Under both alternatives, modeled average August and September flows of 760 cfs in wet water years and 863 cfs in all other water year types would maintain suitable water temperatures for adult upstream migration (not to exceed 60°F in August and early September and 56°F in late September at Douglas City; Table O-11) in the Trinity River (Figure O-17). Although downstream warming during August and September could result in unsuitable water temperatures for migrating coho salmon at some locations (Asarian et al. 2023), the likelihood of this occurring would be the same under Alternative 2 With TUCP Without VA as under the No Action Alternative due to the identical flows.

During the late September to mid-November peak adult migration period, the modeled monthly average flows under Alternative 2 With TUCP Without VA would be the same as the No Action Alternative except in November of above normal water years when the modeled monthly average flow would be 41 cfs lower under Alternative 2 With TUCP Without VA (363 cfs) than the No Action Alternative (403 cfs; Table O-174). In December and January, the only substantial difference in modeled monthly average flow (greater than 5%) between the two alternatives would be a reduction of 51 cfs in December in below normal water years from 931 cfs under the No Action Alternative to 880 cfs under Alternative 2 With TUCP Without VA. Neither the November flow difference nor the December flow difference would have impacts on modeled monthly average water temperature at Lewiston Dam in the respective water year types (Figure O-20 and Figure O-21), and there would be no impacts on water temperature suitability for coho salmon migration and holding relative to the No Action Alternative.

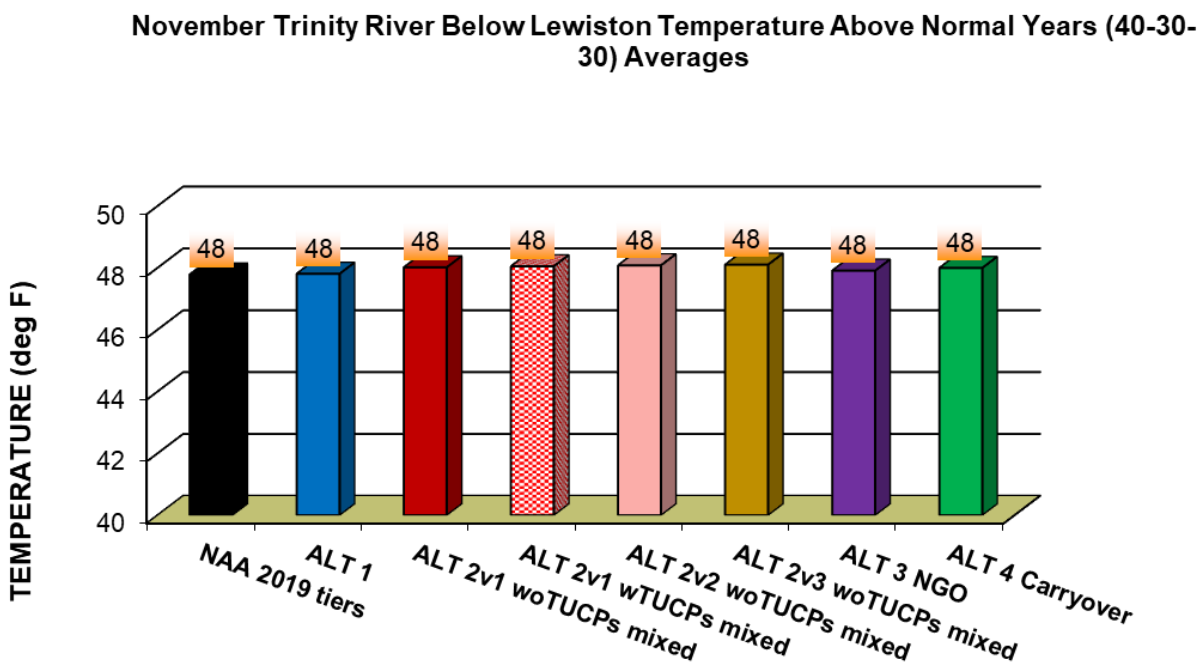

Figure O-20. Modeled November Average Water Temperature in the Trinity River below Lewiston Dam in Above Normal Water Years

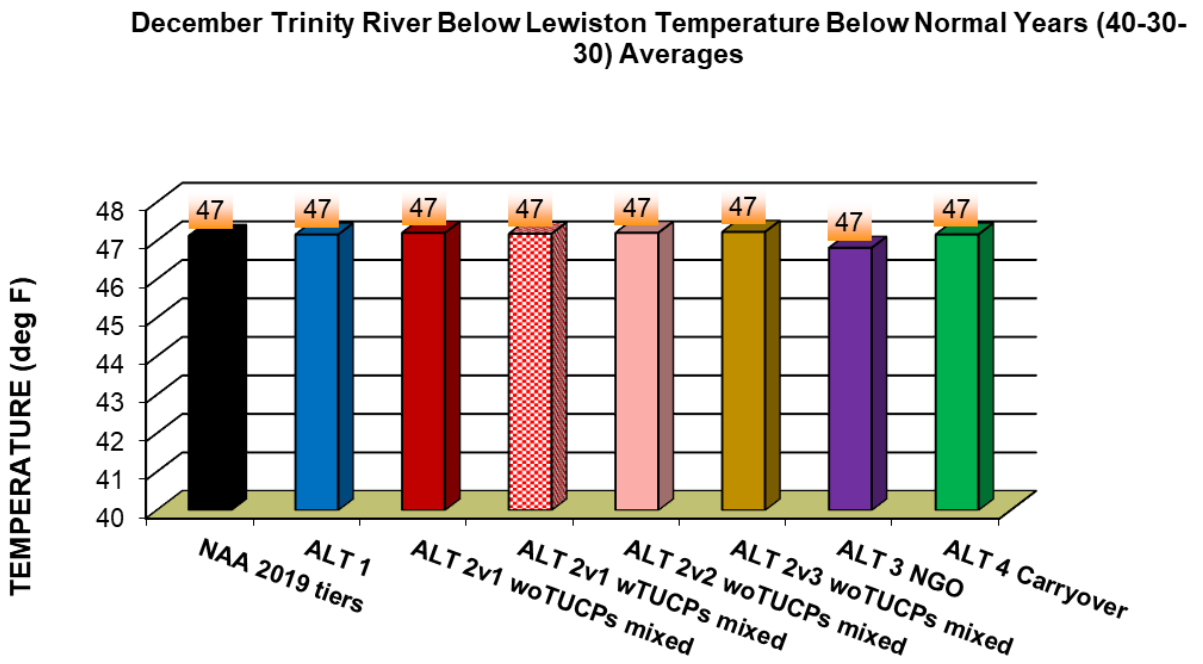

Figure O-21. Modeled December Average Water Temperature in the Trinity River below Lewiston Dam in Below Normal Water Years

Alternative 2 Without TUCP Without VA

Monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to flows under Alternative 2 With TUCP Without VA (Table O-175) so impacts to coho adult upstream migration and holding from flow changes and water temperature would be the same as Alternative 2 With TUCP Without VA and the No Action Alternative.

Alternative 2 Without TUCP With Delta VA

Monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Delta VA would be very similar to flows under Alternative 2 With TUCP Without VA (Table O-176). During the upstream migration and holding period, the differences in modeled monthly average flow and associated differences in modeled monthly average water temperature would have the same impacts on migrating and holding coho salmon as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Systemwide VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be very similar to flows under Alternative 2 With TUCP Without VA (Table O-177). During the upstream migration and holding period, the differences in modeled monthly average flow and associated differences in modeled monthly average water temperature would have the same impacts on migrating and holding coho salmon as those described for Alternative 2 With TUCP Without VA.

O.5.27 Upper Klamath-Trinity River Fall-run Chinook Salmon ESU

O.5.27.1 Trinity River

Spawning and Egg/Alevin Incubation

Most fall-run Chinook salmon in the Trinity River spawn from late October to December, with a peak in spawning occurring in November (Myers et al. 1998, Leidy and Leidy 1984). Optimal spawning temperatures for spawning are reported to be less than 55.4°F (Moyle 2002). At optimal intragravel temperatures (43–54°F) the incubation period lasts 40–60 days and alevins may remain in the gravel for another 4–6 weeks (Moyle 2002). In the Trinity River, fall-run Chinook salmon incubation and emergence typically occurs from December through late February (Leidy and Leidy 1984). The effects of flow and water temperature on fall-run Chinook salmon spawning and egg/alevin incubation may therefore occur from approximately mid-October through February.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, modeled monthly average flows in the Trinity River below Lewiston Dam would be at least 5% lower than the No Action Alternative only in November of above normal water years, in December of below normal water years, and in February of wet water years (Table O-174). Modeled monthly average flows under Alternative 2 With TUCP Without VA would increase by at least 5% in February and March of above normal

water years compared with the No Action Alternative. The November flow decrease would occur during the primary fall-run Chinook salmon spawning period and the December and February flow decreases, as well as the February flow increase, would occur during the egg/alevin incubation period. The monthly flow differences would have minor effects on the availability or suitability of spawning and egg/alevin incubation habitat for fall-run Chinook salmon relative to the No Action Alternative. Under Alternative 2 With TUCP Without VA, like the No Action Alternative, the variable flow regime is expected to maintain spawning habitat quality through periodic scour and redeposition of spawning gravel, which is intended to improve incubation conditions and egg-to-emergence survival by reducing fine sediment.

Modeled monthly average flow in November of above normal water years would decrease from 403 cfs under the No Action Alternative to 363 cfs under Alternative 2 With TUCP Without VA (Table O-174), which may benefit spawning fall-run Chinook salmon by increasing WUA for spawning adults in the primary spawning reach from Lewiston Dam to North Fork Trinity River compared with the No Action Alternative (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999; Rupert et al. 2017a, 2017b). Comparative effects on spawning suitability would vary in downstream reaches, with a decrease in spawning WUA from North Fork Trinity River to South Fork Trinity River and an increase in spawning WUA from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In all reaches of the Trinity River, the effects of flow changes on spawning suitability are likely to vary spatially with channel confinement and incision (Goodman et al. 2018). Where the channel is naturally unconfined and not overly incised and where channel restoration has removed remnant riparian berms and reduced legacy channel confinement and incision, a stronger positive relationship between flow and salmonid habitat suitability, particularly for flows of approximately 300–1,200 cfs, can be expected than in areas of greater channel confinement (see Section O.4.24.1.1 for a detailed discussion). This is mainly a result of increasing habitat area, which provides more space for redds and reduces the risk of redd superimposition by later-spawning salmonids. Although the effects of flow changes on spawning suitability are likely to vary spatially with channel confinement and incision at higher flows (Goodman et al. 2018), the effects of channel geometry are expected to be negligible for flows in the range of 350–400 cfs.

In December of below normal water years modeled monthly average flow in the Trinity River below Lewiston Dam would decrease from 931 cfs under the No Action Alternative to 880 cfs under Alternative 2 With TUCP Without VA (Table O-174). In February of wet water years, modeled monthly average flows would decrease from 1,843 cfs under the No Action Alternative to 1,706 cfs under Alternative 2 With TUCP Without VA. The December and February decreases would occur during the fall-run Chinook salmon egg/alevin incubation period. The lower monthly average flows in December and February under Alternative 2 With TUCP Without VA would be unlikely to change redd hydraulics or redd substrate conditions relative to the No Action Alternative, especially in areas with a confined channel where relatively minor changes in flow have little influence on water depth or velocity, and no effects on egg/alevin incubation suitability are expected.

Modeled monthly average flow in the Trinity River below Lewiston Dam would increase in February of above normal water years from 1,194 cfs under the No Action Alternative to 1,390 cfs under Alternative 2 With TUCP Without VA and in March of above normal water years from 1,021 cfs under the No Action Alternative to 1,095 cfs under Alternative 2 With TUCP Without

VA (Table O-174). The February flow increase would occur during the fall-run Chinook salmon egg/alevin incubation period but is not expected to change redd hydraulics or other conditions that may affect incubation suitability. No effects on egg/alevin incubation suitability are expected.

Modeled monthly average water temperature in the Trinity River below Lewiston Dam in November of above normal water years and December of below normal water years would not differ from the No Action Alternative (Figure O-18 and Figure O-19, respectively), while in February of wet water years the modeled monthly average water temperature may increase slightly under Alternative 2 With TUCP Without VA compared to the No Action Alternative (Figure O-17). November water temperatures under Alternative 2 With TUCP Without VA would remain well below the upper water temperature objective of 56°F (Table O-11) to protect spawning fall-run Chinook salmon in the reach from Lewiston Dam to the North Fork Trinity River (Asarian et al. 2023). In December and February, water temperatures from Lewiston Dam to North Fork Trinity River would remain below the 50°F (10°C) upper optimum limit recommended by USEPA (2001, as cited in Carter 2005) in all water year types to support fall-run Chinook salmon incubation and emergence (Asarian et al. 2023). Water temperatures under Alternative 2 With TUCP Without VA would have negligible effects on fall-run Chinook salmon spawning and incubation suitability compared with the No Action Alternative.

Compared with the No Action Alternative, the effects of seasonal operations under Alternative 2 With TUCP Without VA would likely have minor impacts on the availability and suitability of fall-run Chinook salmon spawning and incubation habitat in the Trinity River. Overall, the impacts in the reaches most heavily used by spawning fall-run Chinook salmon would likely be negligible or slightly beneficial, with spatial variability related to the impacts of channel geometry on habitat suitability.

<u>Alternative 2 Without TUCP Without VA</u>

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be very similar to flows under Alternative 2 With TUCP Without VA, except for a larger increase (greater than 5%) in February of above normal water years (Table O-175). During the fall-run Chinook salmon spawning and incubation period, modeled monthly average flows in November of above normal water years, December of below normal water years, and February of wet water years would be at least 5% less than flows under the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on fall-run Chinook salmon spawning and incubation as those described for Alternative 2 With TUCP Without VA. Compared with the No Action Alternative, the increased average flow in February of above normal water years would result in negligible changes in spawning WUA for fall-run Chinook salmon (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Overall, the impacts of seasonal operations under Alternative 2 Without TUCP Without VA on the availability and suitability of fall-run Chinook salmon spawning and incubation habitat would likely be negligible or slightly beneficial compared with the No Action Alternative, with spatial variability related to the impacts of channel geometry on habitat suitability.

Alternative 2 Without TUCP With Delta VA

Monthly average flows in the Trinity River under Alternative 2 Without TUCP With Delta VA would be nearly identical to flows under Alternative 2 With TUCP Without VA (Table O-176). Compared with the No Action Alternative, substantial (greater than 5%) reductions in monthly average flow under Alternative 2 Without TUCP With Delta VA would occur in November of above normal water years, December of below normal water years, and February of wet water years.

Like Alternative 2 With TUCP Without VA, the November and December flow decreases would not result in measurable changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-18 and Figure O-19). Modeled monthly average water temperature in the Trinity River below Lewiston in February of wet water years may increase slightly under Alternative 2 Without TUCP With Delta VA compared to the No Action Alternative (Figure O-17). The potential impacts on the availability and suitability of fall-run Chinook salmon spawning and egg/alevin incubation habitat that may result from the small differences in modeled monthly average flow and water temperature relative to the No Action Alternative would be the same as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Systemwide VA

Monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be very similar to flows under Alternative 2 Without TUCP Without VA, but with a larger increase in February of above normal water years (Table O-177). Modeled monthly average flows in November of above normal water years, December of below normal water years, and February of wet water years would be at least 5% less than flows under the No Action Alternative. These differences in monthly average flow and associated differences in water temperature would have the same impacts on fall-run Chinook salmon spawning and incubation as those described for Alternative 2 With TUCP Without VA.

In February of above normal water years, modeled monthly average flow would increase by 131 cfs from 1,194 cfs under the No Action Alternative to 1,325 cfs under Alternative 2 Without TUCP With Systemwide VA (Table O-177). This increase would not be expected to have measurable impacts on depth, velocity, or substrate that could affect suitability for incubating fall-run Chinook salmon eggs/alevins. Similarly, the February flow increase would not result in measurable changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-18) and there would be no change in the temperature suitability for incubating fall-run Chinook salmon eggs/alevins relative to the No Action Alternative.

Juvenile Rearing and Emigration

In the Trinity River, fall-run Chinook salmon fry emerge from the gravel beginning in December and most emergence is complete by mid-April. Natural juvenile fall-run Chinook salmon primarily outmigrate as sub-yearlings from the Trinity River. Hatchery releases of fall-run Chinook salmon also include mostly smolts released primarily in late spring and fall. Peak outmigration occurs in March, April, and May but can extend to July based on monitoring in the lower Trinity River near the town of Willow Creek (Moyle 2002, Chesney and Yokel 2003). The effects of flow and water temperature on rearing and emigrating fall-run Chinook salmon may therefore occur primarily from December through July.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, modeled monthly average flows in the Trinity River below Lewiston Dam would be more than 5% lower than the No Action Alternative in December of below normal water years, and in February of wet water years (Table O-174). In February and March of above normal water years, modeled monthly average flows under Alternative 2 With TUCP Without VA would increase by at least 5% compared with the No Action Alternative.

The December, February, and March differences may have spatially variable impacts on the availability and suitability of juvenile rearing and emigration habitat for fall-run Chinook salmon. The decrease in modeled monthly average flow in December of below normal water years from 931 cfs under the No Action Alternative to 880 cfs under Alternative 2 With TUCP Without VA would result in a decrease in fry WUA and an increase in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, an increase in both fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and a decrease in fry WUA and an increase in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The monthly average flow reductions in February of wet water years from 1,843 to 1,706 cfs would result in reductions in WUA for fry and juvenile fall-run Chinook salmon from Lewiston Dam to Dutch Creek, small increases in fry and juvenile WUA from Dutch Creek to North Fork Trinity River, a slight decrease in fry WUA and a small increase in juvenile WUA from North Fork Trinity River to South Fork Trinity River, and little to no change in fry and juvenile WUA from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

The modeled monthly flow increase in February of above normal water years from 1,194 cfs under the No Action Alternative to 1,390 cfs under Alternative 2 With TUCP Without VA would result in an increase in Chinook salmon fry WUA and decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek and a decrease in both fry and juvenile WUA in the reaches from Dutch Creek to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In March of above normal water years, the increase in modeled monthly average flow from 1,021 cfs under the No Action Alternative to 1,095 cfs under Alternative 2 With TUCP Without VA would result in an increase in Chinook salmon fry WUA and decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, a decrease in both fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and an increase in fry WUA and very small decrease in juvenile WUA from South Fork Trinity River to Weitchpec.

Where the channel is naturally unconfined and not overly incised and in locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships and spawning WUA in some restored areas may exhibit a stronger positive relationship to flow up to approximately 3,500 cfs (Cooper-Hertel et al. 2022). Consequently, fall-run Chinook salmon WUA in all reaches is likely to vary spatially with channel confinement and incision and in restored areas may be greater than described in U.S. Fish and Wildlife Service and Hoopa Valley Tribe (1999). See Section

O.4.24.1.1 for additional details. The potential changes in WUA for fall-run Chinook salmon fry and juveniles may have minor, short-term impacts on the ability of these life stages to access cover and preferred habitat that would occur only in a few months of the rearing period and in some reaches of the Trinity River.

In December of below normal water years and February and March of above normal water years, differences in modeled monthly average flows between Alternative 2 With TUCP Without VA and the No Action Alternative would not result in changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-19). In February of wet water years, reductions in modeled monthly average flows between Alternative 2 With TUCP Without VA and the No Action Alternative may slightly increase modeled monthly average water temperatures below Lewiston Dam compared to the No Action Alternative (Figure O-17). In December of below normal water years, February of wet water years, and February and March of above normal water years, the modeled monthly average water temperatures at Trinity River below Lewiston Dam under Alternative 2 With TUCP Without VA would remain well below the 62.6°F water temperature objective for emigrating juvenile fall-run Chinook salmon recommended for normal and wetter water year types and the 68°F objective recommended for dry and critically dry water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the objectives are intended to be measured at Weitchpec and applicable prior to July 9, historical data and model results suggest that water temperatures in December, February, and March would remain below both objectives under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating fall-run Chinook salmon under Alternative 2 With TUCP Without VA relative to the No Action Alternative.

Compared with the No Action Alternative, seasonal operations under Alternative 2 With TUCP Without VA would likely have negligible impacts on the availability and suitability of fall-run Chinook salmon juvenile rearing and emigration habitat in the Trinity River. The impacts would vary spatially due to the impacts of channel geometry on habitat suitability.

<u>Alternative 2 Without TUCP Without VA</u>

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to Alternative 2 With TUCP Without VA and impacts on rearing and emigrating juvenile fall-run Chinook salmon would be the same.
Alternative 2 Without TUCP With Delta VA.

Compared with the No Action Alternative, substantial (greater than 5%) reductions in monthly average flow under Alternative 2 Without TUCP With Delta VA would occur in February of wet water years. Effects on spring-run Chinook salmon spawning and egg/alevin incubation at these times would be nearly identical to those under Alternative 2 With TUCP Without VA. Increased flow (greater than 5%) in February of above normal water years would be unlikely to change redd hydraulics or redd substrate conditions relative to the No Action Alternative is not expected to affect egg/alevin incubation suitability.

These differences in monthly average flow and associated differences in water temperature would have the same effects on spring-run Chinook salmon juvenile rearing and emigration as those described for Alternative 2 With TUCP Without VA for February.

Alternative 2 Without TUCP With Systemwide VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be nearly identical to flows under Alternative 2 Without TUCP With Delta VA and the impacts on fall-run Chinook salmon would be the same.

Adult Upstream Migration and Holding

Adult fall-run Chinook salmon typically enter the Trinity River from September through October (Moyle et al. 2015). Two to four weeks after river entry, adults have made it to the primary spawning reach which extends from Lewiston Dam downstream to the confluence of the North Fork Trinity River. After entering freshwater, fall-run Chinook salmon remain in deep pools until the onset of the spawning season, which typically ranges from the third week of September through November, peaking in October (Chensey and Knechtle 2012). The effects of flow and water temperature on migrating and pre-spawning fall-run Chinook salmon adults may therefore occur from August through November.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, seasonal operations in the Trinity River are expected to provide similar habitat conditions for fall-run Chinook salmon during the upstream migration and pre-spawning period to the No Action Alternative. Like the No Action Alternative, Trinity River flow and water temperature below Lewiston Dam would be managed to maintain suitable habitat conditions for anadromous fish including Chinook salmon. During the August–November fall-run Chinook salmon upstream migration and pre-spawning period there would be no differences in modeled monthly average flow between the two alternatives from August–October and greater than 5% reduction in flows in November of above normal years (Table O-174). The minor differences in November are not expected to result in changes in habitat suitability for migrating and holding fall-run Chinook salmon, as modeled monthly average flows would decrease only from 403 to 363 cfs towards the end of the migration period. During the entirety of the adult upstream migration and holding period, modeled monthly average flows would be approximately 300 cfs or greater in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and habitat to support pre-spawning fall-run Chinook salmon.

Under both alternatives, September through October flows would maintain suitable water temperatures for adult upstream migration (would not exceed 56°F from August through October at Douglas City [RM 93.7]; Table O-11) (Asarian et al. 2023). Under Alternative 2 With TUCP Without VA, suitability for adult fall-run Chinook salmon upstream migration and holding would be the same as under the No Action Alternative.

Alternative 2 Without TUCP Without VA

During August–November when fall-run Chinook salmon are migrating upstream and preparing to spawn, modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to flows under Alternative 2 With TUCP Without VA, with no differences in modeled monthly average flow between the two alternatives from August through November and greater than 5% reduction in flows in above

normal years in November (Table O-175). The monthly average flows and associated monthly average water temperatures would have the same impacts on migrating and holding fall-run Chinook salmon as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Delta VA

During the August–November fall-run Chinook salmon upstream migration and pre-spawning period, modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Delta VA would be nearly identical to flows under Alternative 2 With TUCP Without VA, with no differences in modeled monthly average flow between the two alternatives from August through November and greater than 5% reduction in flows in above normal years in November (Table O-176). The monthly average flows and associated monthly average water temperatures would have the same impacts on fall-run Chinook salmon during the upstream migration and pre-spawning period as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Systemwide VA

During the August-November fall-run Chinook salmon upstream migration and pre-spawning period, modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be nearly identical to flows under Alternative 2 With TUCP Without VA, with no differences in modeled monthly average flow between the two alternatives from August through November and greater than 5% reduction in flows in above normal years in November (Table O-177). The monthly average flows and associated monthly average water temperatures would have the same impacts on fall-run Chinook salmon during the upstream migration and pre-spawning period as those described for Alternative 2 With TUCP Without VA.

O.5.28 Klamath Mountains Province Steelhead DPS

O.5.28.1 Trinity River

Monthly average flows in the Trinity River below Lewiston Dam would generally be similar under Alternative 2 to flows under the No Action Alternative. Considering the full simulation period, minor differences in monthly average flows between Alternative 2 and the No Action Alternative would occur in November through April of some water year types, with most differences less than 5%. Monthly average flows under the four phases of Alternative 2 would be very similar, with some differences (greater than 5%) from the No Action Alternative occurring in November through March of some water year types among the Alternative 2 phases.

Spawning and Egg/Alevin Incubation

Spawning across run types in the Trinity River may occur anytime from December through May so effects of flow and water temperature on spawning may occur during this period.

Steelhead eggs and alevins across run types in the Trinity River may be present in the gravel from December through June, so effects of flow and water temperature on steelhead eggs and alevins may occur during this period.

Potential Changes to Steelhead from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, modeled monthly average flows in the Trinity River below Lewiston Dam would be at least 5% lower than the No Action Alternative within the spawning and incubation period in November of above normal water years, December of below normal water years, and in February of wet water years (Table O-174). Like all other phases of Alternative 2, monthly average flows averaged across the full simulation period would be slightly less in November through April than monthly average flows under the No Action Alternative.

Reduced monthly average flow in November of above normal water years from 403 cfs to 363 cfs would have little to no change in spawning WUA for steelhead in the reach from Lewiston to North Fork Trinity and from South Fork Trinity to Weitchpec and negligible increases in the reach from North Fork Trinity to South Fork Trinity (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

Reduced monthly average flow in December of below normal water years from 931 cfs to 880 cfs would have little to no change in spawning WUA for steelhead in the reach from Dutch Creek to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999)(steelhead spawning WUA estimates are not available at discharges over 800 cfs from Lewiston Dam to Dutch Creek).

Reduced monthly average flow in February of wet water years from 1,843 cfs to 1,706 cfs would have little to no change in spawning WUA for steelhead in the reach from Dutch Creek to South Fork Trinity and negligible decreases from South Fork Trinity to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

Increased monthly average flow in February of above normal water years from 1,194 cfs to 1,390 cfs would have little to no change in spawning WUA for steelhead in the reach from Dutch Creek to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

Increased monthly average flow in March of above normal water years from 1,021 cfs to 1,095 cfs would have little to no change in spawning WUA for steelhead in the reach from Dutch Creek to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

The December flow decreases would not result in measurable changes in modeled average water temperature in the Trinity River below Lewiston Dam (Appendix F, Figure F.2.11-1-1) and average water temperatures under Alternative 2 With TUCP Without VA would remain well below the upper water temperature objective of 56°F to protect spawning salmonids in the reach from Lewiston Dam to the North Fork Trinity River (Table O-11).u

In February of wet water years, monthly average flows in the Trinity River below Lewiston Dam would be reduced from 1,843 cfs under the No Action Alternative to 1,706 cfs under Alternative 2 With TUCP Without VA. In February and March of wet water years, monthly average flows would slightly increase under Alternative 2 With TUCP Without VA relative to the No Action Alternative. The higher monthly average flows in February and March under Alternative 2 With

TUCP Without VA in above normal water years would be unlikely to change redd hydraulics or redd substrate conditions relative to the No Action Alternative, especially in areas with a confined channel where minor changes in flow have relatively little influence on water depth or velocity. However, the February flow reduction under Alternative 2 With TUCP Without VA could slightly increase the risk of dewatering of redds constructed in January compared to the No Action Alternative. This is because average monthly flows under Alternative 2 With TUCP Without VA would decrease by 157 cfs from January (1,863 cfs) to February (1,706 cfs), in contrast to the No Action Alternative under which flows would decrease by only 29 cfs from January (1,872 cfs) to February (1,843 cfs) (Table O-174).

Modeled average water temperature in the Trinity River below Lewiston Dam in February and March of wet water years may increase slightly under Alternative 2 With TUCP Without VA compared to the No Action Alternative (Figure O-17) but would remain below the 50°F upper suitability limit recommended by Washington State Department of Ecology (WDOE) (2002, as cited in Carter 2005) and would support steelhead incubation and emergence.

Alternative 2 Without TUCP Without VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to flows under Alternative 2 With TUCP Without VA (Table O-175) so impacts to steelhead spawning, egg incubation, and fry emergence habitat from flow changes and water temperature would be the same as Alternative 2 With TUCP Without VA. Alternative 2 Without TUCP With Delta VA

With regard to spawning, egg incubation, and fry emergence, modeled monthly average flows in the Trinity River under Alternative 2 Without TUCP With Delta VA would be nearly identical to flows under Alternative 2 With TUCP Without VA in November and February (Table O-176). Compared to the No Action Alternative, substantial (greater than 5%) reductions in monthly average flow under Alternative 2 Without TUCP With Delta VA would occur in November of above normal water years and February of wet water years nearly the same as Alternative 2 With TUCP Without VA. Flow increases are predicted to occur in February of above normal water years nearly the same as Alternative 2 With TUCP Without VA.

Monthly average water temperature in the Trinity River below Lewiston Dam in February and March of wet water years may increase slightly under Alternative 2 Without TUCP With Delta VA compared to the No Action Alternative (Figure O-17). The potential impacts on the availability and suitability of steelhead spawning and egg/alevin incubation habitat that may result from the small differences in monthly average flow and water temperature relative to the No Action Alternative would be the same as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Systemwide VA

Monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be nearly identical to flows under Alternative 2 Without TUCP With Delta VA and impacts from flow and temperature changes would be the same for spawning, egg incubation, and fry emergence habitat as Alternative 2 Without TUCP With Delta VA. Juvenile Rearing and Emigration

Rearing or moving (migrating or redistributing) fry and/or juveniles can occur downstream of Lewiston Dam any time of year with three peak emigration times in March, May/June, and October/November.

Potential Changes to Steelhead from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, modeled monthly average flows in the Trinity River below Lewiston Dam would be more than 5% lower than the No Action Alternative in November of above normal water years, in December of below normal water years, and in February of wet water years (Table O-174). These differences may have spatially variable impacts on the availability and suitability of juvenile rearing and emigration habitat for steelhead. The decrease in modeled monthly average flow in November of above normal water years from 403 cfs under the No Action Alternative to 363 cfs under Alternative 2 With TUCP Without VA (Table O-174) would result in overall minor increases in observed and predicted WUA for fry and juvenile steelhead across reaches of the Trinity River from Lewiston Dam to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Similarly, the decrease in monthly average flow in December of below normal water years from 931 cfs under the No Action Alternative to 880 cfs under Alternative 2 With TUCP Without VA would result in overall minor increases in observed and predicted WUA for fry and juvenile steelhead from Lewiston Dam to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

In contrast, the reduced monthly average flows in February (from 1,843 cfs to 1,706 cfs) of wet water years would result in reductions in WUA for fry and increases for juvenile steelhead from Lewiston Dam to Dutch Creek; negligible increases for fry and juvenile WUA from Dutch Creek to North Fork Trinity River; a slight decrease in fry WUA and little to no change in juvenile WUA from North Fork Trinity River to South Fork Trinity River; and decreases in fry and little to no change in juvenile WUA from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). These changes in WUA for steelhead fry and juveniles may have minor, short-term impacts on the ability of these life stages to access cover and preferred habitat that would occur only in a few months of the year and in wet water years in some reaches of the Trinity River.

Modeled flow increases in February and March of above normal water years would result in minor increases in estimated fry and juvenile WUA in the reach between Lewiston Dam and Dutch Creek, minor decreases for both in the reach from Dutch Creek to South Fork Trinity, and minor increases in fry WUA and minor decreases in juvenile WUA in the reach from South Fork Trinity to Weitchpec.

In November of above normal water years, December of below normal water years, and February and March of above normal water years, differences in modeled monthly average flows between Alternative 2 With TUCP Without VA and the No Action Alternative would not result in changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-18 and Figure O-19, respectively). In February of wet water years, differences in monthly average flows between Alternative 2 With TUCP Without VA and the No Action Alternative may slightly increase modeled monthly average water temperatures compared to the No Action Alternative (Figure O-17). In November, December, February, and March of the

aforementioned water year types, modeled monthly average water temperatures at Trinity River below Lewiston Dam under Alternative 2 With TUCP Without VA would remain well below the 59°F water temperature objective for emigrating salmon recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the 59°F objective is intended to be measured at Weitchpec and applicable prior to June 4, historical data and model results suggest that water temperatures in November, December, February, and March would remain below the 59°F objective under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating steelhead under Alternative 2 With TUCP Without VA relative to the No Action Alternative. The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 2 With TUCP Without VA through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives in some months at downstream locations in some water year types under Alternative 2 With TUCP Without VA, water temperatures and the potential impacts on steelhead would not differ from the No Action Alternative.

Alternative 2 Without TUCP Without VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to flows under Alternative 2 With TUCP Without VA so impacts to steelhead juvenile rearing and emigration from flow changes and temperature would be the same as Alternative 2 With TUCP Without VA (Table O-175).
Alternative 2 Without TUCP With Delta VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Delta VA would be nearly identical to flows under Alternative 2 With TUCP Without VA for November of above normal water years, February of wet water years, and February of above normal water years and would result in the same minor increases in fry and juvenile WUA in November of above normal water years and the same spatially variable minor increases and decreases in fry and juvenile WUA in February of wet and above normal water years (Table O-176). Modeled temperature changes would also be the same as Alternative 2 With TUCP Without VA for November of above normal water years, February of wet water years, and February of above normal water years and no adverse temperature impacts are expected to juvenile rearing and emigration from Alternative 2 Without TUCP With Delta VA relative to the No Action Alternative..

Alternative 2 Without TUCP With Systemwide VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would be nearly identical to flows under Alternative 2 Without TUCP With Delta VA (Table O-177) and therefore impacts would be the same as Alternative 2 Without TUCP With Delta VA. Adult Upstream Migration and Holding

Consistent adult monitoring data are limited by environmental conditions and challenges in overlapping populations with different run timing, kelting or “runbacks”, and half pounders but summer/fall steelhead (stream-maturing steelhead) are thought to return from the ocean about April through November and hold for varying lengths of time in the Klamath-Trinity watershed

(Moyle et al. 2017; Moyle et al. 2015; Pinnix et al 2007). Winter steelhead (ocean-maturing steelhead) can return from the ocean about November through March (Moyle et al. 2017; Moyle et al. 2015; Pinnix et al 2007). Given the overlapping run timings and varying life history strategies, adults at various stages of maturation can enter the Klamath-Trinity watershed, hold in Trinity River, and/or migrate up or down Trinity River and into tributaries in any month of the year.

Potential Changes to Steelhead from Seasonal Operations

Alternative 2 With TUCP Without VA

Under Alternative 2 With TUCP Without VA, seasonal operations in the Trinity River are expected to provide similar habitat conditions for steelhead migration and holding to the No Action Alternative. Like the No Action Alternative, Trinity River flow and water temperature below Lewiston Dam would be managed to maintain suitable habitat conditions for anadromous fish including steelhead. Modeled monthly average flows in the Trinity River below Lewiston Dam would be more than 5% lower than the No Action Alternative in November of above normal water years, December of below normal water years, and February of wet water years (Table O-174). These differences may result in minor, short-term changes in habitat conditions but monthly average flows would be equal to or greater than 300 cfs in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and holding habitat to support pre-spawning steelhead.

Modeled monthly average flows in August and September are typically at or near seasonal highs (Asarian et al. 2023), would be the same under Alternative 2 With TUCP Without VA as under the No Action Alternative (Table O-174). Under both alternatives, modeled average August and September flows of 760 cfs in wet water years and 863 cfs in all other water year types would maintain suitable water temperatures for adult upstream migration (would not exceed 56°F from August through October at Douglas City [RM 93.7]; Table O-11) in the Trinity River at Lewiston Dam (Figure O-17). Although downstream warming during August and September could result in unsuitable water temperatures for migrating steelhead at some locations, the likelihood of this occurring would be the same under Alternative 2 With TUCP Without VA as under the No Action Alternative due to the identical flows.

The monthly average flows under Alternative 2 With TUCP Without VA would be the same as the No Action Alternative except in November of above normal water years when the modeled monthly average flow would be 41 cfs lower under Alternative 2 With TUCP Without VA (363 cfs) than the No Action Alternative (403 cfs; Table O-174). In December and January, the only substantial difference in modeled monthly average flow (greater than 5%) between the two alternatives would be a reduction of 51 cfs in December in below normal water years from 931 cfs under the No Action Alternative to 880 cfs under Alternative 2 With TUCP Without VA. Neither the November flow difference nor the December flow difference would have measurable impacts on modeled monthly average water temperature at Lewiston Dam in the respective water year types (Figure O-20 and Figure O-21) and there would be no impacts on water temperature suitability for steelhead migration and holding relative to the No Action Alternative.

Alternative 2 Without TUCP Without VA

Monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP Without VA would be nearly identical to flows under Alternative 2 With TUCP Without VA (Table O-175) so Alternative 2 Without TUCP Without VA would have the same impacts on migrating and holding steelhead as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Delta VA

Monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Delta VA would be very similar to flows under Alternative 2 With TUCP Without VA (Table O-176) but without the modeled increase in average monthly flow in December of below normal water years or the small increase in flow in March of above normal water years. These differences are negligible for adult migration and holding habitat and overall differences in modeled monthly average flow and associated differences in modeled monthly average water temperature would have the same impacts on migrating and holding steelhead as those described for Alternative 2 With TUCP Without VA.

Alternative 2 Without TUCP With Systemwide VA

Modeled monthly average flows in the Trinity River below Lewiston Dam under Alternative 2 Without TUCP With Systemwide VA would nearly identical to flows under Alternative 2 Without TUCP With Delta VA (Table O-177) and the impacts to migrating and holding adult steelhead would be the same.

O.5.29 Northern DPS Green Sturgeon

O.5.29.1 Trinity River

Spawning and Egg Incubation

Northern DPS green sturgeon adults spawn primarily from March through July, though most spawning takes place from April to June (O.1.2.5.1, *Green Sturgeon, Northern* DPS). Northern DPS green sturgeon eggs hatch approximately a week after fertilization, and optimal temperatures for incubation range from 51.8–62.6°F (Van Eenennaam et al. 2005). The effects analysis period for incubating eggs is considered to be the same as the spawning period due to the short incubation period and includes March through July.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Modeled flows in the Trinity River downstream of Lewiston Dam under Alternative 2 would generally be similar to flows under the No Action Alternative. Flows under each phase of Alternative 2 would be very similar as under the No Action Alternative, with minor differences among the phases occurring in November through April of some water year types and most differences being less than 5%. A few months in certain water year types between November and March would have differences in modeled monthly average flows greater than 5% relative to the No Action Alternative.

Green sturgeon are only known to occur within the lower 43 miles of the Trinity River ranging as far upstream as Grays Falls near Burnt Ranch, approximately 70 miles downstream of Lewiston Dam (Benson et al. 2007). Water temperature and habitat conditions within this section of the

Trinity River are heavily influenced by several tributaries that enter the Trinity River (e.g., Canyon Creek, North Fork Trinity River, New River, South Fork Trinity River, and small tributaries). Results of previous water temperature modeling for the Trinity River predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43, and smaller temperature differences are expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations are unlikely to have a detectable influence on the water temperature suitability for spawning and egg incubation of green sturgeon.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be more than 5% higher than the No Action Alternative during the spawning period in March of above normal water years (Table O-174). The March flow increase would occur during the green sturgeon spawning and egg incubation period. This very small increase in flows in above normal water years would be negligible for spawning habitat and egg incubation because flows would still be above 1,876 cfs and would increase slightly relative to the No Action Alternative.
- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be identical to Alternative 2 With TUCP Without VA in the spawning season so impacts to spawning, egg incubation, and emergence would be the same as Alternative 2 With TUCP Without VA.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would not differ from the No Action Alternative more than 5% in any month or water year type during the spawning period (Table O-176).
- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would no differ from the No Action Alternative more than 5% in any month or water year type during the spawning period (Table O-177).

Larval and Juvenile Rearing and Emigration

The northern DPS green sturgeon spawning period is from March through July, and the larval period is considered to be from March through September. The juvenile stage of green sturgeon begins when metamorphosis of the larva is complete, typically about 45 days after hatching and approximately up to 2 cm TL. Juveniles (up to 150 cm TL) typically slowly migrate downstream, and rear in the lower Klamath River for up to a year or until approximately their first summer, and optimal growth temperatures range from 59–66.2°F (Moyle 2002; Mayfield and Cech, Jr. 2004). During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near Burnt Ranch to the Klamath River Estuary (Section O.1.2.5.1, *Green Sturgeon, Northern DPS*). The effects analysis period for larval and juvenile life stages in the Trinity River should be considered April to September.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 2 would generally be similar to flows under the No Action Alternative. Minor differences in monthly average flows between Alternative 2 and the No Action Alternative would occur in November through April of some water year types, with most differences being less than 5%. Flows under each phase of Alternative 2 would be very similar, but minor differences among the phases would occur in November through April of some water year types and nearly all differences would be less than 5%.

Green sturgeon larvae and juveniles are only known to occur within the lower 43 miles of the Trinity River, and after hatching, they begin to migrate downstream. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of approximately 1°F in water temperature for flows of between 300 cfs and 450 cfs near RM 43, and smaller temperature differences are expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations would not likely have a detectable influence on the water temperature suitability for larval and juvenile rearing and emigration of green sturgeon.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be almost identical to the No Action Alternative during the larval and juvenile rearing period from April through September and would correspond to the No Action Alternative flows, which are currently managed to improve habitat conditions for anadromous fish (Table O-174). Alternative 2 With TUCP Without VA monthly average flows would have no impacts to negligible impacts on larval and juvenile rearing and emigration of green sturgeon when compared with the No Action Alternative.
- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be almost identical to the No Action Alternative during larval and juvenile rearing period from April through September and would correspond to the No Action Alternative flows, which are currently managed to improve habitat conditions for anadromous fish (Table O-175). Alternative 2 Without TUCP Without VA monthly average flows would have no impacts to negligible impacts on larval and juvenile rearing and emigration of green sturgeon when compared with the No Action Alternative.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be almost identical to the No Action Alternative during larval and juvenile rearing period from April through September and would correspond to the No Action Alternative flows, which are currently managed to improve habitat conditions for anadromous fish (Table O-176). Alternative 2 Without TUCP With Delta VA monthly average flows would have no impacts to negligible impacts on larval and juvenile rearing and emigration of green sturgeon when compared with the No Action Alternative.

- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be almost identical to the No Action Alternative during the larval and juvenile rearing period from April through September and would correspond to the No Action Alternative flows, which are currently managed to improve habitat conditions for anadromous fish (Table O-177). Alternative 2 Without TUCP With Systemwide VA monthly average flows would have no impacts to negligible impacts on larval and juvenile rearing and emigration of green sturgeon when compared with the No Action Alternative.

Adult Upstream Migration and Holding

Green sturgeon adults enter the Trinity River from the Klamath River Estuary as early as February to make their way upstream to spawn in deep pools from the lower section of the mainstem Trinity River to the confluence with the Klamath River upstream approximately 43 miles to Gray's Falls near Burnt Ranch. After spawning, the adults remain in mainstem river pools for varying amounts of time, representing distinct migration patterns. Directly after spawning, 25% emigrate back to the Klamath River Estuary and ocean, but freshwater residency may last up to 199 days (Moyle 2002, Section O.1.3.2.5, *Green Sturgeon, Northern DPS*). With the extended adult holding period, the effects analysis period of flow and water temperature on adult upstream immigration, holding, and emigration may occur from February through December.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 2 would generally be similar to flows under the No Action Alternative. Under Alternative 2, a reduction in flows greater than 5% would occur in February of wet years and in November of above normal years for all Alternative 2 phases, and in December of below normal years for Alternative 2 phases without VA compared to the No Action Alternative.

Green sturgeon adults are only known to occur within the lower 43 miles of the Trinity River, and they have variable freshwater residence time (Benson et al. 2007). Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43, and smaller temperature differences are expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations are not likely to have a detectable influence on the water temperature suitability for migration and holding of adult green sturgeon.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be similar to or less than the No Action Alternative from February to December (Table O-174). During the green sturgeon upstream migration and holding period, a greater than 5% flow reduction would occur under the No Action Alternative in February of wet years, in November of above normal years, and in

December of below normal years. The decrease in flow in February of wet years would be negligible because releases would still average 1,706 cfs. Monthly average flows during the summer and fall months under Alternative 2 With TUCP Without VA compared with the No Action Alternative would be identical and would provide adequate flows for downstream movement and holding in pool habitats. Reduced flows under Alternative 2 With TUCP Without VA in November and December would remain above 300 cfs, and this reduction would likely have a negligible effect on green sturgeon migration movements.

- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be nearly identical to Alternative 2 With TUCP Without VA (Table O-175) and impacts on adult green sturgeon would be the same.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With VA, monthly average flows would be similar or less to the No Action Alternative from February to December (Table O-176). During the green sturgeon upstream migration and holding period, a greater than 5% flow reduction would occur compared to the No Action Alternative in February of wet years, in November of above normal years, and in December of below normal years. The decreased flow in wet years during would be negligible because releases would average 1,693 cfs. Monthly average flows during the summer and fall months under Alternative 2 Without TUCP With Delta VA compared with the No Action Alternative would be identical, except for reduced flows in November of above normal years, and would provide adequate flows for downstream movements and holding in pool habitats. Reduced flows under Alternative 2 With TUCP Without VA in November of above normal water years would remain above 300 cfs, and this reduction would likely have a negligible effect on green sturgeon migration movements.
- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP Systemwide VA, monthly average flows would be nearly identical to Alternative 2 Without TUCP With Delta VA(Table O-176) and therefore impacts to adult green sturgeon would be the same.

O.5.30 Eulachon

O.5.30.1 Lower Klamath River from Confluence With Trinity River to Pacific Ocean

Spawning and Egg Incubation

Eulachon adults spawn from December through May, with peak spawning occurring in March and April (O.1.2.6 *Eulachon*). Eulachon eggs hatch in 20 to 40 days depending on water temperature, with cooler temperatures leading to longer incubation times. Spawning is reported to occur at temperatures from 39 to 50°F; colder temperatures may stop migration (National Marine Fisheries Service 2017a). The effects analysis period for eulachon spawning and egg incubation is December through June.

Potential Changes to Eulachon from Seasonal Operations

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek

and even Weitchpec (Yurok Tribal Fisheries Program 1998). Water temperature and habitat conditions within this section Klamath River below the confluence with the Trinity River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River (e.g., Canyon Creek, North Fork Trinity River, New River, South Fork Trinity River, and small tributaries). Previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 2 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for spawning and egg incubation of eulachon in the Lower Klamath River.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and December during below normal water years (Table O-174) during the eulachon spawning and egg incubation period. There would also be an increase in flows of greater than 5% in February and March of above normal water years. The modeled flow reductions would likely be negligible for spawning and egg incubation as flows would average 1,706 cfs in February of wet water years and 880 cfs in December of below normal water years. These modeled flows changes will likely have a negligible impact on flows in the lower Klamath River where eulachon spawning and egg incubation will take place.
- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and December during below normal water years (Table O-174) during the eulachon spawning and egg incubation period. There would also be an increase in flows of greater than 5% in February and March of above normal water years. These flow changes of greater than 5% would occur during the eulachon spawning and egg incubation period. The reduction in flows would not likely impact eulachon spawning and egg incubation as flows would remain an average of 1,699 cfs in February of wet water years and 880 cfs in December in below normal water years. These modeled flows changes will likely have a negligible impact on flows in the lower Klamath River where eulachon spawning and egg incubation will take place.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years (Table O-174) during the eulachon spawning and egg incubation period. There would also be a modeled increase in flows of greater than 5% in February of above normal water years. The reduction in flows would likely be negligible for spawning and egg incubation as flows would remain an average of 1,693 cfs in February of wet water years. These modeled flows changes would be rare and will likely have a negligible impact on flows in the lower Klamath River where eulachon spawning and egg incubation will take place.

- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and more than 5% higher in February of above normal water years (Table O-174) during the eulachon spawning and egg incubation period. The reduction in flows would not likely impact eulachon spawning and egg incubation as flows would average 1,698 cfs in February of wet water years. These modeled flows changes will likely have a negligible impact on flows in the lower Klamath River where eulachon spawning and egg incubation will take place.

Larval Emigration

Eulachon spawning period is from December through May and eggs hatch in 20 to 40 days, so the larval period is considered to be January through June. After hatching, larval eulachon are quickly carried out to the ocean by river currents (Scott and Crossman 1973). Larval eulachon only remain in the Klamath River for about 5 days until they are washed out to sea. Larvae live on their yolk sac reserves after hatching —they do not feed while in fresh water (Gustafson et al. 2022). Effects of flow and water temperature on eulachon larvae may occur from January through June in the Klamath River.

Potential Changes to Eulachon from Seasonal Operations

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Eulachon larvae are washed downstream to the ocean immediately after hatching. Water temperature and habitat conditions within this section Klamath River below the confluence with the Trinity River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 2 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for eulachon larval emigration.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and 5% higher in February and March of above normal water years (Table O-174) during the eulachon larval emigration period. The modeled reduction in flows would likely be negligible for larval emigration as flows would only decrease 137 cfs with an average of 1,706 cfs in February in wet water years, a small proportion of the total flow in the lower Klamath River. This modeled flow change would have a negligible impact on flows in the lower Klamath River where eulachon spawning and egg incubation occurs.

- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and 5% higher in February and March of above normal

water years (Table O-174)during the eulachon larval emigration period. The reduction in flows would not likely impact larval emigration as flows would only decrease 143 cfs with an average of 1,699 cfs in February of wet water years, a small proportion of the total flow in the lower Klamath River. This modeled flow change would have a negligible impact on flows in the lower Klamath River where eulachon spawning and egg incubation occurs.

- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and 5% higher in February of above normal water years (Table O-174) during the eulachon larval emigration period. The reduction in flows would likely be negligible for larval emigration as flows would only decrease 150 cfs with an average of 1,693, a small proportion of the total flow in the lower Klamath River. This modeled flow change would have a negligible impact on flows in the lower Klamath River where eulachon spawning and egg incubation occurs.
- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and 5% higher in February of above normal water years (Table O-174)during the eulachon larval emigration period. The reduction in flows would not likely impact larval emigration as flows would only decrease 144 cfs and average 1,698 cfs in February in wet water years, a small proportion of the total flow in the lower Klamath River. This modeled flow change would have a negligible impact on flows in the lower Klamath River where eulachon spawning and egg incubation occurs.

Adult Upstream Migration

The spawning migration period for adult eulachon in the Klamath River begins in December and continues until May, with peak migration occurring in March and April (Yurok Tribal Fisheries Program 1998; Larson and Belchik 1998, Section O.1.2.6). Eulachon distribution in the Trinity River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Eulachon are broadcast spawners most commonly over sand, though spawning substrates can range from silt, sand or gravel to cobble and detritus (California Department of Fish and Wildlife 2010; National Marine Fisheries Service 2017a). Eulachon usually die after spawning. The effects analysis period for eulachon adult upstream migration is December through May.

Potential Changes to Eulachon from Seasonal Operations

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Water temperature and habitat conditions within this section of the Klamath River below the confluence with the Trinity River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley

Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations are unlikely to have a detectable influence on the water temperature suitability for eulachon adult upstream migration.

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and December during below normal water years and 5% higher in February and March of above normal water years (Table O-174) during the eulachon adult migration period. The modeled reduction in flows would likely be negligible for eulachon adult migration as flows would still average 1,706 cfs, a decrease of only 137 cfs, in February of wet water years and average 880 cfs, a decrease of only 51 cfs, in December of below normal water years, a small proportion of the total flow in the lower Klamath River. These modeled flow change would have a negligible impact on flows in the lower Klamath River where eulachon adult migration occurs.
- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and December during below normal water years and greater than 5% higher in February of above normal water years and 5% higher in February and March of above normal water years (Table O-174) during the eulachon adult migration period. The reduction in flows would likely be negligible for eulachon adult migration as flows would still average 1,699 cfs, a decrease of only 143 cfs, in February of wet water years and average 880 cfs, a decrease of only 51 cfs, in December of below normal water years, a small proportion of the flow in the lower Klamath River. These modeled flow change would have a negligible impact on flows in the lower Klamath River where eulachon adult migration occurs.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and more than 5% higher in February of above normal water years (Table O-174) during the eulachon adult migration period. The reduction in flows would likely be negligible for eulachon adult migration as flows would still average 1,693 cfs in wet water years, only a decrease of 150 cfs, a small proportion of flow in the Klamath River. This modeled flow change would have a negligible impact on flows in the lower Klamath River where eulachon adult migration occurs..
- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and 5% higher in February of above normal water years (Table O-174) during the eulachon adult migration period. The reduction in flows would likely be negligible for eulachon adult migration as flows would still average 1,698 cfs in February in wet water years, a decrease of only 144 cfs, a small proportion of the flow in the lower Klamath River. This modeled flow change would have a negligible impact on flows in the lower Klamath River where eulachon adult migration occurs..

O.5.31 Coastal Cutthroat Trout

O.5.31.1 Lower Klamath River from Confluence With Trinity River to Pacific Ocean

Spawning and Egg Incubation

Generally, spawning of anadromous and resident coastal cutthroat trout may occur from September to April (Moyle 2002). Coastal cutthroat trout are associated with shaded streams and instream cover with water temperatures below 64°F, while preferred temperatures range from 48–54°F, with spawning temperatures of 43–63°F (Moyle 2002). Spawning habitat is typically found in headwater streams with 1–3 feet/sec flow velocities and unembedded small- to medium-sized gravel (0.08–4 inches) (Moyle 2002). Embryos hatch about 6–7 weeks following incubation and alevins emerge 1–2 weeks thereafter (Moyle 2002).

The effects analysis period for coastal cutthroat trout spawning and egg incubation is September through June.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would be lower than or similar to flows under the No Action Alternative with a greater than 5% decrease in flows in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for spawning and egg incubation as Trinity River flows do not impact tributaries where coastal cutthroat trout spawn and modeled flow reductions occur outside the spawning and egg incubation period.
- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years, November in above normal water years, and December during below normal water years and greater than 5% higher in February and March of above normal water years (Table O-174). These reductions in flows would be negligible for spawning and egg incubation as Trinity River flows do not impact tributaries where coastal cutthroat trout spawn and modeled flow reductions occur outside the spawning and egg incubation period.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). These reduction in flows would likely be negligible for spawning and egg incubation as Trinity River flows do not impact tributaries where coastal cutthroat trout spawn and modeled flow reductions occur outside the spawning and egg incubation period.

- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). The reduction in flows would likely be negligible for spawning and egg incubation as Trinity River flows do not impact tributaries where coastal cutthroat trout spawn and modeled flow reductions occur outside the spawning and egg incubation period.

Seasonal operations under the various phases of Alternative 2 are not expected to impact suitable habitat conditions for coastal cutthroat trout spawning and egg incubation in the Trinity River. Compared to the No Action Alternative, no adverse impacts on coastal cutthroat trout are expected.

Juvenile Rearing and Emigration

Juvenile coastal cutthroat trout may spend anywhere from one to three years in freshwater to rear. Cutthroat fry are typically associated with slow water velocities (less than 1 foot/sec, while they prefer <0.3 feet/sec), and trout are typically found in shaded streams with instream cover and water temperatures below 64°F, while preferred temperatures range from 48–54°F (Moyle 2002).

For the amphidromous life history, most coastal cutthroat trout leave their streams for the summer months and return to overwinter in fresh water, even as non-spawning fish (Moyle 2002). During outmigration, many of the trout migrate to estuaries or lagoons and if they do go to the ocean, they remain close to the coast (Moyle 2002). In a Klamath River tributary, yearling and older cutthroat emigration occurred mainly between April and June (Moyle 2002). For individuals that emigrated to an estuary, Wallace (2004) found that the residence time within the estuary ranged from 5 to 89 days, with a mean of 27 days. Resident coastal cutthroat trout will remain in freshwater their entire lives, rather than emigrating to a lagoon or estuary or the ocean.

The effects analysis period for coastal cutthroat trout juvenile rearing and emigration is April through June for amphidromous coastal cutthroat trout and January through December for resident coastal cutthroat trout.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would lower than or similar to flows under the No Action Alternative with a greater than 5% decrease in flows in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for coastal cutthroat trout juvenile rearing and emigration as flows would still average 1,706 cfs in February of wet water years, 363 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows would occur in February and March of above normal water years, but this is not anticipated to have an impact on coastal cutthroat trout juvenile rearing and emigration.

- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for coastal cutthroat trout juvenile rearing and emigration as flows would still average 1,699 cfs in February of wet water years, 362 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows would occur in February and March of above normal water years, but this is not anticipated to have an impact on coastal cutthroat trout juvenile rearing and emigration.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). These reduction in flows would likely be negligible for coastal cutthroat trout juvenile rearing and emigration would still average 1,693 cfs in February of wet water years and 337 cfs in November of above normal water years.
- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). The reduction in flows would likely be negligible for coastal cutthroat trout juvenile rearing and emigration as flows would still average 1,698 cfs in wet water years and 339 cfs in above normal water years.

Seasonal operations under the various phases of Alternative 2 are expected to maintain suitable habitat conditions for coastal cutthroat trout juvenile rearing and emigration in the Trinity River. Compared to the No Action Alternative, changes in the availability or suitability of coastal cutthroat trout juvenile rearing and emigration habitat would be minimal and adverse impacts on coastal cutthroat trout would be negligible.

Adult Holding and Migration

Migration of coastal cutthroat trout to freshwater typically occurs between August and October between the ages of one and five (Moyle 2002). While most anadromous salmonids die after completing spawning, coastal cutthroat may survive spawning, re-enter the ocean, and return the following year(s) to spawn up to five times (Moyle 2002). Overwintering coastal cutthroat trout prefer pools with cover (e.g., logs, undercut banks, boulders) (Moyle 2002).

The effects analysis period for coastal cutthroat trout adult holding and migration is August through October for amphidromous coastal cutthroat trout and January through December for resident coastal cutthroat trout. Because operational changes in flows beyond 5% are only expected in November, December and February, there would be no adverse impacts across all Alternative 2 phases on amphidromous coastal cutthroat trout and the following analysis applies to resident coastal cutthroat trout.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would lower than or similar to flows under the No Action Alternative with a greater than 5% decrease in flows in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for coastal cutthroat trout adult holding and migration as flows would still average 1,706 cfs in February of wet water years, 363 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows is modeled in February and March of above normal water years, but this is not anticipated to have an impact on coastal cutthroat trout adult holding and migration.

- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for coastal cutthroat trout adult holding and migration as flows would still average 1,706 cfs in February of wet water years, above 363 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows is modeled in February and March of above normal water years, but this is not anticipated to have an impact on coastal cutthroat trout adult holding and migration.

- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). These reduction in flows would likely be negligible for coastal cutthroat trout adult holding and migration and would still average 1,693 cfs in February in wet water years and 337 cfs in November of above normal water years.

- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). The reduction in flows would likely be negligible for adult holding and migration as flows would still average 1,698 cfs in February of wet water years and 339 cfs in November of above normal water years.

Seasonal operations under the various phases of Alternative 2 are expected to maintain suitable habitat conditions for coastal cutthroat trout adult holding and migration in the Trinity River for all life history strategies. Compared to the No Action Alternative, substantial changes in the availability or suitability of coastal cutthroat trout adult holding and migration habitat would be minimal and negligible adverse impacts on coastal cutthroat trout are expected.

O.5.32 Brown Trout

O.5.32.1 Trinity River

Spawning and Egg Incubation

Brown trout spawn in fall and winter, most commonly in November and December in California (Moyle 2002). Trout typically mature and spawn in their second or third year, but they may wait longer (7 or 8 years) (Moyle 2002). Adults begin selecting spawning locations when water temperatures are between 42.8–50°F (Moyle 2002). Spawning habitat is comprised of pea- to walnut-sized gravel in less turbulent waters, which are typically found at pool tailouts (Moyle 2002). Embryos hatch in 7–8 weeks (ranging from 4–21 weeks), with alveins emerging 3–6 weeks later, depending on water temperature.

The effects analysis period for brown trout spawning and egg incubation is November through April.

Potential Changes to Brown Trout from Seasonal Operations

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would lower than or similar to flows under the No Action Alternative with a greater than 5% decrease in flows in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for spawning and egg incubation as flows would still average 1,706 cfs in February of wet water years,363 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows is modeled in February and March of above normal water years, but this is not anticipated to have an impact on brown trout spawning and egg incubation.
- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for spawning and egg incubation as flows would still average 1,699 cfs in February of wet water years, 362 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows is modeled in February and March of above normal water years, but this is not anticipated to have an impact on brown trout spawning and egg incubation.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February wet water years and November of above normal water years (Table O-174). These reduction in flows would likely be negligible for spawning and egg incubation as flows would still average 1,693 cfs in February of wet water years and 337 cfs in November of above normal water years. A greater than 5% increase in flows is modeled in February of above normal water years, but this is not anticipated to have an impact on brown trout spawning and egg incubation.

- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). The reduction in flows would likely be negligible for spawning and egg incubation as flows would still average 1,698 cfs in February of wet water years and 339 cfs in November of above normal water years. A greater than 5% increase in flows is modeled in February of above normal water years, but this is not anticipated to have an impact on brown trout spawning and egg incubation.

Seasonal operations under the various phases of Alternative 2 are expected to maintain suitable habitat conditions for brown trout spawning and egg incubation in the Trinity River. Compared to the No Action Alternative, substantial changes in the availability or suitability of brown trout spawning and egg incubation habitat would be minimal resulting in negligible adverse impacts on brown trout.

Juvenile Rearing and Emigration

The ideal temperature range for brown trout is between 53.6–68°F, with optimal growth between 62.6–64.4°F; they can survive for only short period at higher temperatures up to 84.2°F (Moyle 2002). Cold temperatures reduce brown trout's ability to effectively capture prey: when temperatures reduced from 58.5°F to 42.3°F the foraging effectiveness reduced from 96% to 53% (Watz and Piccolo 2010, as cited in Asarian et al., 2023).

In California, brown trout reach 2–3 inches in length their first year, 5–6 inches in their second year, 8–11 inches in their third, and 14–16 inches in their fourth year (Moyle 2002). Fry rear in edge-water habitat that is slow and shallow (<12 inches deep), with juveniles selecting riffles and pools with deeper water (20–30 inches), higher velocities (0.3–1.3 feet/second), and cover from overhead, rocks, and logs (Moyle 2002). It is uncertain the degree to which brown trout exhibit an anadromous life history in the Trinity River, with juveniles emigrating to the ocean, or are riverine (potamodromous) with juveniles emigrating further downstream while continuing to remain in freshwater. In Ireland, where they are native, brown trout juveniles emigrated to brackish or marine habitats throughout the year, with distinct seasonal peeks in spring (March through June) and fall (September through December) (Wynne et al., 2023).

The effects analysis period for brown trout juvenile rearing and emigration is January through December.

Potential Changes to Brown Trout from Seasonal Operations

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would lower than or similar to flows under the No Action Alternative with a greater than 5% decrease in flows in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for juvenile rearing and emigration as flows would still average 1,706 cfs in February of wet water years, 363 cfs in November of above normal water years, and880 cfs in December of below normal water years. A greater than 5% increase in flows is modeled in February and March of above normal water years, but this is not anticipated to have an impact on brown trout juvenile rearing and emigration.

- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for juvenile rearing and emigration as flows would still average 1,699 cfs in February of wet water years, 362 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows is modeled in February and March of above normal water years, but this is not anticipated to have an impact on brown trout juvenile rearing and emigration.
- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). These reduction in flows would likely be negligible for juvenile rearing and emigration as flows would still average 1,693 cfs in February of wet water years, 337 cfs in November of above normal water years. A greater than 5% increase in flows is modeled in February of above normal water years, but this is not anticipated to have an impact on brown trout juvenile rearing and emigration.
- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February of wet water years and November of above normal water years (Table O-174). The reduction in flows would likely be negligible for juvenile rearing and emigration as flows would still be average 1,698 cfs in February of wet water years and 339 cfs in November of above normal water years. A greater than 5% increase in flows is modeled in February of above normal water years, but this is not anticipated to have an impact on brown trout juvenile rearing and emigration.

Seasonal operations under the various phases of Alternative 2 are expected to maintain suitable habitat conditions for brown trout juvenile rearing and emigration in the Trinity River. Compared to the No Action Alternative, substantial changes in the availability or suitability of brown trout juvenile rearing and emigration habitat would be minimal and would have negligible adverse impacts on brown trout.

Adult Holding and Migration

Upstream migration occurs in fall and winter, prior to spawning, which most commonly occurs in November and December. Sullivan and Hilemean (2018) noted a shift in migration timing on the Trinity River to later in the season following the implementation of the Record of Decision (ROD) flows (2005-2011, 2017), as compared to the between baseline Pre-ROD flows (1982–2002). In rivers, adults will hold in a wide range of habitats, but are often associated with low velocity pools ranging from 2.3–11.5 feet deep that have cover (Moyle 2002).

The effects analysis period for brown trout adult holding and migration is January through December with migration primarily in November and December.

Potential Changes to Brown Trout from Seasonal Operations

- **Alternative 2 With TUCP Without VA:** Under Alternative 2 With TUCP Without VA, monthly average flows would lower than or similar to flows under the No Action Alternative with a greater than 5% decrease in flows in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for migrating and holding adults as flows would still be average 1,706 cfs in February of wet water years, 363 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows modeled in February and March of above normal water years, but this is not anticipated to have an impact on brown trout adult migration and holding.

- **Alternative 2 Without TUCP Without VA:** Under Alternative 2 Without TUCP Without VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years, November in above normal water years, and December during below normal water years (Table O-174). These reductions in flows would likely be negligible for migrating and holding adults as flows would still average 1,706 cfs in February of wet water years, 363 cfs in November of above normal water years, and 880 cfs in December of below normal water years. A greater than 5% increase in flows modeled in February of above normal water years, but this is not anticipated to have an impact on brown trout adult migration and holding.

- **Alternative 2 Without TUCP With Delta VA:** Under Alternative 2 Without TUCP With Delta VA, monthly average flows would be greater than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). These reduction in flows would likely be negligible for adult migration and holding as flows would still average 1,693 cfs in February of wet water years and 337 cfs in November of above normal water years. A greater than 5% increase in flows is modeled in February of above normal water years, but this is not anticipated to have an impact on brown trout adult migration and holding.

- **Alternative 2 Without TUCP With Systemwide VA:** Under Alternative 2 Without TUCP With Systemwide VA, monthly average flows would be more than 5% lower than the No Action Alternative in February in wet water years and November of above normal water years (Table O-174). The reduction in flows would likely be negligible for adult migration and holding as flows would still average 1,698 cfs in February of wet water years and above 339 cfs in November of above normal water years. A greater than 5% increase in flows is modeled in February of above normal water years, but this is not anticipated to have an impact on brown trout adult migration and holding.

Seasonal operations under the various phases of Alternative 2 are expected to maintain suitable habitat conditions for brown trout adult migration and holding in the Trinity River. Compared to the No Action Alternative, substantial changes in the availability or suitability of brown trout adult migration and holding habitat would be minimal and would have negligible adverse impacts on brown trout.

O.5.33 Trinity Reservoir Species

O.5.33.1 Trinity Reservoir

Spawning and Egg Incubation

Coldwater fish species (rainbow trout, brown trout, Kokanee, and landlocked Chinook salmon) in the lake generally migrate into tributaries to spawn either during from December through March (rainbow trout), November–December (brown trout), or August through April (kokanee). Populations of rainbow trout, brown trout, and Kokanee are sustained through a combination of natural reproduction and fish hatchery stocking practices. Landlocked Chinook salmon do not typically reproduce (Perales et al. 2015) and are supported by annual stocking practices.

Warmwater fish species (smallmouth bass, largemouth bass, white catfish, and brown bullhead) typically rely on habitat in the lake during all life stages. In general, smallmouth and largemouth bass spawn from April through July in shallow water (1.5 feet to 6.0 feet deep) along the lake margins at water temperatures ranging from 55°F to 75°F (Moyle 2002). These nests are vulnerable to differences in water levels. Rapid drops in water levels may cause guarding males to abandon the nests, increase predation, and limit water circulation and dissolved oxygen levels around the eggs (USFWS 1983, Habitat Suitability Information: Smallmouth Bass, FWS/OBS-82/10.36). White catfish spawning typically occurs during June and July when water temperatures exceed 68°F, but spawning can sometimes extend into September; spawning occurs in sandy substrate adjacent to cover (e.g., rocks, wood, or aquatic vegetation) and eggs hatch in about a week (Moyle 2002). Brown bullhead spawn from May through mid-July and will build their nests in sand or gravel near cover (Moyle 2002). Warmwater fish species in Trinity Lake are currently self-sustaining through natural reproduction.

The effects analysis period for coldwater fish species spawning and egg incubation is August through April. The effects analysis period for warmwater fish species spawning and egg incubation is April through September.

CalSim 3 monthly average volume in Trinity Reservoir shows that modeled reservoir volume would not change more than 5% for any of the Alternative 2 phases across all months (Table O-178 through Table O-181); therefore, impacts to reservoir species spawning and incubation would be negligible across all four phases of Alternative 2.

Larval and Juvenile Rearing and Emigration

Rainbow trout fry emerge three to four weeks after fertilization and will remain in the gravel for about 2–3 weeks (Moyle 2002, USFWS 1984, Habitat Suitability Information: Rainbow Trout, FWS/OBS-82/10.60). Juvenile rainbow trout may spend two summers in their natal stream and two summers in a reservoir or lake before maturing. Brown trout fry typically hatch in twomonths, though it can range from one to five months depending on water temperature, and larvae will emerge from the gravel around 1 month later. Juveniles will spend several years in tributaries before emigrating to the reservoir where they will become sexually mature (Moyle 2002, Belica 2007).

Smallmouth and largemouth bass fry prefer shallow water and are vulnerable to fluctuations in water levels. These fry hatch in two to seven days and then spend another week in the nest.

Larval bass stay in shallow water on the edge of vegetation (Moyle 2002). Rapid drops in water levels may cause stranding. Juvenile bass tend to live in deeper water habitats with submerged shelter (e.g., logs or boulders). White catfish will move throughout the reservoir and don't have a regular seasonal migration, thought they tend to concentrate at depts of 10–30 ft but will move deeper in the summer as temperatures increase (Moyle 2002). Brown bullhead typically live in deeper water (6–30 ft deep) in areas with aquatic plants and muddy substrate (Moyle 2002).

The effects analysis period for both coldwater and warmwater fish species larval and juvenile rearing and emigration is January through December.

CalSim 3 monthly average volume in Trinity Reservoir shows that modeled reservoir volume would not change more than 5% for any of the Alternative 2 phases across all months (Table O-178 through Table O-181); therefore, impacts to reservoir species larval and juvenile rearing and emigration would be negligible across all four phases of Alternative 2.

Adult Holding

The life expectancy of rainbow trout can be four to eight years in northern California lake populations. After maturing, resident rainbow trout will migrate upstream to spawn in tributaries. They can spawn annually and will quickly move back downstream to the reservoir or lake (Moyle 2002), moving to cooler, deeper waters during the summer months (Belica 2007). Brown trout typically become sexually mature at age two or three and have been found as old as can live for up to 9 years in California, spawning several times during their life (Moyle 2002, Belica 2007). Brown trout will use varying habitats within the reservoir and will also move to cooler waters in the summer habitats (Belica 2007).

Warmwater species will remain in the reservoir their entire lives. Smallmouth bass prefer narrow bays and upstream ends of reservoirs or along the shore where rocky shelves are present at a depth of 1–10m (Moyle 2002). They become sexually mature at age three to four and typically live less than seven years (USFWS 1983, Habitat Suitability Information: Smallmouth Bass, FWS/OBS-82/10.36). Age of largemouth bass in California reservoirs is four to five years and they typically spawn during their second season (Moyle 2002). Adult bass tend to prefer deeper, colder waters in lakes and reservoirs in areas with vegetation and other forms of cover (USFWS 1983b, Habitat Suitability Information: Largemouth Bass, FWS/OBS-82/10.16). White catfish will move throughout the reservoir and don't have a regular seasonal migration, thought they tend to concentrate at depts of 10–30 ft but will move deeper in the summer as temperatures increase (Moyle 2002). Brown bullhead typically live in deeper water (6–30 ft deep) in areas with aquatic plants and muddy substrate (Moyle 2002). They become sexually mature at age three and will spawn multiple times during their lifetime of up to eight to 10 years (Moyle 2002).

The effects analysis period for both coldwater and warmwater fish species adult holding is January through December.

CalSim 3 monthly average volume in Trinity Reservoir shows that modeled reservoir volume would not change more than 5% for any of the Alternative 2 phases across all months (Table O-178 through Table O-181); therefore, impacts to reservoir species adult migration and holding would be negligible across all four phases of Alternative 2.

O.5.34 Central Valley Reservoir Species

O.5.34.1 Potential Changes to Central Valley Reservoir Species from Seasonal Operations

Shasta Reservoir

Warmwater Species

Reductions in Shasta Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-166.

- For **Alternative 2 With TUCP Without VA**, WSE reductions of 6 feet or more would be similar to those under the No Action Alternative during all months except May, in which there would be eight fewer reductions under Alternative 2 With TUCP Without VA. These results indicate that Alternative 2 With TUCP Without VA would have a beneficial effect on warmwater species in Shasta Reservoir.
- For **Alternative 2 Without TUCP Without VA**, WSE reductions of 6 feet or more would be similar to those under the No Action Alternative during all months except May, in which there would be nine fewer reductions under Alternative 2 Without TUCP Without VA. These results indicate that Alternative 2 Without TUCP Without VA would have a beneficial effect on warmwater species in Shasta Reservoir.
- For **Alternative 2 Without TUCP Delta VA**, WSE reductions of 6 feet or more would be similar to those under the No Action Alternative during all months except May, in which there would be nine fewer reductions under Alternative 2 Without TUCP Delta VA. These results indicate that Alternative 2 Without TUCP Delta VA would have a beneficial effect on warmwater species in Shasta Reservoir.
- For **Alternative 2 Without TUCP Systemwide VA**, WSE reductions of 6 feet or more would be similar to those under the No Action Alternative during all months except May and June, in which there would be eight and six fewer reductions, respectively, under Alternative 2 Without TUCP Systemwide VA. These results indicate that Alternative 2 Without TUCP Systemwide VA would have a beneficial effect on warmwater species in Shasta Reservoir.

Overall, Alternative 2 would have beneficial effects on warmwater species in Shasta Reservoir.

Coldwater Species

Shasta Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-166.

- For **Alternative 2 With TUCP Without VA**, storage would be similar to that of the No Action Alternative during most months of wet, above normal, and below normal water years. Storage would be 5.1-5.7% greater under Alternative 2 With TUCP Without VA during July through October of dry water years and 7.6-33.8% higher in all months evaluated in critically dry water years, representing large beneficial effects to coldwater reservoir species.
- For **Alternative 2 Without TUCP Without VA**, storage would be similar to that of the No Action Alternative during most months of wet, above normal, below normal, and dry water years. In critical water years, storage under Alternative 2 Without TUCP Without VA would be up to 12.6% higher than storage under the No Action Alternative, representing a beneficial effect to coldwater reservoir species.
- For **Alternative 2 Without TUCP Delta VA**, storage would be similar to that of the No Action Alternative during most months of wet, above normal, below normal, and dry water years. In critical water years, storage under Alternative 2 Without TUCP Without VA would be up to 15.5% higher than storage under the No Action Alternative, representing a beneficial effect to coldwater reservoir species.
- For **Alternative 2 Without TUCP Systemwide VA**, storage would be similar to that of the No Action Alternative during most months of wet, above normal, below normal, and dry water years. In critical water years, storage under Alternative 2 Without TUCP Without VA would be up to 14.4% higher than storage under the No Action Alternative, representing a beneficial effect to coldwater reservoir species.

Overall, Alternative 2 would have beneficial effects on coldwater species in Shasta Reservoir, particularly in critically dry water years.

Whiskeytown Reservoir

Warmwater Species

Reductions in Whiskeytown Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-167. These results indicate that, for all 4 phases of Alternative 2, there would be no or negligible difference in WSE month-over-month reductions of 6 feet or more relative to the No Action Alternative. Therefore, there would be negligible effects of Alternative 2 on warmwater species in Whiskeytown Reservoir.

Coldwater Species

Whiskeytown Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-168.

For all phases of Alternative 2, end-of-month storage volume would be similar to that of the No Action Alternative. These results indicate that Alternative 2 would have negligible effects on coldwater species in Whiskeytown Reservoir.

Folsom Reservoir

Warmwater Species

Reductions in Folsom Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-169. There would be zero to four more reductions under Alternative 2 than the No Action Alternative depending on month and phase. However, the low frequency of these reductions is not expected to have a negative effect on warmwater species.

Coldwater Species

Folsom Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-170.

- For **Alternative 2 With TUCP Without VA**, storage would be similar to that of the No Action Alternative during wet, above normal, below normal, and dry water years. Storage would be 4.1-10.9% higher under Alternative 2 With TUCP Without VA during July through October of critical water years, representing a beneficial effect to coldwater reservoir species.
- For **Alternative 2 Without TUCP Without VA**, storage would be similar to that of the No Action Alternative during most months of wet, above normal, below normal, and dry water years. In critical water years, storage under Alternative 2 Without TUCP Without VA would be 7.4-12.7% % lower than storage under the No Action Alternative, representing a negative effect to coldwater reservoir species.
- For **Alternative 2 Without TUCP Delta VA**, storage would be similar to that of the No Action Alternative during most months of wet, above normal, below normal, and dry water years. In critical water years, storage under Alternative 2 Without TUCP Without VA would be 9.1-13.7% lower than storage under the No Action Alternative, representing a negative effect to coldwater reservoir species.
- For **Alternative 2 Without TUCP Systemwide VA**, storage would be similar to that of the No Action Alternative during wet and below normal water years. In above normal, dry, and critical water years, storage under Alternative 2 Without TUCP Without VA would be up to 11.9% lower than storage under the No Action Alternative, representing a negative effect to coldwater reservoir species.

Overall, Alternative 2 effects on coldwater species would be mixed depending on phase, but mostly negative, particularly in critically dry water years and under Alternative 2 Without TUCP Systemwide VA.

New Melones Reservoir

Warmwater Species

Reductions in New Melones Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Melones 2.

For all phases of Alternative 2, there would be zero to two fewer reductions of 6 feet or more than under the No Action Alternative depending on month. The low frequency of these reductions is not expected to provide a beneficial effect on warmwater species in New Melones Reservoir.

Coldwater Species

New Melones Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-172.

- For **Alternative 2 With TUCP Without VA**, **Alternative 2 Without TUCP Without VA**, and **Alternative 2 Without TUCP Delta VA**, end-of month storage would be similar to storage under the No Action Alternative during all months evaluated and in all water year types.
- For **Alternative 2 Without TUCP Systemwide VA**, storage would be up to 5.7% higher in dry water years and up to 9.4% lower in critical water years.

These results suggest that there would be negligible effects under Alternative 2 With TUCP Without VA, Alternative 2 Without TUCP Without VA, and Alternative 2 Without TUCP Delta VA, and both small beneficial and negative effects of Alternative 2 Without TUCP Systemwide VA on coldwater fish species in New Melones Reservoir.

O.5.35 Delta-Mendota Canal / California Aqueduct Species

O.5.35.1 Potential Changes to Delta-Mendota Canal/California Aqueduct Species from Seasonal Operations

Water from the Delta is diverted through the California Aqueduct and Delta-Mendota Canal and held for off-stream storage (e.g., in San Luis Reservoir) and there is no coldwater habitat in the Delta-Mendota Canal. Therefore, no analysis of coldwater habitat was conducted. Warmwater species such as black basses and striped bass support recreational fishing in the California Aqueduct. Water velocity in the canal is not specifically managed to support or enhance recreational fisheries. Increases in water velocity may decrease water temperatures and flowing water for species, improving conditions; while decreases in water velocity may increase water temperatures and lead to stagnant water for species, diminishing conditions.

Differences in flows and velocity under the four phases of Alternative 2, compared to the No Action Alternative, are expected to be minimal thus, impacts to species present are not expected to change.

O.5.36 San Luis Reservoir Species

O.5.36.1 Potential Changes to San Luis Reservoir Species from Seasonal Operations

Warmwater Species

Reductions in San Luis Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects. Please see Section O.4.33.2, *Methods,* for details on the methods used in this analysis. Results are presented in Table O-173.

- For **Alternative 2 With TUCP Without VA**, there would be between one more and 22 fewer reductions than under the No Action Alternative depending on month, representing a beneficial effect to warmwater reservoir species.
- For **Alternative 2 Without TUCP Without VA**, there would be between more and 26 fewer reductions than under the No Action Alternative depending on month, representing a beneficial effect to warmwater reservoir species.
- For **Alternative 2 Without TUCP Delta VA**, there would be between five more and 22 fewer reductions than under the No Action Alternative depending on month, representing a slight negative and larger beneficial effect to warmwater reservoir species.
- For **Alternative 2 Without TUCP Systemwide VA**, there would be between six more and 23 fewer reductions than under the No Action Alternative depending on month, representing a slight negative and larger beneficial effect to warmwater reservoir species.

Overall, the four phases of Alternative 2 would predominantly have no or beneficial effects on warmwater species in San Luis Reservoir, with some slight negative effects under the two phases with VAs.

O.5.37 Southern Resident Killer Whale

O.5.37.1 Nearshore Pacific Ocean on the California Coast

Changes in water operations under the alternatives could have the potential to affect Chinook salmon prey for Southern Resident Killer Whale (Southern Resident) relative to the No Action Alternative. Outlined below are expected changes in Southern Residents' prey. Four lines of evidence were used (Salmort, XT, CVPIA SIT LCM, and DPM), and Attachment F.7, *Change in Abundance Estimate of Central Vally Chinook Salmon Available to Southern Resident Killer Whales*, provides detailed results of all models and analyses.

- Based on the lines of evidence, **Alternative 2 Without TUCP Without VAs** is predicted to have an annual abundance of about 232,725 Chinook salmon that survive to adulthood or about 3,494,361 pounds of Chinook salmon biomass in the ocean available as potential prey to Southern Residents. This is about 26 less Chinook salmon or 385 pounds less than the No Action Alternative. This is likely a negligible difference in Chinook salmon and biomass available to Southern Residents for prey between the No Action Alternative and Alternative 2 Without TUCP Without VAs.
- Based on the lines of evidence, **Alternative 2 With TUCP Without VAs** is predicted to have an annual abundance of about 232,730 Chinook salmon that survive to adulthood or about 3,494,444 pounds of Chinook salmon biomass in the ocean available as potential prey to Southern Residents. This is about 20 less Chinook salmon or 302 pounds less than the No Action Alternative. This is likely a negligible difference in Chinook salmon and biomass available to Southern Residents for prey between the No Action Alternative and Alternative 2 With TUCP Without VAs.
- Based on the lines of evidence, **Alternative 2 Without TUCP with Delta VAs** is predicted to have an annual abundance of about 232,722 Chinook salmon that survive to adulthood or about 3,494,314 pounds of Chinook salmon biomass in the ocean available as potential prey to Southern Residents. This is about 29 less Chinook salmon or 432 pounds less than the No Action Alternative. This is likely a negligible difference in Chinook salmon and biomass available to Southern Residents for prey between the No Action Alternative and Alternative 2 Without TUCP with Delta VAs.
- Based on the lines of evidence, **Alternative 2 Without TUCP with Systemwide VAs** is predicted to have an annual abundance of about 232,931 Chinook salmon that survive to adulthood or about 3,497,453 pounds of Chinook salmon biomass in the ocean available as potential prey to Southern residents. This is about 180 more Chinook salmon or 2,707 pounds more than the No Action Alternative. This is likely a negligible difference in Chinook salmon and biomass available to Southern residents for prey between the No Action Alternative and Alternative 2 Without TUCP with Systemwide VAs.

None of the Alternative 2 phases differ greatly from the No Action Alternative but the Alternative 2 Without TUCP with systemwide VAs is the only alternative that is modeled to increase Southern Resident food relative to the No Action Alternative and therefore performs the best with regard to Southern Resident food availability out of all the Alternative 2 phases. The other three phases decrease the amount of Southern Resident food relative to the No Action Alternative but the decrease is likely negligible.

O.6 Alternative 3

Alternative 3 (Modified Natural Hydrograph) represents actions informed by discussions with some of the environmental NGOs involved in state-wide water projects. Alternative 3 combines additional Delta outflow with measures to improve drought protection and temperature management through increased reservoir carryover storage. To read more about how Alternative 3 applies a priority order for meeting downstream demands, see EI*S Chapter 3, Alternatives*.

O.6.1 Trinity River

O.6.1.1 Trinity River Flows below Lewiston Dam

CalSim 3 modeling suggests that average flow released at Lewiston Dam under Alternative 3 would generally be higher than or similar to flow under the No Action Alternative, except in below normal water years in March and wet water years in April when the Alternative 3 flows would be substantially lower (greater than 5% decrease) than the No Action Alternative flows (Table O-246). Average monthly flows under Alternative 3 would be substantially higher (greater than 5% increase) in wet years December through February; above normal years in February; and below normal years in December. Table O-246 shows that the highest flows for both alternatives are expected primarily in May and June of all water year types and during winter, spring, and early summer of wet water years and January through March and May through July of above normal water years. Throughout the full simulation period, flows on average are higher under Alternative 3 in November through March, with the greatest increases in flow (greater than 5%) December through February and a slight average decrease in flow in April.

O.6.1.2 Trinity Reservoir Storage

CalSim 3 modeling suggests that average monthly Trinity Reservoir storage under Alternative 3 would generally be higher than storage under the No Action Alternative, except in wet years April through December when Trinity Reservoir storage would be slightly lower than the No Action Alternative (Table O-247). Table O-247 shows that there are substantial increases in storage under Alternative 3 compared with the No Action Alternative (greater than 5%) in below normal years July through December; dry years August through November; and critically dry years April through January. Throughout the full simulation period, storage on average is slightly higher under Alternative 3 across all months.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.6.2 Sacramento River

Alternative 3 (Modified Natural Hydrograph) represents actions informed by discussions with some of the environmental NGOs involved in state-wide water projects. Flow releases are high during the summer to satisfy downstream demands of water users and Delta water quality, and to meet water temperature requirements of incubating Winter-run Chinook salmon eggs and alevins downstream of Keswick Dam. Subject to modeling demonstrating that operations are reasonably likely to meet the Shasta Reservoir storage requirements for water temperature management, Alternative 3 bypasses 55% of unimpaired inflow to Shasta Reservoir from December through May to achieve the monthly Delta Outflow criteria in Table 3.5-1 (see EIS Chapter 3). When the monthly Delta Outflow criteria in Table 3.5-1 is met, then releases from Shasta Reservoir that month may be reduced to 45% of unimpaired inflows from December to May. Reclamation would reduce deliveries from stored water releases from Shasta Reservoir to meet the storage requirements May through November of 3.6 MAF (EOA Storage) and 1.9 MAF (EOS Storage) on critically dry water year types, and 3.9 MAF (EOA Storage) and 2.2 MAF (EOS Storage) all other water year types (WRO 90-5). In addition, Reclamation would release unstored water to meet Delta outflow requirements described in EIS Chapter 3, Section 3.5.1.2 from December through May to the extent modeling indicates doing so was consistent with meeting these storage requirements.

O.6.2.1 Sacramento River Flows below Keswick Dam

Under Alternative 3 compared to the No Action Alternative, CalSim 3 modeling suggests monthly average flows below Keswick Dam are higher in May and December and lower April, June, and July (Table O-248). The largest decreases under Alternative 3 compared to the No Action Alternative are expected in May of critically dry water years (21%) and June (17%) of above normal water years. The largest increases under Alternative 3 compared to the No Action Alternative are expected in December of above normal water years (33%) and August of dry water years.

O.6.2.2 Sacramento River Flows below Red Bluff Diversion Dam

Under Alternative 3 compared to the No Action Alternative, CalSim 3 modeling suggests monthly average flows below Red Bluff Diversion Dam are higher in December, May, and August and lower June and July throughout the full simulation period (Table O-249Table O-249). The largest decreases in flow under Alternative 3 are expected in June and July of above normal years (18% and 15%, respectively). The largest increases in flow under Alternative 3 are expected in May of wet and above normal year types (27% and 23%, respectively) and August of dry years (23%).

O.6.2.3 Sacramento River Flows at Wilkins Slough

Under Alternative 3 compared to the No Action Alternative, CalSim 3 modeling suggests monthly average flows are higher in May and August and lower in June, July, and September throughout the full simulation period (Table O-250). The largest decreases in flow under Alternative 3 are expected in June and July of above normal years (28% and 26%, respectively). The largest increases in flow under Alternative 3 are expected in May of wet and above normal year types (35% and 37%, respectively) and August of dry years (43%).

O.6.2.4 Sacramento River Flows at Hamilton City

Under Alternative 3 compared to the No Action Alternative, CalSim 3 modeling suggests that monthly average flows are higher in May and August and lower June and July throughout the full simulation period (Table O-251). The largest decreases in flow under Alternative 3 are expected in June and July of above normal years (22% and 19%, respectively). The largest increases in flow under Alternative 3 are expected in May of wet and above normal year types (29% and 27%, respectively) and August of dry years (29%).

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.6.3 Bay-Delta

Alternative 3 assumes a single unit operation is feasible for exports to meet public health and safety and would be shared between the CVP and SWP. From whichever is earlier, either January 1 or the onset of OMR management, until the earlier of June 30 or the offramp of OMR Management, flows shall not exceed -5,000 cfs on a 14-day running average. These requirements do not apply when San Joaquin River flows at Vernalis are greater than 20,000 cfs. In addition, when the SVI has been classified as a critically dry year for a second (or more) consecutive year, OMR flows shall not exceed -2,500 cfs on a 14-day running average. From April 1 to May 31, Reclamation and DWR would operate to achieve a 2:1 ratio of San Joaquin River inflow at Vernalis to combined CVP/SWP exports in all water year types. In addition to the requirements under D-1641, Reclamation and DWR would operate to meet the Delta Outflow criteria in Chapter 3 Alternatives Table 3.5 1 for the months of July to November. From December through June, Reclamation and DWR would operate to meet Delta Outflow that is the lesser of 65 percent of unimpaired Delta inflow or the Delta Outflow criteria in Chapter 3 Alternatives Table 3.5 1. Reclamation and DWR may release stored water to meet Delta outflow criteria in May through November. Reclamation and DWR may release stored water to meet Delta outflow criteria in May through November. Reclamation and DWR would prioritize meeting the storage requirements described in Chapter 3 Alternatives 3.5.5 Delta before making additional reservoir releases beyond what is required to meet D-1641 and human health and safety. In the summer and fall, Alternative 3 is the same as Alternative 2, except releases from upstream reservoirs are constrained to a Delta outflow of 7,100 cfs in November of wet and above normal years. Fall salinity may vary based on the ability of export reductions to achieve Fall X2 subject to public health and safety.

O.6.3.1 Delta X2

CalSim 3 modeling suggests that the estimated X2 position under Alternative 3 when compared to the No Action Alternative is further seaward in December and May for wet years, November–January in above normal years, in January in below normal years, in January and August–September for dry years and in December for critically dry years. (Table O-252). Table O-252 suggests that most landward X2 positions are expected during late summer to fall months in the critically dry years and the most seaward positions are expected during the winter to early spring months in wet years for both alternatives. For the full simulation period, when comparing Alternative 3 to the No Action Alternative, X2 was more seaward in December.

O.6.3.2 Delta Exports

CalSim 3 modeling suggests that the total exports of the SWP and CVP under Alternative 3 when compared to the No Action Alternative generally decrease across all water year types and months. Exports only increased in October for the dry water year type and August for the critical water year type. (Table O-253). Table O-253 suggests that exports were generally highest in February in above normal water year types for Alternative 3 and highest in July–August and November in the wet water year type for the No Action Alternative. Exports were generally the lowest in April-May during the critically dry water year type for Alternative 3 and in July–August during the critically dry water year type for the No Action Alternative. For the full simulation period, total exports when compared to the No Action Alternative decreased across all months.

O.6.3.3 Delta Outflow

Under Alternative 3 when compared to the No Action Alternative, total Delta outflow generally increases across most months and water year types. Outflow decreases in June and July of wet, above normal and below normal water year types and in September of wet, above normal and critically dry water year types and in October of the dry water year type (Table O-254). Table O-254 suggests total Delta outflow is highest in February during wet years and lowest in the late summer–fall during the critically dry water year type for both alternatives. For the full simulation period when compared to the No Action Alternative, total Delta outflow increased from November to May and August.

O.6.3.4 Delta OMR

CalSim 3 modeling suggests that Old and Middle River (OMR) combined flows under Alternative 3 when compared to the No Action Alternative is generally less negative across all water year types and months except for October in dry years and August in critically dry years (Table O-255). Table O-255 suggests that OMR flows were generally the most negative in November of below normal years for Alternative 3 and August of above normal years for the No Action Alternative, and the least negative in May during wet water years for both alternatives. For the full simulation period, OMR flows were less negative across all months.

O.6.3.5 Sacramento River at Rio Vista

CalSim 3 modeling suggests that average flows in the Sacramento River at Rio Vista under Alternative 3 compared to the No Action Alternative are similar or increased from November through May and similar or decreased June through October (Table O-256). The greatest reductions are expected during July of an above normal water year type under Alternative 3 compared to the No Action Alternative. The greatest increase is expected during April of critically dry water year types under Alternative 3 compared to the No Action Alternative.

O.6.4 Clear Creek

Under Alternative 3, Reclamation would release water through Whiskeytown Dam to provide intra-annual variation to emulate natural processes. As provided in Figure 3.4-1 and Table 3.4-2 (EIS, Chapter 3), flows would oscillate over a one-year period, with releases transitioning from 300 cfs in the winter, down to 100 cfs in the summer, and back to 300 cfs by the following winter. Reclamation, through the Clear Creek Technical Team, may modify the timing and flow rates provided in Figure 3.4-1 and Table 3.4-2 by February 1 and update through May on a case-by-case basis; the flow schedule is subject to agreement by Redding Electric Utility for use of their facilities.

Reclamation would release up to 10,000 acre-feet from Whiskeytown Dam for channel maintenance, spring attraction flows, and to meet other physical and biological objectives, except in years with significant uncontrolled flow. In critical years, Reclamation would release up to 5,000 acre-feet. Reclamation, through the Clear Creek Technical Team, would develop pulse flow schedules, which include measures (e.g., nighttime down ramping, slow down ramping rates, coordination with natural precipitation events) to mitigate for potential risks (e.g., potential juvenile fish stranding). Due to unknowns in winter precipitation, Clear Creek pulse flows are not to occur prior to the February SVI reporting. The full pulse flow volume (10,000 acre-feet) will be available if the SVI is greater than 5.4, at the SVI updates (i.e., dry or wetter years). If the SVI updates are equal to or less than 5.4 (critical years), Reclamation would limit releases of pulse(s) flows to 5,000 acre-feet. Reclamation would also target Whiskeytown Dam releases at except that Reclamation will manage Whiskeytown Dam releases to not exceed mean daily water temperatures of 60°F at the Igo gauge from June 1 through September 15 and 56°F from September 15 through November 15. In dry, critical, or import curtailment years, Reclamation may not be able to meet these water temperatures and will operate Whiskeytown Dam as close to these water temperatures as practicable within the constraints of minimum instream flows.

O.6.4.1 Clear Creek below Whiskeytown Dam

CalSim 3 modeling suggests that monthly average flows below Whiskeytown Dam under Alternative 3 compared to the No Action Alternative are expected to increase November through January and March through May, and decrease February and June through October (Table O-257). The largest increases under Alternative 3 compared to the No Action Alternative are expected March through May. The largest decreases under Alternative 3 compared to the No Action Alternative are expected in June through August.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.6.5 Lower American River

Under Alternative 3, management actions for the lower American River would be the same as the No Action Alternative Reclamation and would implement the minimum release requirement (MRR) proposed by the Sacramento Area Water Forum, based on the month and annual hydrology, Figure 3.2-3 and Figure 3.2-4 (EIS, Chapter 3), except it would implement End of September 300 TAF (230 TAF in a second consecutive dry or critical water year type) and End of December 300 TAF as necessary to achieve storage targets. Reclamation will use the 90% exceedance from the Sacramento River Index in January and the lower American River Index in February through December to develop the MRR (with certain spills subtracted). Subject to annual modeling demonstrating that operations are reasonably likely to meet the storage requirements described above, Alternative 3 bypasses 55% of unimpaired inflows to Folsom Reservoir from December through May to achieve the monthly Delta Outflow criteria in Table 3.5-1 (EIS, Chapter 3). Subject to achieving the storage requirements described above, Reclamation may release stored water from May to November to meet the Delta Outflow criteria described in Table 3.5-1 (EIS, Chapter 3). If the monthly Delta Outflow criteria is met, then releases from Folsom Reservoir that month may be reduced to 45% of unimpaired inflows from December through May.

O.6.5.1 Lower American River for Folsom Reservoir Storage

CalSim 3 modeling suggests that monthly average volume of Folsom Storage under Alternative 3 compared to the No Action Alternative is generally expected to be similar, except in April and May when storage is expected to be lower (Table O-258). The largest increases are expected July through November in above normal and below normal water year types. The largest decreases are expected April and May (up to 10%) of above normal and below normal water year types.

O.6.5.2 Lower American River below Nimbus Dam

CalSim 3 modeling suggests that monthly average flows under Alternative 3 compared to the No Action Alternative are similar (less than a 5% difference) September through February, and are expected to increase or decrease depending on the month March through August (Table O-259). Under Alternative 3 compared to the No Action Alternative, the largest increases in flow were in April and decreases would are expected in June of almost all water year types except wet and critically dry water year types. Wet water year types could generally be similar most months except June and September would be lower under Alternative 3 compared to the No Action Alternative; in critically water year types, the largest increases in flow are expected in December (up to 62%) and decreases would be expected in November (up to 29%).

O.6.5.3 Lower American River at H Street

CalSim 3 modeling suggests monthly average flows in the lower American River at H street under Alternative 3 compared to the No Action Alternative are similar (less than a 5% difference) September through February, and are expected to increase or decrease depending on the month March through August (Table O-260). Under Alternative 3 compared to the No Action Alternative, the largest increases in flow were in April and decreases would are expected in June of almost all water year types except wet and critically dry water year types. Wet water year types could generally be similar most months except June and September would be lower under Alternative 3 compared to the No Action Alternative; in critically water year types, the largest increases in flow are expected in December and decreases are expected in November.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.6.6 Stanislaus River

Consistent with the 2018 Bay-Delta Water Quality Control Plan, this component is consistent with the No Action Alternative in the summer and fall and it requires New Melones Reservoir to meet 40% of unimpaired inflow on a 7-day running average to the confluence with the San Joaquin River in February through June; in these months, Reclamation also would make releases from New Melones Dam as necessary to contribute its share (29%) of meeting the 1,000 cfs minimum flow at Vernalis. Reclamation would reduce deliveries to all contractors to achieve a minimum end of September storage in New Melones of 700 TAF. Reclamation through Governance, would schedule fall pulse flow volumes consistent with the volumes in the SRP and potentially release additional flows in October and November.

O.6.6.1 Stanislaus River below Goodwin Dam

CalSim 3 modeling suggests monthly average flows under Alternative 3 compared to No Action Alternative below Goodwin Dam will increase February through June, and decrease August, September, December, and January (Table O-261). Under Alternative 3 compared to the No Action Alternative, the largest increases in flow are expected in February, March, or June and decreases are expected in June or December of almost all water year types. Under Alternative 3 compared to the No Action Alternative, critically water year types are projected to have similar flow conditions almost all months except June, when these would be higher.

O.6.6.2 Stanislaus River at Mouth

CalSim 3 modeling suggests monthly average flows under Alternative 3 compared to No Action Alternative at the mouth of the Stanislaus River will increase February through July and decrease August, September, December, and January (Table O-262). Under Alternative 3 compared to the No Action Alternative, the largest increases in flow are expected in March, April, or June and decreases are expected in January, August, or December of almost all water year types except critically dry water year types. Under Alternative 3 compared to the No Action Alternative, critically water year types are projected to have lower or similar flow conditions and may have the greatest flow decrease in July.

O.6.7 San Joaquin River

Under Alternative 3, Reclamation will operate the Friant Division consistent with the San Joaquin River Restoration Program Record of Decision, which is a related action not included in this consultation. There are anticipated changes in San Joaquin River flow below the confluence with the Stanislaus River, because of changes in operations at New Melones Reservoir.

O.6.7.1 San Joaquin River at Vernalis

CalSim 3 modeling suggests that monthly average flows in the San Joaquin River at Vernalis under Alternative 3 compared to No Action Alternative will increase slightly in May and February and decrease all other months (Table O-263). There are no anticipated increases greater than a 5% difference under Alternative 3 compared to the No Action Alternative. The largest decreases under Alternative 3 compared to the No Action Alternative are expected in April of all water year types.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.6.8 Sacramento River Winter-run Chinook Salmon ESU

O.6.8.1 Sacramento River

Spawning and Egg/Alevin Incubation

Winter-run Chinook salmon adults spawn from April through August with peak spawning between May and July (Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). Fry emergence occurs up to three months after eggs are spawned, so effects of flow and water temperature on winter-run eggs and alevins may occur from May through November, but primarily occur during June through October.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 3, differences in mean spawning WUA increases in above normal, below normal, and dry water year types, and decreases in wet and critically dry water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 3 and the No Action Alternative is a 5.6% increase in wet water years. The largest reduction in estimated spawning habitat is a -0.3% decrease in critically dry water year types.

The monthly median value of spawning WUA under Alternative 3 similar to the No Action Alternative in May, June, and August but is slightly higher in July. Spawning WUA median values for all the modeled alternatives are relatively similar in May, June, and August. In July, the median values of spawning WUA are lower across all alternatives when compared to the other months of spawning. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in July than in the other three months (Table O-248). This results in lower spawning WUA results because the winter-run spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 5,000 to 10,000 cfs).

The results of suitable habitat analysis using the SIT LCM habitat models indicate that spawning habitat for winter-run Chinook salmon in the upper Sacramento River may not a limiting factor under both the No Action Alternative and Alternative 3 (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The results of the two spawning habitat analyses based on CalSim 3 simulated flows suggest that Alternative 3 may have a minor increase (5.6%) in estimated spawning habitat during above normal water year types when compared to the No Action Alternative, and that spawning habitat may not be a limiting factor for winter-run Chinook salmon in the mainstem upper Sacramento River.

SIT Winter-run Lifecycle Model: Spawner Abundance

In the CVPIA winter-run SIT life cycle model, mean winter-run Chinook salmon spawner abundance in the central valley under Alternative 3 is similar to the No Action Alternative, with up 3.6% increase in above normal water year types and 1.0% decrease in critically dry water year types (Attachment F.2, *CVPIA SIT Winter-run LCM*). For all years, the mean annual spawner

abundance was similar under Alternative 3 compared to the No Action Alternative. Over the full model run period (1980–1999), abundance growth under Alternative 3 was slightly higher by 0.8% than abundance under the No Action Alternative. Overall, the spawner abundance predicted by the CVPIA winter-run life cycle model is expected to be similar under Alternative 3 and the No Action Alternative, with a slight annual decrease in abundance, with abundance decreases during critically dry and above normal years and increases during above normal and wet years.

IOS: Egg Survival

Under Alternative 3, in critically dry water years, mean predicted winter-run Chinook salmon egg survival is 32.05% higher than when compared to the No Action Alternative. Alternative 3 reflects a change of 0.224 mean predicted winter-run Chinook salmon egg survival when compared to the No Action Alternative (0.698 under the No Action Alternative to 0.922 under Alternative 3). The change in mean predicted winter-run Chinook salmon egg survival in all other water year types less than or equal to ± 0.004. Alternative 3 provides a substantial benefit to predicted survival of winter-run Chinook salmon eggs during critically dry years when compared to the No Action Alternative.

OBAN: Spawner Abundance and Probability of Quasi-Extinction

Predicted spawner abundance under Alternative 3 was greater than under the No Action Alternative (1% greater median proportional difference, Table O-30). This increase under Alternative 3 would have a beneficial effect on winter-run Chinook salmon.

Probability of quasi-extinction under Alternative 3 was less than under the No Action Alternative (0.94, Table O-30). This decrease under Alternative 3 would have a beneficial effect on winter-run Chinook salmon.

IOS: Female Escapement

Under Alternative 3 VA in all water year types, mean annual predicted female escapement of winter-run Chinook salmon is 16.87-27.28% higher than when compared to the No Action Alternative. The change in mean annual predicted female escapement of in all water year types ranging from 359 to 1,000 individuals. Alternative 3 provides a substantial positive impact to mean annual predicted female escapement of winter-run Chinook salmon when compared to the No Action Alternative.

OBAN: Egg-to-Fry Survival

Egg to fry survival under Alternative 3 was less than under the No Action Alternative (-0.033 difference, Table O-30).

Redd Dewatering Analysis

Alternative 3 shows minor increases in winter-run Chinook salmon redd dewatering potential from wet to dry water years, and an intermediate level for critically dry years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). During winter and spring, the principal incubation periods for the other Chinook salmon races and steelhead, redd dewatering is generally higher during wet water years because periodic storms and high runoff, which increase flow fluctuations, tend to be more frequent in such water years. However, winter-run Chinook salmon spawning and incubation occur during late spring through early fall, when flows tend to

be less variable. The low percentages of winter-run Chinook salmon redd dewatering in wet years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*) may result from increased stability in project operations related to greater reservoir storage levels. For individual months, median redd dewatering is highest for spawning in July and August and lowest for spawning in May (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). The largest difference between the No Action Alternative and Alternative 3 is a 14.4% increase for wet water years and the largest reduction is 11.9% for above normal water years. Note that these large percentages may be misleading as they represent, respectively, 1.0% and 1.4% absolute differences in percent of redds dewatered (Attachment L.4, *Sacramento River Redd Dewatering Analysis*).

Overall, the results indicate that redd dewatering potential under Alternative 3 would be generally similar to that under the No Action Alternative, with some notable increases and reductions depending on water year type. In terms of absolute change, all differences are small.

Temperature Dependent Mortality (TDM)

Differences in monthly temperatures on the upper Sacramento River under Alternative 3 compared with the No Action Alternative may have effects on water-temperature-related mortality of winter-run Chinook salmon eggs and alevins. These possible differences were evaluated using several quantitative temperature-dependent models (TDM), hereinafter referred to as the Martin and Anderson models.

Both Martin and Anderson models are responsive to modeled Sacramento River temperatures at Keswick Dam, at the confluence with Clear Creek, and at Bend Bridge. The modeling was based on HEC-5Q water temperature estimates for the years used in the HEC-5Q modeling (1922–2021).

Under Alternative 3 for the Anderson model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.065, 0.312, and 0.006 (56% less than the No Action Alternative in critically dry water year types; 75% greater than the No Acton Alternative in wet water year types). Expected proportional TDM values for the Anderson model were less under Alternative 3 than No Action Alternative for all water year types except wet.

Under Alternative 3 for the Martin model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.089, 0.389, and 0.011 (all less than the No Action Alternative, up to 44% less in a critically dry water year type). Expected proportional TDM values for the Martin model were less under Alternative 3 than No Action Alternative in all water year types (up to 82% less in a below normal water year type).

Relative to the Anderson model, expected proportional TDM values were higher for the Martin model across all water year types combined and for all water year types. For the Anderson and Martin models, greater than 70% of modeled water years resulted in expected proportional TDM values less than 0.125. For critically dry water year types, at least 12.5% of modeled water years resulted in expected proportional TDM values less than 0.5. For above normal and wet water year types only, expected proportional TDM never exceeded 0.125 (Attachment L.2, *Egg-to-fry Survival and Temperature Dependent Mortality*). A decrease in TDM under Alternative 3

compared with the No Action Alternative in all but a wet water year type would generally have a beneficial effect on incubating winter-run Chinook salmon eggs.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during January through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 16 for Keswick Dam and Table 18 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during January through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 20 for Keswick Dam and Table 22 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during May through November are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 24 for Keswick Dam and Table 26 for below Clear Creek.

Results for the three analyses are summarized in Table O-31. Table O-31, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 42.1°F to 55°F range for spawning initiation, there were eight to 11 month-water year type combinations (22.9% to 31.4%) with favorable results, depending on location, no combinations (0% of total combinations during the period) with unfavorable results at Keswick Dam, and one combination (2.9%) with unfavorable effects below Clear Creek (Table O-31). For the 59.9°F adult pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were four to six combinations (11.4% to 17.1%) with favorable results, depending on location, and one combination (2.9%) with unfavorable results at each location. These results suggest that there would be mostly no effect or positive biologically meaningful temperature-related effects of Alternative 3 on winter-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River, although there were some negligible negative effects on spawning initiation and egg incubation and fry emergence.

Summary

Alternative 3 relative to the No Action Alternative is expected to have possible beneficial to adverse impacts on spawning and redd dewatering habitat, possible beneficial or adverse impacts on spawner abundance depending on water year type, possible substantial beneficial impacts on female escapement, and possible beneficial impacts on the probability of quasi-extinction due to differences in flow. Alternative 3 relative to the No Action Alternative are expected to have possible beneficial impacts using three secondary biological models: IOS, and both Anderson and Martin (TDM). OBAN results suggest differences in temperature between Alternative 3 and the No Action Alternative are expected to have possible adverse impacts on egg to fry survival due to differences in water temperature. Using a coarser analysis, Alternative 3 relative to the No Action Alternative is expected to have a possible minor beneficial impact on spawning and egg/alevin incubation but minor adverse impacts on spawning initiation and egg incubation and fry emergence due to differences in water temperature.

Juvenile Rearing and Emigration

Winter-run Chinook salmon juveniles rear in the Sacramento River primarily from late summer to late winter and emigrate from the river to the Delta beginning in November (see Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). The proportion of juveniles surviving to emigrate to the Delta depends largely on habitat conditions, including flow and water temperature. Inundated floodplain habitat has been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001a, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 3, mean fry rearing WUA increases in all water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increases in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 2.1% increase in wet and critically dry water years. There are no anticipated reductions in mean fry rearing WUA in comparison to the No Action Alternative.

The monthly median value of fry rearing WUA under Alternative 3 is similar to the No Action Alternative throughout the fry rearing period (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Fry rearing WUA median values for all the modeled alternatives are relatively similar September through December but slightly lower in August. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in August in comparison to the other fry rearing months, with an average flow of 10,225 cfs under Alternative 3 (Table O-248). Segment 5, which has the highest distribution of winter-run Chinook salmon spawning, has decreased WUA values when flows are between 5,000 and 10,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), leading to lower WUA values during higher flows in August. Winter-run Chinook salmon fry rearing WUA starts to increase at flows above 10,000 cfs, and peak at flows around 30,000 cfs. The peak rearing flows are not expected to occur under the No Action Alternative or Alternative 3 during the fry rearing period in the Sacramento River below Keswick Dam. Winter-run Chinook salmon is the only Sacramento River salmonid race or species that shows this pattern.

The results of the winter-run Chinook salmon fry rearing habitat analysis suggest that Alternative 3 may have a minor (less than 2.5%) increase in estimated fry rearing habitat across all water year types and potentially no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Juvenile Rearing Habitat Analyses

Under Alternative 3, mean juvenile rearing WUA increases in wet, above normal, and critically dry water year types and decreases in below normal and dry water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 0.7% increase in critically dry water years. The largest reduction in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 0.5% decrease in below normal water year types.

The monthly median value of juvenile rearing WUA under Alternative 3 is similar to the No Action Alternative October through January (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are higher in January compared to the other months of juvenile rearing (Table O-248). Segment 5 has decreased WUA values when flows are between 5,000 and 10,000 cfs but the WUA values do not change as drastically with juvenile rearing in comparison to fry rearing. Winter-run Chinook salmon juvenile rearing WUA values start increasing at flows above 15,000 cfs, and peak at flows around 30,000 cfs. These peak rearing flows are not expected to occur under the No Action Alternative or Alternative 3 during the juvenile rearing period in the Sacramento River below Keswick Dam. Winter-run Chinook salmon is the only Sacramento River salmonid race or species that shows this pattern.

The results of suitable habitat analysis using the SIT LCM habitat models suggest that instream juvenile rearing habitat for winter-run Chinook salmon in the upper Sacramento River under Alternative 3 have a 0.8% to -3.0% difference between the months of October through January in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest increase in estimated habitat may occur in November and the greatest reduction in estimated habitat may occur in January under Alternative 3 in comparison to the No Action Alternative.

The two winter-run Chinook salmon juvenile rearing habitat analyses suggest that Alternative 3 may have a negligible (less than 1%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and potentially no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles who generally are stronger swimmers. Alternative 3 shows a large and consistent reduction in stranding of winter-run juveniles from critically dry to wet water year types (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*) and an increase from July to October (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Winter-run Chinook salmon fry rearing occurs primarily during summer through early fall, when flows tend to be less variable. The minimum rates of stranding for winter-run fry during wet years may result from increased stability in project operations related to greater reservoir storage levels. Alternative 3 has lower juvenile stranding of winter-run fry than the No Action Alternative in above normal, below normal, and critically dry water year types, but the reductions are not large (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The differences in mean stranding range from 7.8% lower stranding for Alternative 3 in above normal water year types to 1.9% higher in wet water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*).

Overall, winter-run Chinook salmon juvenile stranding for fry is lower under Alternative 3 in comparison to the No Action Alternative.

Survival and Travel Time: XT and Flow Survival Threshold Models

Del Rosario et al. (2013) found that ≥5% catch at the Knights Landing Rotary Screw Trap coincided with first day of flow of at least ~14,100 cfs (400 cm) at Wilkins Slough. Acoustically tagged fish released at locations in the upper Sacramento River under varying hydrological conditions are used to estimate survival probabilities and travel times rates. As fish migrate downstream towards the Delta, individuals encounter a range of environmental conditions and transition from reaches with unidirectional flow (upstream) to reaches with bidirectional flow (tidally driven, downstream). Outmigrating juveniles may be exposed to predation and as inflow declines and tidal influence moves upstream, travel time and distance may increase leading to higher exposure to predators. Michel et al. (2021) identified an optimal flow threshold condition favorable for outmigration for juvenile Chinook salmon, 10,712 cfs, which could provide an additional 2.7-fold increase in survival. Travel and survival rates of Chinook salmon in upper Sacramento River reaches are strongly correlated (Notch et al. 2020). Authors hypothesize one mechanism for the threshold is faster outmigration rates due to higher flows decrease exposure to possible predation (Michel et al. 2021).

Differences in daily flows (Upper Sacramento River Daily Operations Model, USRDOM) under Alternative 3 compared with the No Action Alternative may have effects on juvenile Chinook salmon's travel time and survival probabilities in the Upper Sacramento River. These possible differences were evaluated using several quantitative models: XT and Flow Survival Threshold.

Mean daily Sacramento River flows at Keswick Dam were equal or greater under Alternative 3 compared with the No Action Alternative in wet, above normal, and below normal water year types but were equal or less under Alternative 3 compared with the No Action Alternative in dry and critically dry water year types. Mean daily Sacramento River flows below Wilkins Slough (March 15th to June 15th) were equal or greater under Alternative 3 compared with the No Action Alternative (Attachment J.4, *XT Model;* Attachment J.5, *Flow Threshold Salmon Survival Model*). These two quantitative models provide results that demonstrate the flows under Alternative 3 compared with the No Action Alternative could increase survival and decrease travel time for outmigrating juvenile Chinook salmon on the Sacramento River limiting juveniles' exposure to predation and poor environmental conditions.

Annual mean survival probability under Alternative 3 was greater than annual mean survival probability under the No Action Alternative in wet, above normal, and critically dry water year types (16% greater in wet water year types and up to 25% greater in critically dry water year types). Annual mean survival probability under Alternative 3 was less than annual mean survival probability under the No Action Alternative in below normal and dry water year types (up to 3% less in dry water year types). The decrease would have a minimal effect while the increase (up to 25% greater) would have a large beneficial effect on outmigrating juvenile Chinook salmon. Under both scenarios, average annual mean survival probability was highest during the wet water year types and decreased as the water year type became drier. (Attachment J.5, *Flow Threshold Salmon Survival Model*).

Mean survival probability for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 3 was equal to the mean survival probability under the No Action Alternative in wet and below normal water year types. Survival

under Alternative 3 was 1% greater than survival under the No Action Alternative in above normal water year types and 1% less than survival under the No Action Alternative in critically dry and dry water year types. This range among water years from 1% less to 1% greater would not have an effect on outmigrating juvenile Chinook salmon. (Attachment J.4, *XT Model*).

Mean travel time (days) for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 3 was both greater than and less than mean travel time under the No Action Alternative (4-5% less in above normal water year type to the terminus of both reaches and 3-5% greater in wet water year type to the terminus of both reaches). This increase of 5% and decrease of 5% may have a minimal effect on outmigrating juvenile Chinook salmon, particularly dependent on predator presence and environmental conditions (e.g., water temperature) (Attachment J.4, *XT Model*).

<u>Winter-run Juvenile Production Index (JPI)</u>

Under Alternative 3, the mean predicted JPI is generally higher than No Action Alternative, ranging from 39.30% higher in 2017 to 49.26% lower in 2018. For years analyzed (2002-2021) roughly half (9) resulted in a higher JPI under Alternative 3 than the No Action Alternative. These results suggest that Alternative 3 is expected to have no effect, either positive or negative, on the number of juveniles produced annually when compared to the No Action Alternative.

<u>IOS: Fry Survival and Juvenile River Migration Survival</u>

Under Alternative 3, in critically dry water years, mean predicted winter-run Chinook salmon fry survival is 27.69% higher than when compared to the No Action Alternative. Alternative 3 reflects a change of 0.182 mean predicted winter-run Chinook salmon fry survival when compared to the No Action Alternative (0.65 under the No Action Alternative to 0.832 under Alternative 3). The change in mean predicted winter-run Chinook salmon fry survival in all other water year types was less than or equal to ± 0.003. Alternative 3 provides a substantial benefit to predicted survival of winter-run Chinook salmon fry during critically dry water years when compared to the No Action Alternative.

Under Alternative 3, in all water years, mean predicted river migration survival of winter-run Chinook salmon juveniles is higher than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to 0.003. There is not a substantial difference in predicted river migration survival of winter-run Chinook salmon juveniles between Alternative 3 and the No Action Alternative.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 28 for Keswick Dam, Table 30 for Red Bluff Diversion Dam, and Table 32 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 34 for Keswick Dam, Table 36 for Red Bluff Diversion Dam, and Table 38 for Hamilton City.

Results for the two analyses are summarized in Table O-32. Table O-32, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 55.4°F to 68°F optimum temperature range analysis, there were zero to three month-water year type combinations (0% to 10% of total combinations during the period) with favorable results, depending on location, and there were zero to two combinations (0% to 6.7%) with unfavorable months, depending on location (Table O-32). For the 75.2°F upper incipient lethal temperature under Alternative 3, there would be no favorable or unfavorable results at any location. These results suggest that there would be slight positive water temperature-related effects of Alternative 3 on winter-run Chinook salmon juvenile rearing and outmigration in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have possible minor beneficial to minor adverse impacts on fry and juvenile rearing habitat, no impact to slightly beneficial impact on behavior (fry stranding, juvenile production index), and a possible substantial beneficial impact on fry survival particularly in critically dry years due to differences in flow. Alternative 3 relative to the No Action Alternative could have a minor adverse to minor beneficial impact on travel time and a possible substantial beneficial impact on individuals' survival in the upper Sacramento River due to differences in flow. Alternative 3 and the No Action Alternative are expected to have a slight beneficial impact on juvenile rearing and emigration due to differences in water temperature.

Adult Upstream Migration and Holding

Winter-run Chinook salmon adults enter the Sacramento River from the Delta and make their way to the upper Sacramento River, beginning as early as December through late spring (May/June) (see Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). They hold in the upper River within 10 to 15 miles of Keswick Dam until they are ready to spawn, which may extend through August (Windell et al. 2017). Most of the run passes Red Bluff Diversion Dam from January to May with the peak in mid-March (Hallock and Fisher 1985).

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

CalSim 3 Flows

Releases from Shasta Reservoir during November through early May may be reduced to conserve water for the May through October winter-run Chinook salmon and spring-run Chinook salmon spawning and incubation periods, resulting in reduced flow in the middle Sacramento River. Lower flow in the Sacramento River relative to flow from the lower Yolo and Sutter bypasses and agricultural drains may affect navigation cues and straying of winter-run adults into canals and behind weirs, increasing their stranding risk. Once the adults have migrated upstream on the Sacramento River, they reach holding habitat in the upper Sacramento River. In the upper Sacramento River, they are more directly affected by Shasta Reservoir and Keswick Dam operations designed to preserve cold water for the winter-run Chinook salmon and spring-run Chinook salmon spawning and incubation periods.

During the December through May/June period of adult winter-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 3 at Sacramento River below Keswick Dam, below Red Bluff Diversion Dam, Hamilton City, and Wilkins Slough would range from less than to greater than flows under the No Action Alternative, depending on month and water year type. At Keswick Dam, Red Bluff Diversion Dan, and Hamilton City flows under Alternative 3 in June under all water year types were lower than flows under the No Action Alternative and in December were greater than flows under the No Action Alternative. At the above three locations, flows under Alternative 3 in more dry water year types (dry and critically dry) were less than the No Action Alternative in February, March, April and May. At Wilkins Slough flows under Alternative 3 December through March in all water year types were similar to or greater than flows under the No Action Alternative, up to 7% greater in January of a critically dry water year type. Flows under Alternative 3 in April through June varied from 37% greater to 28% lower compared to the No Action Alternative. Flows in July at Hamilton City and Wilkins Slough under Alternative 3 would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 3 between December and May/June would be greater than 4,700 cfs at Wilkins Slough and greater than 8,400 cfs at Hamilton City (Table O-248, Table O-249, Table O-251, Table O-250).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range for winter-run Chinook salmon adult migration and holding are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 4 for Keswick Dam, Table 6 for Red Bluff Diversion Dam, and Table 8 for Hamilton City.

Results are summarized in Table O-33. Table O-33, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Table O-33 indicates that, under Alternative 3, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at all locations, except Hamilton City, at which there was one combination (3.3%) with an unfavorable result (Table O-33). These results suggest that there would be minimal effects of Alternative 3 on water temperature conditions for winter-run Chinook salmon adult migrants in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a minor adverse to minor beneficial impact, depending on location and month, on upstream migrating and holding adult winter-run Chinook salmon, as average monthly flows at Hamilton City and Wilkins Slough are high enough to allow upstream passage. Alternative 3 and the No Action Alternative are expected to have no impact to minimal adverse impacts on upstream migrating and holding adult winter-run Chinook salmon due to differences in water temperature.

O.6.8.2 Bay-Delta

Juvenile Rearing and Emigration

Rearing winter-run Chinook salmon are present in the Delta from October to May (see Section O.1.9.1.1, *Winter-run Chinook Salmon, Sacramento River ESU*). Key habitat attributes relevant to seasonal operations in the Delta include out-migration cues and entrainment risk. Juveniles enter the Delta primarily during December through April and most emigrate past Chipps Island by the end of April but can potentially exit as late as May (Brandes and McLain 2001; del Rosario et al. 2013). A critical assumption in these analyses is LAD criteria used to identify juveniles (vs genetic ID) are sufficient to represent juveniles' downstream migration patterns.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Differences in hydrology in the Delta under Alternative 3 compared with the No Action Alternative may have effects on flow routing into junctions and the hydrodynamic footprint of the export facilities. These possible differences were evaluated using two quantitative models which estimate the spatial extent of influence of exports under CVP and SWP diversions and estimate the proportion of flow entering a Delta junction: Zone of Influence and Flow into Junctions.

<u>Zone of Influence</u>

For a full description of Zone of Influence model background, see Section O.4.8.2, *Sacramento River Winter-run Chinook Salmon ESU, Juvenile Rearing and Emigration in the Bay-Delta*. The following section covers discussion of differences in spatial extent of export influence presented as a direction between Alternative 3 and the No Action Alternative. For a detailed explanation of methods and analyses, see Attachment I.3, *Delta Export Zone of Influence Analysis*.

The proportional overlap of Alternative 3 (pumping vs no pumping) was less than the proportional overlap of the No Action Alternative (pumping vs no pumping) at Turner Cut and San Joaquin River at Jersey Point under the two more positive OMR bins (-2,000 and -3,500; Attachment I.3, *Delta Export Zone of Influence Analysis*). The proportional overlap of Alternative 3 (pumping vs no pumping) was less than the proportional overlap of the No Action Alternative (pumping vs no pumping) at Old River at Middle River under the two more positive OMR bins (-2,000 and -3,500).

With incremental decreases in OMR under Alternative 3 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping.

<u>Flow into Junctions</u>

For a full description of Flow into Junctions model background, see Section O.4.8.2, *Sacramento River Winter-run Chinook Salmon ESU, Juvenile Rearing and Emigration in the Bay-Delta*. The following section covers discussion of the Central Valley Project and Head of Old River junctions. An expanded set of junction analysis results can be found in Attachment I.10, *Flow into Junctions*.

Under Alternative 3 in the -2,000 and -3,500 OMR bins, predicted proportion of flow entering the Central Valley Project (CVP) is greater than the No Action Alternative, and less than the No Action Alternative in the -5,000 and <-5,500 OMR bins. Changes in predicted proportion of flow entering the CVP when OMR was -2,000, -3,500, and -5,000 were less than ± 0.0406, indicating a negligible difference from the No Action Alternative. However, when OMR was <-5,500 the change in flow into CVP was -0.0933, indicating that slightly less flow will be routed into CVP under Alternative 3 than when compared to the No Action Alternative.

Under Alternative 3 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the Head of Old River (HOR) is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.0404, indicating a negligible difference between Alternative 3 and the No Action Alternative.

Summary

Alternative 3 relative to the No Action Alternative are expected to influence flow into the HOR and CVP junctions due to differences in flow. Under Alternative 3, no change to possibly less flow into CVP under OMR -3,500; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 3 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Winter-run Chinook Salmon

Salvage Density and Negative Binomial

Predictions from the salvage density model for genetic and LAD winter-run Chinook salmon include mean monthly total exports. Predictions from the negative binomial loss model for LAD winter-run Chinook salmon include mean monthly total exports and mean monthly San Joaquin River flows at Vernalis. Table O-253 shows modeled mean monthly total exports at SWP and CVP and Table O-263 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of genetic winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through May of all water year types for Alternative 3 was less than predicted average monthly loss under the No Action Alternative for wet, above normal, and below normal water year types with up to a 57% reduction in predicted loss for wet water year types. Predicted loss from Alternative 3 compared to the No Action Alternative for genetic winter-run Chinook salmon for dry and critically dry water year types increased with up to a 26% increase in predicted loss for dry water year types (Table O-36). Predicted average monthly loss of genetic winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April for Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for all water year types with a reduction of up to 68% for the critically dry water year types (Table O-37). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly loss of LAD winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through April of all water year types Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for wet, above normal, and below normal water year types, with up to a 55% reduction in predicted loss for wet water year types. Predicted loss of LAD winter-run Chinook salmon from Alternative 3 compared to the No Action Alternative at Banks for dry and critically dry water year types increased with up to a 13% increase in predicted loss (Table O-34). Predicted average monthly loss of LAD winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for all water year types. Predicted loss of LAD winter-run Chinook salmon from Alternative 3 compared to the No Action Alternative had a reduction of up to 60% for critically dry water year types (Table O-35). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly salvage of LAD winter-run Chinook salmon at the Delta fish collection facilities for the months of December through April under Alternative 3 was lower than predicted average monthly salvage under the No Action Alternative for all water year types except for the above normal water year types which had an increase of 4%. Predicted loss for genetic and LAD winter-run Chinook salmon under Alternative 3 compared to the No Action Alternative was less for all other water year types, with up to a 53% reduction in loss for wet water year types (Table O-38). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.

Winter-run Chinook Salmon Coded Wire Tag Salvage Model

The Winter-run Chinook Salmon Coded Wire Tag (CWT) Proportional Salvage Model was developed to estimate the fraction of juvenile winter-run Chinook salmon in the Delta predicted to be salvaged based on hydrologic conditions and fish size. To apply this model to hydrologic scenarios outside of those used to construct the model, a fixed number of winter-run Chinook salmon entering the Delta each month was used. The raw output of the model is the number of fish salvaged. However, an offset variable was used to convert this number to a proportion. In this way, the model predicts the magnitude of salvage independent of the number of fish that may actually be in the Delta during a given month.

Predicted mean of annual and monthly proportion of winter-run Chinook salmon salvaged at CVP and SWP for all months October through May under Alternative 3 in all water year types, varied from positive to negative between months when compared to the No Action Alternative (Attachment I.9, *Winter-run Chinook Salmon Coded Wire Tag Salvage Model*). Salvage is predicted to increase in wet years under Alternative 3 when compared to the No Action Alternative, however all predicted proportion salvaged are less than ± 0.01 in all months and years. Overall, there is not a substantial difference in predicted proportion salvaged between Alternative 3 and the No Action Alternative.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a potential beneficial impact on the entrainment of genetically and LAD identified juvenile winter-run Chinook salmon in the Delta at both fish facilities due to differences in flow, supported by results from two quantitative models. The beneficial impact under Alternative 3 occurs in all water year types

at Jones for both LAD and genetically identified winter-run Chinook salmon. However, possible adverse impacts occur at Banks in water year types with poor conditions (dry, critically dry). A third model suggests no impact under Alternative 3 relative the No Action Alternative due to differences in flow on predicted salvage proportion of juvenile winter-run Chinook salmon.

Potential Changes to Routing of Winter-run Chinook Salmon

Winter-run Chinook salmon travel through different migratory pathways. Using a conceptual model, a single fish in any location could have arrived at that location via one of several pathways (Figure O-14). For example, a fish observed salvage could have arrived via one of many pathways (e.g., Sacramento Origin via the mainstem Sacramento then below Cache Slough, then South Delta or via the DCC and Central Delta then the South Delta). If a proportion of fish is higher down a migratory pathway documented as a route with higher survival rates for juvenile salmonids, then fish migrating through that route will likely have a better chance of surviving to the ocean than fish migrating through a sub-optimal route (e.g., experiencing potential entrainment into the Central Delta through the DCC or Georgiana Slough).

Empirical estimates of acoustically tagged late-fall run Chinook salmon from Coleman National Fish Hatchery (CNFH) tracked in December 2006, January and December 2007, and January 2008 experienced routing in the mainstem Sacramento from 35.2% to 49.8%, through Georgiana Slough 0% to 31.1%, and through the Sutter and Steamboat sloughs 19.8% to 41.4% (Perry 2010). Results suggest the proportion of fish entering each route generally follows river flow but is not always in agreement with the proportion of discharge entering that route, suggesting another parameter may affect fish routing. Release groups experienced different discharge and export conditions leading to wide ranges in routing probabilities. Other studies also report proportional flow is a strong predictor of route selection (Kemp et al. 2005; Cavallo et al. 2015; Romine et al. 2021). Additionally, variables like DCC gate status (open / closed) will change routing and survival probabilities for fish traveling along the mainstem Sacramento River when they get to both Georgiana Slough and the DCC junctions. Newman and Brandes (2010) reported that exports affect routing of fish released in Georgiana Slough more than fish released at Ryde (upstream of Georgiana Slough on the Sacramento River) and the fraction of fish released in Georgiana Slough recovered at the fish collection facilities increased with increased exports.

Differences in monthly flows on the Sacramento River under Alternative 3 compared with the No Action Alternative may have effects on juvenile Chinook salmon's routing and survival probabilities in the Sacramento River.

<u>STARS</u>

Average Sacramento River flows at Freeport December through May are greater under Alternative 3 compared with the No Action Alternative. The STARS model is responsive to modeled Freeport flows and daily operations of the DCC gates, both obtained from CalSim 3.

The STARS model provides predictions of routing and survival probabilities, in this section routing results are discussed. In the "survival" section survival results are discussed. Mean proportion of particles routed to the Interior Delta via either Georgiana Slough or the DCC), averaged across all water year types by month under Alternative 3 was less than the No Action Alternative for all months December through April (up to 3.4% less in April) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*). The decrease in proportion of particles

routed to the Interior Delta under Alternative 3 could have a minimal beneficial effect on outmigrating juveniles.

ECO-PTM

Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under Alternative 3 ranged from less than the No Action Alternative (up to 18% less under -5,000 cfs) to greater than the No Action Alternative (up to 5% greater under -3,500 cfs) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in Attachment I.7, *ECO-PTM*. The decrease in routing to the Interior Delta could have a large beneficial effect on outmigrating juveniles while the increase in routing could have an adverse effect on outmigrating juveniles.

Summary

The two flow-based quantitative models suggest depending on considered variables, flows under Alternative 3 compared with the No Action Alternative may be adverse or beneficial for outmigrating juvenile winter-run Chinook salmon when results are binned by OMR grouping. Alternative 3 relative to the No Action Alternative using STARS suggests possible minimal beneficial impact on routing into the Interior Delta in all water year types in all months December through April, due to differences in flow. Alternative 3 and the No Action Alternative using ECO-PTM suggest an adverse or beneficial impact with a smaller proportion routed to Interior Delta between December and March, particularly under OMR -5,000.

Potential Changes to Through Delta Survival of Winter-run Chinook Salmon

Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. Juvenile Chinook salmon entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010, 2018).

STARS

Average Sacramento River flows at Freeport December through May are greater under Alternative 3 compared with the No Action Alternative. The STARS model is responsive to modeled Freeport flows and daily operations of the DCC gates, both obtained from CalSim 3.

The STARS model provides predictions of routing and survival probabilities, in this section survival results are discussed. In the "routing" section routing results are discussed. Mean predicted through-Delta survival of particles across all routes, averaged across all water year types by month under Alternative 3 was greater than the No Action Alternative in all months December through April (up to 3.5% in April) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*). This increase in survival could have a beneficial effect on outmigrating juveniles, particularly if environmental conditions are sub-optimal.

ECO-PTM

Mean through-Delta percent survival December through March under Alternative 3 ranged from less than the No Action Alternative (up to 9% less under -3,500 cfs) to greater than the No Action Alternative (up to 16% more under <-2,000 cfs) (Attachment I.7, *ECO-PTM*). Survival through Delta-specific routes is discussed further in Attachment I.7, *ECO-PTM*. The increase in survival under some OMR conditions could have a large beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have a large adverse effect on outmigrating juveniles.

Delta Passage Model

Under Alternative 3, in all water year types, predicted mean survival of winter-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). The change in mean predicted mean survival to Chipps Island in all water year types is less than or equal to ± .022.

IOS: Through-Delta Survival

Under Alternative 3 in all water years, mean predicted through Delta survival of winter-run Chinook salmon juveniles is higher than when compared to the No Action Alternative. The change in mean predicted river migration survival in all water year types less than or equal to .018.

OBAN: Delta Survival

Delta survival under Alternative 3 was greater than under the No Action Alternative (19%, Table O-30). This increase would have a beneficial effect on outmigrating juvenile winter-run Chinook salmon.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a potential adverse or beneficial impact on survival of outmigrating juvenile winter-run Chinook salmon, due to differences in flow, and depending on OMR grouping and model.

O.6.9 Central Valley Spring-run Chinook Salmon ESU

O.6.9.1 Sacramento River

Spawning and Egg/Alevin Incubation

Spring-run Chinook salmon adults spawn from August through October (Williams 2006) with peak spawning in September (see Section O.1.3.2). Monitoring spring-run Chinook salmon spawning in the mainstem Sacramento River is complicated due to lack of spatial/geographic segregation and temporal isolation from fall-run Chinook salmon. Most spring-run Chinook salmon spawning occurs between the Keswick Dam and Ball Ferry Bridge (NMFS 2017c). Fry emergence occurs up to three months after eggs are spawned (Moyle 2002), so effects of flow in the upper Sacramento River on incubating spring-run Chinook salmon eggs and alevins potentially occur from August through January, peaking in December.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 3, mean spawning WUA is higher in wet, above normal, and critically dry water year types and lower in below normal and dry water year types (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 3 and the No Action Alternative is a 5.7% increase in above normal water year types. The largest reduction in estimated spawning habitat is a -2.5% decrease for Alternative 3 in below normal water year types (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The monthly median value of spawning WUA under Alternative 3 is similar to the No Action Alternative in September and October, and lower in August (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA for all of the modeled alternatives are substantially lower in August than in September or October. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in August than in the other two months (Table O-248). This results in lower spawning WUA results because the fall-run Chinook salmon spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), which were used to estimate spring-run Chinook salmon spawning WUA, peak at relatively low flows (approximately 3,000 to 6,000 cfs).

The results of suitable habitat availability analysis using the SIT LCM habitat models indicate that spawning habitat for spring-run Chinook salmon in the upper Sacramento River may not a limiting factor under both the No Action Alternative and Alternative 3 (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The two spawning habitat analyses based on CalSim 3 simulated flows suggest that Alternative 3 may have a minor (5.7%) increase in estimated spawning habitat during above normal water year types when compared to the No Action Alternative, but that spawning habitat may not be a limiting factor for spring-run Chinook salmon in the mainstem upper Sacramento River.

SIT Spring-run Lifecycle Model: Spawner Abundance

In the CVPIA spring-run SIT Chinook salmon life cycle model, mean spring-run Chinook salmon spawner abundance in the Central Valley under Alternative 3 in Chinook salmon spawner abundances are similar to the No Action Alternative in the Central Valley. The largest increase in abundance between the No Action Alternative and Alternative 3 was a 0.2% increase in critically dry water year types and 0.6% decrease in above normal water year types (Attachment F.3, *CVPIA SIT Spring-run LCM*). Under Alternative 3 and the No Action Alternative there is a year-to-year abundance decrease in dry years and an increase in all other water year types; a negative value indicates a decrease in annual spawner abundance. Over the full model run period (1980–1999), abundance under Alternative 3 was equal to abundance under the No Action Alternative. Overall the spawner abundance predicted by the CVPIA Spring run life cycle model is expected to be similar under Alternative 3 and the No Action Alternative.

Redd Dewatering Analysis

Under Alternative 3, the spring-run Chinook salmon redd dewatering results show a consistent reduction in redd dewatering potential from wetter to drier water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation is expected for spring-run Chinook salmon because their spawning occurs in the fall, with incubation extending into early winter. During wet winters, periodic storms and high runoff increase flow fluctuations, which tends to result in greater estimates of redd dewatering potential. In drier winters, flow fluctuations are reduced and fewer redds are potentially dewatered. Most differences between the No Action Alternative and Alternative 3 are reductions, with a maximum reduction of 17.9% in above normal water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). Other large differences include a 10.8% reduction for wet water years and a 9.2% increase for dry water years. For individual months, redd dewatering for September spawning is moderately higher than that for October spawning (Attachment L.4, *Sacramento River Redd Dewatering Analysis*).

Overall, the results indicate that redd dewatering potential under Alternative 3 would be lower than that under the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 48 for Keswick Dam and Table 50 for Red Bluff Diversion Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 54 for Keswick Dam and Table 56 for Red Bluff Diversion Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during September through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 60 for Keswick Dam and Table 62 for Red Bluff Diversion Dam.

Results for the three analyses are summarized in Table O-39. Table O-39, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 42.1°F to 55°F spawning initiation range analysis, there were nine and zero month-water year type combinations (25.7% and 0% of total combinations during the period) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively, and there were no combinations with unfavorable results at either location (Table O-39). For the 59.9°F pathogen virulence threshold, there were three and 11 combinations (8.6% and 31.4%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively, and there were zero and two combinations (0% and 5.7%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. For the 42.8°F to 56°F range for egg incubation and fry emergence, there was one combination (2.9%) with favorable results at each location, and one and zero combinations with unfavorable results (2.9% and 0%) below Keswick Dam and at Red Bluff Diversion Dam, respectively. These results suggest that there

would be positive effects of Alternative 3 on spring-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a minor beneficial impact on spring-run Chinook salmon spawning, spawner abundance, and egg/alevin incubation (mortality) due to differences in flow. Flow for spawning habitat is not expected to be a limiting factor for spring-run Chinook salmon. Redd dewatering has a minor beneficial impact under Alternative 3 compared to the No Action Alternative. Water temperatures for spawning and egg/incubation and pathogen virulence have a beneficial impact under Alternative 3 compared to the No Action Alternative.

Juvenile–Yearling Rearing and Emigration

Spring-run Chinook salmon juveniles rear in the Sacramento River primarily from November through June and most emigrate to the Delta during December and again in March and April (Roberts 2007) (see Section O.1.3.2, *Spring-run Chinook Salmon*). Migratory cues, such as increased flow and/or turbidity from runoff, may spur emigration of juveniles from the upper Sacramento River basin when they have reached the appropriate stage of maturation (NMFS 2009a). Inundated floodplain habitats have been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001a, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 3, mean fry rearing WUA increases in below normal and dry water year types and decreases in wet, above normal, and critically dry water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increases in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 0.8% increase in dry water year types. The largest reduction in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 1.5% decrease in above normal water year types.

There are some differences in fry rearing WUA on a monthly scale between Alternative 3 and the No Action Alternative. In December and February, there is a 5% reduction in the median value of fry rearing WUA under Alternative 3 in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). In November, there is a 5% increase in the median value of fry rearing WUA under Alternative 3 in comparison to the No Action Alternative. Alternative 3 and the No Action Alternative are similar during the other fry rearing months. Fry rearing WUA median values for all the modeled alternatives are similar across December, January, and March, which are important months for rearing. The results during these three months show little variation in the third quartile of the WUA distributions. This limited variation occurs because the fry rearing WUA curves peak at the lowest flows encountered in the river and Keswick Dam flow releases are frequently low during these months in critically dry years when Shasta Reservoir is operated to rebuild storage volume (Table O-248). The first

quartile is much wider because a greater range of flows affect the fry rearing WUA values below the median. November and April have the lowest median WUA values across all alternatives.

The results of the spring-run Chinook salmon fry rearing habitat analysis suggest that Alternative 3 may have a minor (less than 2%) increase and/or decrease in estimated spring-run Chinook salmon fry rearing habitat across all water year types in comparison to the No Action Alternative. There are some differences in estimated rearing WUA habitat when looking at a monthly scale, with December and February having a minor (5%) decrease in estimated fry rearing habitat and November with a minor (5%) increase in estimated fry rearing habitat.

Juvenile Rearing Habitat Analyses

Under Alternative 3, mean juvenile rearing WUA increases in wet water year types and decreases in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 1.1% increase in wet water year types. The largest reduction in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 1.7% decrease in critically dry water year types.

The monthly median value of juvenile rearing WUA under Alternative 3 is similar to the No Action Alternative January through May (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The juvenile rearing WUA values under all of the modeled alternatives are similar for January through March, but they are generally lower for April and May. For the January through March period, as described above for spring-run Chinook salmon fry rearing WUA, the third quartiles of the WUA distributions have high values and reduced variation. This occurs because, as described for the fry rearing WUA curves, the juvenile rearing WUA curves peak at the lowest flows encountered in the river and low flows are frequent during January through March in dry and critically dry years when Shasta Reservoir is operated to rebuild storage (Table O-248).

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for spring-run Chinook salmon in the upper Sacramento River show a 3.3% to -3.0% difference between the months of January and May (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest increase in estimated habitat may occur in April and the greatest reduction in estimated habitat may occur in January under Alternative 3 in comparison to the No Action Alternative.

The results of the two spring-run Chinook salmon juvenile rearing habitat analyses suggest that Alternative 3 may have a minor (equal to or less than 3.3%) increase and/or decrease in estimated spring-run Chinook salmon juvenile rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who generally are stronger swimmers. Alternative 3 shows a large increase in mean stranding of spring-run Chinook salmon fry from critically dry, dry, and below normal water years to above normal and wet years (Attachment L.5,

Sacramento River Juvenile Stranding Analysis). Spring-run Chinook salmon fry rearing occurs primarily during late fall and winter. For individual months, Alternative 3 shows the highest stranding in November and February (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The higher mean stranding levels for spring-run Chinook salmon fry during February and in wetter water year types likely results because of periodic storms and high runoff that produce increased variability of flow. Fry stranding means are similar between Alternative 3 and the No Action Alternative in all water year types except for a 7.8% increase under Alternative 3 in critically dry water year types (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*).

Overall, spring-run Chinook salmon stranding of fry is similar under Alternative 3 in comparison to the No Action Alternative, except for an increase in stranding under critically dry water years.

Survival and Travel Time: XT and Flow Survival Threshold Models

Differences in daily flows (Upper Sacramento River Daily Operations Model, USRDOM) under Alternative 3 compared with the No Action Alternative may have effects on juvenile Chinook salmon's travel time and survival probabilities in the Upper Sacramento River. These possible differences were evaluated using several quantitative models. For a detailed description of how flows under Alternative 3 may impact juveniles and yearlings' travel time and survival probabilities in the Upper Sacramento River, see Alternative 3, Sacramento River Winter-run Chinook Salmon ESU (Section O.6.8.1).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for juvenile growth, smoltification, and predation vulnerability during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 66 for Keswick Dam, Table 68 for RBDD, and Table 70 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating juveniles during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 74 for Keswick Dam, Table 76 for RBDD, and Table 78 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for yearling growth, smoltification, and predation vulnerability are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 82 for Keswick Dam during April through December, Table 84 for RBDD during April through December, and Table 98 for Hamilton City during October through December (migration only). Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating yearlings are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 88 for Keswick Dam during April through December, Table 90 for RBDD during April through December, and Table 106 for Hamilton City during October through December (migration only).

Results for the four analyses are summarized in Table O-40. Table O-40, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 55.4°F to 68°F juvenile optimum water temperature range under Alternative 3, there were zero to one month-water year type combinations (0% to 2.5% of total combinations during the period) with favorable results depending on location (Table O-40). There were zero to six combinations (0% to 15.0%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles under Alternative 3, there would be no combinations with either favorable or unfavorable results at any location. For the 55.4°F to 68°F yearling optimum temperature range under Alternative 3, there would be zero to one combinations with favorable results (0% to 6.7%) with favorable results depending on location. There would be zero to eight combinations (0% to 17.8%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating yearlings under Alternative 3, there would be no combinations with either favorable or unfavorable results at any location.

These results indicate that there would generally be a mix of minor favorable and unfavorable water temperature-related effects under Alternative 3 on optimum water temperatures on juveniles and yearlings, with the exception of Keswick Dam, where there would be negative effects on both juveniles and yearlings. There would be negligible effects of Alternative 3 on lethal water temperatures.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor adverse impacts on spring-run Chinook salmon juvenile and yearling rearing habitat due to differences in flow. Stranding is similar in comparison to the No Action Alternative except in critically dry years. Mean annual survival would be increased, and mean survival and travel time would have a minimal impact on juvenile and yearling spring-run Chinook salmon. Water temperatures for optimum juvenile and yearling rearing is a mix, except at Keswick Dam, where water temperatures could have an adverse impact on both life stages. There are no impacts related to the critical upper temperature limit for juveniles and yearlings.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon enter the San Francisco Estuary from the Pacific Ocean to begin their upstream spawning migration in late January and early February (California Department of Fish and Wildlife 1998). Spring-run Chinook salmon generally enter rivers as sexually immature fish and must hold in freshwater for up to several months before spawning (Moyle 2002). While maturing, adults hold in deep pools with cold water. Documentation of holding locations in the Sacramento River was not identified.

Spring-run Chinook salmon adults enter the Sacramento River from March to September, primarily in May and June (Moyle 2002; Yoshiyama et al. 1998). In the upper Sacramento River, migration extends from mid-March through July with peak migration in late May and early June (California Department of Fish and Wildlife 1998).

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

During the January through June/July period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 3 at Sacramento River below Keswick Dam, below Red Bluff Diversion Dam, Hamilton City, and Wilkins Slough would generally be similar to or greater than flows under the No Action Alternative, from January through March,

except during February of a critically dry water year type below Keswick Dam when flows would be up to 12% less. Flows under Alternative 3 in April through July would be less than 5% greater than flows under the No Action Alternative at all four locations, except during wet and above normal years in May when flows would be up to 37% greater at Wilkins Slough. Flows at all sites range from -5% to -28% at Wilkins Slough in June during an above normal year. Flows at Hamilton City under Alternative 3 would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 3 between January and June/July would be greater than 5,500 cfs at Wilkins Slough (except in June) and greater than 7,500 cfs (except in June) at Hamilton City (Table O-248, Table O-249, Table O-250, Table O-251).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during March through September are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 40 for Keswick Dam, Table 42 for RBDD, and Table 44 for Hamilton City.

Results for the analysis are summarized in Table O-41. Table O-41, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3, there were zero to two month-water year type combinations (0% to 5.7% of total combinations during the period) with favorable results and zero to one combination (0% to 2.9%) with unfavorable results, depending on location (Table O-41). These results suggest that there would be mostly negligible water temperature-related effects of Alternative 3 on spring-run Chinook salmon migration and holding in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have some adverse impacts during June and July, little to no impact from January to April, and a beneficial impact in May during wet and above normal water years, depending on location and month, on upstream migrating and holding adult spring-run Chinook salmon. Average monthly flows at Hamilton City and Wilkins Slough are high enough to allow upstream passage. Differences in water temperatures between Alternative 3 and the No Action Alternative are expected to have a negligible impacts on upstream migrating and holding adult spring-run Chinook salmon.

O.6.9.2 Clear Creek

Spawning and Egg Incubation

Spawning occurs in gravel substrate in relatively fast-moving, moderately shallow riffles or along banks with relatively high water velocities to promote higher oxygen levels. Spawning in Clear Creek normally occurs between mid-August and early October, peaking in September (Moyle 2002).

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 3, mean spawning WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean spawning WUA under Alternative 3 in comparison to the No Action Alternative. The largest reduction in estimated spawning habitat is a 21.2% decrease in wet water year types. On average across all water year types, there is a 19.9% reduction in estimated spawning habitat under Alternative 3.

The mean values of spawning WUA by month are lower under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). October is expected to have higher WUA values under Alternative 3.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that spawning habitat for spring-run in Clear Creek may be a limiting factor under all of the modeled alternatives and that spawning habitat may decrease 15.3-20.1% in September and October for Alternative 3 in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The two spawning habitat analyses suggest that Alternative 3 may have an adverse effect, as spring-run Chinook salmon spawning habitat may decrease on average by 19.9% across all water year types in Clear Creek when compared to the No Action Alternative, and that spawning habitat may be a limiting factor for spring-run Chinook salmon in Clear Creek.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 52 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 58 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during September through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 6 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-42. Table O-42, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 42.1°F to 55°F spawning initiation range analysis, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-42). For the 59.9°F pathogen virulence threshold, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown

Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on spring-run Chinook salmon spawning in Clear Creek.

Summary

Alternative 3 relative to the No Action Alternative is expected to include a decrease in flows and moderate to adverse impact on spawning habitat area. Alternative 3 relative to the No Action Alternative is expected to have a negligible impact on spawning, pathogen virulence, or egg incubation and fry emergence due to differences in water temperature.

Juvenile–Yearling Rearing and Emigration

While the majority of juvenile spring-run Chinook salmon outmigrate as fry, a proportion rears in Clear Creek through the spring and summer and emigrates as subyearlings with the first rainstorms in the fall or winter following their birth (NMFS 2014a). Spring-run Chinook salmon outmigration from Clear Creek occurs during late October through late April with peak emigration of juveniles occurring in November, and few fish exiting through the end of May.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 3, mean fry rearing WUA increases in all water year types compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 7.6% increase in dry water year types. There are no anticipated reductions in mean fry rearing WUA under Alternative 3 in comparison to the No Action Alternative.

The mean values of fry rearing WUA by month are similar to or higher under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). January, February, and March are expected to have the highest fry rearing WUA values.

The results of the spring-run fry rearing habitat analysis suggest that Alternative 3 may have a minor (less than 8%) increase in estimated spring-run Chinook salmon fry rearing habitat across all water year types in Clear Creek.

Juvenile Rearing Habitat Analyses

Under Alternative 3, mean juvenile rearing WUA decreases in all water year types compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under Alternative 3 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 7.7% decrease in critically dry water year types. On average across all water year types, there is a 4.7% reduction in estimated juvenile rearing habitat under Alternative 3.

The mean values of juvenile rearing WUA by month are lower June through August and higher in April and May under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). May is expected to have the highest juvenile rearing WUA values under Alternative 3 throughout the juvenile rearing period.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for spring-run Chinook salmon in Clear Creek may decrease 13.6-20.3% during the summer months (June through August) but may increase 5.5-14.2% in the spring months April and May under Alternative 3 compared to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest decrease in estimated juvenile rearing habitat may occur in August and the greatest increase in estimated juvenile rearing habitat may occur in May.

The results of the two spring-run Chinook salmon juvenile rearing habitat analyses suggest that Alternative 3 may have a minor adverse effect, as rearing habitat may decrease up to 7.7% across all water year types in comparison to the No Action Alternative, and that there may be increases to habitat in the spring and reductions in habitat in the summer in Clear Creek.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for juvenile growth, smoltification, and predation vulnerability during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 72 below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating juveniles during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 80 below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for yearling growth, smoltification, and predation vulnerability are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 86 below Whiskeytown Dam April through December. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating yearlings are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 92 below Whiskeytown Dam for April through December.

Results for the four analyses are summarized in Table O-43. Table O-43, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 55.4°F to 68°F juvenile optimum temperature range under Alternative 3, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-43). For the 75.2°F UILT for rearing and migrating juveniles, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam. For the 55.4°F to 68°F yearling optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam. For the 75.2°F UILT for rearing and migrating

yearlings, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on juvenile and yearling rearing and holding in Clear Creek.

Summary

Alternative 3 relative to the No Action Alternative is expected have a minor beneficial impact fry rearing habitat, an adverse impact on juvenile rearing habitat during the summer months, and a beneficial impact on juvenile rearing habitat during the spring months, due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have a negligible impact on rearing and emigration due to differences in water temperature.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon migrate into Clear Creek from April to August, and peak passage occurs in May and June (Clear Creek Technical Team 2018; Giovannetti et al 2013). Adults distribute throughout Clear Creek and hold in deep pools throughout the summer from Whiskeytown Dam (river mile 18.3) as far downstream as river mile 4.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

During the April through August period of adult spring-run Chinook salmon immigration and holding in Clear Creek, the mean monthly flows under Alternative 3 will be increased in April and May but decreased from June to August. Flows from June to August will range from 94 cfs during a critically dry year in August to 232 cfs in June (Table O-257).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during March through September are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 46 below Whiskeytown Dam.

Results for the analysis are summarized in Table O-44. Table O-44, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 37.9°F to 68°F successful adult migration range, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-44). These results suggest that there would be negligible water temperature-related effects of Alternative 3 on spring-run Chinook salmon adult upstream migration and holding in Clear Creek.

Summary

Alternative 3 relative to the No Action Alternative may have an adverse impact from June to August on upstream migrating and holding, due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on upstream migrating and holding due to differences in water temperature.

O.6.9.3 Bay-Delta

Juvenile–Yearling Rearing and Emigration

Juvenile spring-run Chinook salmon show two distinct out-migration patterns in the Central Valley: out-migrating to the Delta and ocean during their first year of life as YOY or holding over in their natal streams and out-migrating the following fall/winter as yearlings. YOY spring-run Chinook salmon presence in the Delta peaks during April and May, as suggested by the recoveries of Chinook salmon in the CVP and SWP salvage operations and the Chipps Island trawls of a size consistent with the predicted size of spring-run fish at that time of year.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Zone of Influence

Differences in hydrology under Alternative 3 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions. With incremental decreases in OMR under Alternative 3 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under Alternative 3 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 3, Sacramento River Winter-run Chinook Salmon ESU (Section O.6.8.2, *Zone of Influence*).

Flow into Junctions

For a full description of Flow into Junctions model background, see Section O.4.8.2, *Sacramento River Winter-run Chinook Salmon ESU, Juvenile Rearing and Emigration in the Bay-Delta*. The following section covers discussion of the Central Valley Project and Head of Old River junctions. An expanded set of junction analysis results can be found in Attachment I.10, *Flow into Junctions*.

Under Alternative 3 in the -2,000 and -3,500 OMR bins, predicted proportion of flow entering the Central Valley Project (CVP) is greater than the No Action Alternative, and less than the No Action Alternative in the -5,000 and <-5,500 OMR bins. Changes in predicted proportion of flow entering the CVP when OMR was -2,000, -3,500, and -5,000 were less than ± 0.0406, indicating a negligible difference from the No Action Alternative. However, when OMR was <-5,500 the change in flow into CVP was -0.0933, indicating that slightly less flow will be routed into CVP under Alternative 3 than when compared to the No Action Alternative.

Under Alternative 3 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the Head of Old River (HOR) is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.0404, indicating a negligible difference between Alternative 3 and the No Action Alternative.

Summary

Alternative 3 relative to the No Action Alternative is expected to influence flow into the HOR and CVP junctions. Under Alternative 3, no change to possibly less flow into CVP under OMR -3,500; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 3 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Spring-run Chinook Salmon

Differences in exports and flows under Alternative 3 compared with the No Action Alternative may have effects on juvenile winter-run Chinook salmon entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using two quantitative models: Salvage Density and Negative Binomial.

Salvage Density and Negative Binomial

Predictions from the salvage density model for genetic and LAD spring-run Chinook salmon include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP and Table O-263 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of genetic spring-run Chinook salmon at SWP Banks Pumping Plant for all the months December through May of all water year types for Alternative 3 was less than predicted average monthly loss under the No Action Alternative for wet, above normal, and below normal water year types with up to a 57% reduction in predicted loss for wet water year types. Predicted loss from Alternative 3 compared to the No Action Alternative for genetic spring-run Chinook salmon for dry and critically dry water year types increased with up to a 26% increase in predicted loss for dry water year types (Table O-47). Predicted average monthly loss of genetic spring-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April for Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for all water year types with a reduction of up to 68% for the critically dry water year types (Table O-47). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly loss of LAD spring-run Chinook salmon at SWP Banks Pumping Plant for all the months December through April of all water year types Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for wet, above normal, and below normal water year types, with up to a 55% reduction in predicted loss for wet water year types. Predicted loss of LAD spring-run Chinook salmon from Alternative 3 compared to the No Action Alternative at Banks for dry and critically dry water year types increased with up to a 13% increase in predicted loss (Table O-45). Predicted average monthly loss of LAD spring-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for all water year types. Predicted loss of LAD spring-run Chinook salmon from Alternative 3 compared to the No Action Alternative had a reduction of up to 60% for critically dry water year types (Table O-45). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly salvage of LAD spring-run Chinook salmon at the Delta fish collection facilities for the months of December through April under Alternative 3 was lower than predicted average monthly salvage under the No Action Alternative for all water year types except for the above normal water year types which had an increase of 4%. Predicted loss for genetic and LAD spring-run Chinook salmon under Alternative 3 compared to the No Action Alternative was less for all other water year types, with up to a 53% reduction in loss for wet water year types (Table O-47). For detailed information on average monthly salvage by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a potential beneficial impact due to differences in flow on the entrainment and salvage of the genetic and LAD identified juvenile spring-run Chinook salmon in the Delta at both fish facilities, supported by results from the two quantitative models.

Potential Changes to Routing of Spring-run Chinook Salmon

ECO-PTM

Alternative 3 relative to the No Action Alternative may have effects due to differences in flow on juvenile Chinook salmon's routing to Interior Delta via Georgiana Slough in the Delta. This possible difference was evaluated using ECO-PTM. For a detailed description of how flows under Alternative 3 may impact spring-run Chinook salmon routing, see Alternative 3, Sacramento River Winter-run Chinook Salmon ESU (Section O.6.8.2).

Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under Alternative 3 ranged from less than the No Action Alternative (up to 18% less under -5,000 cfs) to greater than the No Action Alternative (up to 5% greater under -3,500 cfs) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in Attachment I.7, *ECO-PTM*. The decrease in routing to the Interior Delta could have a large beneficial effect on outmigrating juveniles while the increase in routing could have an adverse effect on outmigrating juveniles.

Summary

Alternative 3 relative to the No Action Alternative using ECO-PTM suggest an adverse or beneficial impact due to differences in flow with a smaller proportion routed to Interior Delta between December and March, particularly under OMR -5,000.

Potential Changes to Through Delta Survival of Spring-run Chinook Salmon

ECO-PTM

For a detailed description of how flows under Alternative 3 may impact spring-run Chinook salmon through-Delta survival, see Alternative 3, Sacramento River Winter-run Chinook Salmon ESU (Section O. 6.8.2).

Mean through-Delta percent survival December through March under Alternative 3 ranged from less than the No Action Alternative (up to 9% less under -3,500 cfs) to greater than the No Action Alternative (up to 16% more under <-2,000 cfs) (Attachment I.7, *ECO-PTM*). Survival through Delta-specific routes is discussed further in Attachment I.7, *ECO-PTM*. The increase in survival under some OMR conditions could have a large beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have a large adverse effect on outmigrating juveniles.

Delta Passage Model

Under Alternative 3, in all water year types, predicted mean survival of spring-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). The change in mean predicted survival to Chipps Island in all water year types is less than or equal to ± .028.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a possible adverse or beneficial impact due to differences in flow on survival of outmigrating juvenile spring-run Chinook salmon, under certain OMR conditions, according to the ECO-PTM model. Under the DPM, the mean predicted survival is only slightly higher.

O.6.10 California Central Valley Steelhead DPS

O.6.10.1 Sacramento River

Spawning and Egg Incubation

Steelhead mostly use the Sacramento River as a migratory corridor for reaching other tributaries to spawn. Data on steelhead spawning in the mainstem Sacramento River is limited and likely restricted to the area upstream of Red Bluff (National Marine Fisheries Service 2009a). No steelhead specific spawner surveys occur in the upper Sacramento River. Data from recent surveys for the four runs of Chinook salmon have found carcasses of O. mykiss but the majority are thought to be resident trout adults (Killam 2022). Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional two to four weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In the Sacramento River, estimated incubation timing based on spawning is December through June.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 3, differences in mean spawning WUA are higher in above normal, below normal, dry, and critically dry water year types, and slightly lower in wet, above normal, and below normal water year types when compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 3 and the No Action Alternative is a 0.9% increase in dry water years. The largest reduction in estimated spawning habitat is a -0.05% decrease in wet water year types.

The monthly median value of spawning WUA under Alternative 3 is similar to the No Action Alternative January through April (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are relatively similar in January through March. In April, the median values of spawning WUA are higher across all alternatives when compared to the other spawning months. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently lowest in April when compared to other spawning months (Table O-248). This results in lower spawning WUA results because the steelhead spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 4,000 to 7,000 cfs).

The results of suitable habitat analysis using the SIT LCM habitat models indicated that spawning habitat for steelhead in the upper Sacramento River may increase in April under all alternatives compared to the other spawning months (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). Lack of consistent spawner estimates for steelhead prevented Reclamation staff from calculating spawner limitation ratios for this species.

The results of the two spawning habitat analyses based on CalSim 3 simulated flows suggest that Alternative 3 may have a negligible (less than 1%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. Out of the four months of steelhead spawning, April has the highest estimated spawning WUA across all alternatives.

Redd Dewatering Analysis

The results for Alternative 3 show a substantial reduction in mean redd dewatering potential from wetter to drier water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation reflects flow conditions for the winter and early spring months, when steelhead spawning and incubation occurs. During wet winters and springs, periodic storms and high runoff increase flow fluctuations, which tend to result in greater redd dewatering. In drier years, flow fluctuations are reduced and fewer redds are dewatered. Differences in mean redd dewatering potential between Alternative 3 and the No Action Alternative are large, ranging from 17.4% lower under critically dry water year types to 13.0% higher for below normal water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). For individual months, median redd dewatering potential under Alternative 3 is highest in February and lowest in April (Attachment L.4, *Sacramento River Redd Dewatering Analysis*).

Overall, the results indicate that redd dewatering potential under Alternative 3 relative to the No Action Alternative is higher in some water year types and lower in other water year types, but the overall difference is small.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis* Table 134 for Keswick Dam and Table 136 for RBDD. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 140 for Keswick Dam and Table 142 for RBDD. Full results of the analysis assessing the percent of

months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 170 for Keswick Dam and Table 172 for RBDD.

Results for the three analyses are summarized in Table O-48. Table O-48, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 45.5°F to 55°F successful spawning range analysis, there were nine and zero month-water year type combinations (30.0% and 0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-48). There were zero and one combinations (0% and 3.3%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there were zero and four combinations (0% and 13.3%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. For the 45°F to 52°F range for optimal egg incubation, there were eight and zero combinations (22.9% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were five and one combinations (14.3% and 2.9%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be frequent beneficial water temperature-related effects and some negative effects of Alternative 3 on steelhead spawning and egg incubation in the Sacramento River.

Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on steelhead spawning behavior and redd dewatering from sudden drops in flow. Redd surveys are occurring during the pulse flow period and redd dewatering has not been observed.

Summary

There are expected adverse and beneficial impacts of seasonal operations on steelhead spawning and egg incubation based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are expected to have a minor increase and/or decrease on spawning habitat area and a minor increase and/or decrease for redd dewatering. There may be adverse impacts to spawning behavior from spring pulse flows. There may be redd dewatering following spring pulse flow events, though this has not been observed during redd surveys. Water temperatures above the successful spawning and optimal egg incubation criteria are expected to modestly decrease in frequency and occasionally increase in frequency below Keswick Dam. Water temperatures above the pathogen virulence threshold are expected to also decrease in frequency at RBDD.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in the Sacramento River. The timing of juvenile outmigration depends on the watershed and water year. The rotary screw trap monitoring station at Knight's Landing indicate outmigration into the

Delta, with median passage starting in January and ending in May from 2006-2024 (Columbia Basin Research, University of Washington 2024).

Potential Changes to Steelhead from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 3, mean fry rearing WUA increases in all water year types in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). WUA curves were not developed for steelhead, so the late fall-run Chinook salmon curves were used to quantify spring-run habitat. The largest increase in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 5.6% increase in critically dry water year types. There are no expected reductions in mean fry WUA under Alternative 3 in comparison to the No Action Alternative.

On a monthly scale, the median value of fry rearing WUA under Alternative 3 has a 5% reduction in April in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The median values are similar throughout the other fry rearing months. The estimated fry rearing WUA values under the modeled alternatives are highly variable across the months, April through October, but are generally highest in April and October (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). WUA values of the fry rearing WUA curve are lowest in the range of approximately 7,000 cfs to 13,000 cfs in Segment 5 (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and flows in this range are more frequent during May through August (Table O-248).

The results of the steelhead fry rearing habitat analysis based on CalSim 3 simulated flows suggest that Alternative 3, compared to the No Action Alternative, may have a minor (up to 5.6%) increase in estimated steelhead fry rearing habitat across all water year types. There are some differences in estimated rearing WUA habitat under Alternative 3 when looking at a monthly scale, with a minor (5%) reduction in estimated fry rearing habitat in April in comparison to the No Action Alternative.

Juvenile Rearing Habitat Analyses

Under Alternative 3, mean juvenile rearing WUA increases in wet and above normal water year types and reductions in all other water year types in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The upper and lower limits of the range in WUA values are determined by the ranges of the juvenile rearing WUA curves for late-fall run since there were no reliable WUA curves for steelhead. The analysis includes all months because steelhead juveniles may reside in freshwater for a year or more before emigrating to the ocean. The largest increase in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 1.0% increase in wet water year types. The largest reduction in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 1.6% decrease in critically dry water year types.

On a monthly scale, the median value of juvenile rearing WUA under Alternative 3 is similar to the No Action Alternative most months of the year but constitutes a 7% increase under Alternative 3 in June and a 6% reduction in August (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The estimated juvenile rearing WUA values under the modeled

alternatives are similar December through March, and gradually decrease until the lowest estimated values in July. As discussed previously for spring-run rearing WUA and steelhead spawning WUA, the high WUA values with low variability in the third quartile for December through March result from the peaking of the WUA curve at the lowest flows and frequent low Keswick Dam flow releases during these months to build Shasta Reservoir storage (Table O-248). The wide range of values in the first quartile of these months reflects the high frequency and variability of higher flows in these wet months. The low juvenile rearing WUA values June through August result from releases in the summer months above 10,000 cfs and estimated peak juvenile rearing at flows below 5,000 cfs.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream rearing habitat for juvenile steelhead in the upper Sacramento River may comprise of a 11.4% to -5.5% difference from January through December (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest increase in estimated habitat may occur in June and the greatest reduction in estimated habitat may occur in August under Alternative 3 in comparison to the No Action Alternative.

The results of the two steelhead juvenile rearing habitat analyses based on CalSim 3 simulated flows suggest that Alternative 3 compared to the No Action Alternative may have a minor (less than 2%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and the greatest increase in estimated habitat may occur in June (7-11%) in the mainstem upper Sacramento River. August may have the greatest reduction (6%) in estimated juvenile rearing habitat.

Fry Stranding Analysis

The analysis of fry stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. Mean stranding of steelhead fry under Alternative 3 shows a consistent reduction from wet water years to critically dry years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Steelhead fry rearing occurs primarily during late winter and spring. Alternative 3 stranding is highest in February, with the median level trending down over the next three months (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The higher stranding levels for steelhead fry during February and wet water year types likely results because of periodic storms and high runoff that produce increased variability of flow. Mean stranding under Alternative 3 is higher than stranding under No Action Alternative for all water year types except for a 4.3% reduction in dry water years. The increases include 25.0% for above normal water years and 13.5% for below normal years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*).

Overall, mean stranding for steelhead fry is higher under Alternative 3 than under the No Action Alternative, including especially large increases for above normal and below normal water year types.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperature range year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 182 for Keswick Dam and Table 184 for RBDD. Full results of the analysis assessing the percent of months with water temperature above

the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 188 for Keswick Dam, Table 190 for Red Bluff Diversion Dam, and Table 192 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 55°F upper limit of successful smoltification during January through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 196 for Keswick Dam, Table 198 for Red Bluff Diversion Dam, and Table 200 for Hamilton City.

Results for the three analyses are summarized in Table O-49. Table O-49, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 66.2°F upper limit of optimum temperature range, there were zero and one month-water year type combinations (0% and 1.7% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-49). There were no combinations (0%) with unfavorable results at both locations. For the 59.9°F juvenile pathogen virulence threshold, there were one to 11 combinations (1.7% and 18.3%, respectively) with favorable results depending on location. There were zero to three combinations (0% to 5.0%) with unfavorable results depending on location. For the 55°F upper limit of successful smoltification, there were zero to eight combinations (0% to 32.0%) with favorable results depending on location. There were zero to one combination (0% to 4%) with unfavorable results depending on location. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 3 on steelhead juvenile rearing and emigration in the Sacramento River.

<u>Sacramento River Pulse Flows</u>

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

<u>Summary</u>

There are expected moderate adverse and moderate beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are expected to have a minor increase and/or decrease on fry and juvenile rearing habitat area. Changes in flows are expected to increase fry stranding during above normal/below normal water year types and cause minor decreases in fry stranding during dry water year types. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. Water temperatures above the smoltification criteria are expected to have a decrease in frequency below Keswick Dam. Water temperatures above the pathogens and disease criteria are expected to decrease in frequency at RBDD and have a minor increase in frequency at Hamilton City under Alternative 3 compared to the No Action Alternative.

Adult Upstream Migration and Holding

Adult steelhead enter the San Francisco Estuary from the Pacific Ocean and will either spawn within a few months of entering freshwater or stage in pools for more extended periods until the first high flows (Moyle 2002; Williams 2006). Historical data at the Fremont Weir have shown that adult steelhead migrate upstream in the Sacramento River during most months of the year, beginning in July, peaking in September, and continuing through March (Hallock 1989; McEwan 2001; Hallock et al. 1957).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

A flow threshold of 3,250 cfs has been used to evaluate the potential for adverse effects on steelhead migrating and holding adults in the Sacramento River (Long-term Operations 2019 EIS). Flows in the Sacramento River rarely drop below this level, and adults have not been observed to experience passage delays, crowding, or other adverse effects at this flow. Therefore, it represents a reasonable threshold for evaluating the potential for adverse effects on migrating and holding adults.

During the steelhead adult upstream migration and holding period, CalSim 3 modeling of Sacramento River mean monthly flows at Wilkins Slough indicate that flows may go below the minimum flow in September of critically dry water years but flows are expected to have a minor (3%) increase under Alternative 3 in comparison to the No Action Alternative (Table O-250). Flows in the Sacramento River at Wilkins Slough range from 3,250 cfs in September of critically dry water years to 19,972 cfs in February of wet water years during the adult migration period. Flows in the Sacramento River at RBDD range from about 5,090 cfs in September of critically dry water years to 37,391 cfs in February of wet water years during the adult migration period (Table O-249). Under Alternative 3, Reclamation will operate minimum instream flows at 2,300 cfs in March, July, and August, and 3,250 cfs from September through February but the schedule may change in critically dry water years (WRO Order 90-5). Since peak adult migration occurs around September, there may be minor beneficial effects to adult steelhead in September of critically dry years if flows are reduced in the lower Sacramento River under Alternative 3.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range for minimal migration impairment during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 110 for Keswick Dam, Table 112 for Red Bluff Diversion Dam, and Table 114 for Hamilton City. Results for the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 118 for Keswick Dam, Table 120 for Red Bluff Diversion Dam, and Table 122 for Hamilton City. Results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for adult migration and holding during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 126 at Keswick Dam, Table 128 for Red Bluff Diversion Dam, and Table 130 for Hamilton City.

Results for the three analyses are summarized in Table O-50. Table O-50, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 41°F to 66.2°F range for minimal migration impairment, there were zero to three month-water year type combinations (0% to 6.7% of total combinations during the period) with favorable results depending on location (Table O-50). There were no combinations (0%) with unfavorable results depending on location. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at any location. There were no combinations (0%) with unfavorable results depending on location. For the 59.9°F adult migration pathogen virulence threshold, there were zero to six combinations (0% to 13.3%) with favorable results depending on location. There were zero to two combinations (0% to 4.4%) with unfavorable results depending on location. These results suggest that there would be positive effects and negligible negative effects of Alternative 3 on steelhead adult upstream migration and holding.

Sacramento River Pulse Flows

There may be beneficial impacts of spring pulse flows on adult migration through decreased travel time.

Summary

There are expected minor beneficial impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under Alternative 3 compared to the No Action Alternative. Under Alternative 3, changes in flows are expected to have a negligible impact in the upper portions of the Sacramento River but may have a minor beneficial impact during peak migration in September of critically dry water year types, in the lower Sacramento River below Wilkins Slough. Spring pulse flow events may decrease travel time for adult migrants. Water temperatures above the pathogens and disease criteria decrease in frequency in the lower Sacramento River at RBDD and below Keswick Dam under Alternative 3. Water temperatures above the pathogens and disease criteria are expected to have negligible increases in frequency in the lower Sacramento River at Hamilton City. Water temperatures outside the optimal migration range also decrease in frequency in the lower Sacramento River at Hamilton City under Alternative 3.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Similar to the section above for adult migration, a threshold of 3,250 cfs has been used to evaluate the potential for adverse effects (Long-term Operations 2019 EIS). Flows in the Sacramento River rarely drop below this level, and adults have not been observed to experience passage delays, crowding, or other adverse effects at this flow. Therefore, it represents a reasonable threshold for evaluating the potential for adverse effects on migrating and holding adults.

During the steelhead kelt emigration period, approximately February through June, CalSim 3 modeling of Sacramento River mean monthly flows do not go below the threshold of 3,250 cfs at Keswick Dam, RBDD, Wilkins Slough or Hamilton City under Alternative 3 and the No Action Alternative (Table O-248 through Table O-251). These results suggest flows are adequate for kelt emigration in the Sacramento River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F migration impairment limit during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 146 for Keswick Dam, Table 148 for Red Bluff Diversion Dam, and Table 150 for Hamilton City. Full results for the percent of months with water temperature above the 69.8°F lethal limit to kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 154 for Keswick Dam, Table 156 for Red Bluff Diversion Dam, and Table 158 for Hamilton City. Full results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 162 for Keswick Dam, Table 164 for Red Bluff Diversion Dam, Table 166 for Hamilton City.

Results for the three analyses are summarized in Table O-51. Table O-51, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 66.2°F migration impairment limit, there were zero to one month-water year type combinations (0% to 4.0% of total combinations during the period) with favorable results depending on location (Table O-51). There were zero to two combinations (0% to 8.0%) with unfavorable results depending on location. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at all locations. There were no combinations (0%) with unfavorable results depending at all locations. For the 59.9°F adult migration pathogen virulence threshold, there were zero to five combinations (0% to 20.0%) with favorable results depending on location. There were zero to two combinations (0% to 8.0%) with unfavorable results depending on location. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 3 on steelhead kelt emigration in the Sacramento River.

Sacramento River Pulse Flows

There may be beneficial impacts of spring pulse flows on kelt emigration through decreased travel time.

Summary

There are expected minor beneficial impacts of seasonal operations on steelhead kelts based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are expected to be above the minimum flow to avoid crowding and passage delays from Keswick Dam to Hamilton City in the Sacramento River. Spring pulse flow events may decrease travel time for kelt emigration. Water temperatures above the pathogens and disease criteria may slightly decrease in frequency at RBDD. Water temperatures above the migration impairment limit may slightly increase in frequency at Hamilton City.

O.6.10.2 Clear Creek

Spawning and Egg Incubation

In Clear Creek, the temporal distribution of redd count data shows spawning December through April, with peak spawning January (Schaefer et al. 2019; Provins and Chamberlain 2019a, 2019b, 2020). Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional two to four weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In Clear Creek, estimated incubation timing based on spawning is late-December through late-May.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 3, mean spawning WUA increases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The greatest increase in estimated spawning habitat is an 7.4% increase in dry water year types under Alternative 3 in comparison to the No Action Alternative. There are no anticipated reductions in mean spawning WUA under Alternative 3 in comparison to the No Action Alternative.

The mean values of spawning WUA by month are higher under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). All spawning months (December through March) are expected to have similar WUA values under Alternative 3.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that steelhead spawning habitat under Alternative 3 may have a minor decrease (0.5-1.9%) in January and March, and a minor increase (3.4%) in February in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The two spawning habitat analyses based on CalSim 3 simulated flows suggest that Alternative 3 may have a minor to moderate beneficial effect (up to 7.4% increase) in steelhead spawning habitat in Clear Creek across all water year types when compared to the No Action Alternative.

The SIT LCM indicates that spawning habitat will likely have a minor decrease in January/March and minor increase in February on a monthly scale in Clear Creek but the other WUA analyses did not see this trend.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis* Table 138 for Clear Creek at Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 144 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 174 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-52. Table O-52, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 45°F to 55°F range for successful spawning, there was one month-water year type combinations (3.3% of total combinations during the period) with both favorable and unfavorable results below Whiskeytown Dam (Table O-52). For the 59.9°F adult pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 45°F to 52°F range for optimal egg incubation, there was one combination (2.9%) with favorable results and three combinations (8.6%) with unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on steelhead spawning and egg incubation in Clear Creek.

Summary

There are expected beneficial impacts of seasonal operations on steelhead spawning and egg incubation based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows may have a beneficial impact on spawning habitat area across all water year types. Water temperatures outside of the optimal egg incubation range are expected to have negligible increases in frequency overall in Clear Creek below Whiskeytown Dam.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in Clear Creek. The timing of juvenile outmigration depends on the watershed and water year. The rotary screw trap monitoring station in lower Clear Creek indicates outmigration into the Sacramento River with median passage starting in November and ending in June, with peak passage between April and June (Schraml and Chamberlain 2019a, 2019b, 2020, 2021).

Potential Changes to Steelhead from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 3, mean fry rearing WUA decreases in wet water year types and increases in all other water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 1.1% increase in dry water year types. The only decrease in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 0.03% decrease in wet water year types.

The mean values of fry rearing WUA by month are similar under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). All fry rearing months (February through June) are expected to have similar WUA values under Alternative 3.

The results of the fry rearing habitat analysis based on CalSim 3 simulated flows suggest that Alternative 3 may have a negligible (less than 1.2%) increase and/or decrease in estimated steelhead fry rearing habitat across all water year types in Clear Creek.

Juvenile Rearing Habitat Analyses

Under Alternative 3, mean juvenile rearing WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under Alternative 3 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is an 6.5% decrease in dry water year types. On average across all water year types, there is a 6% reduction in estimated juvenile rearing habitat under Alternative 3.

The mean values of juvenile rearing WUA by month are lower July through October and higher in November and December under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the period analyzed, December is expected to have the highest juvenile rearing WUA values under Alternative 3.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for steelhead in Clear Creek may decrease 0.3-20.3% in February and June through October and may increase 4.1-14.2% November through January and March through May under Alternative 3 in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest decrease in estimated juvenile rearing habitat may occur in August and the greatest increase in juvenile rearing habitat may occur in May.

The results of the two steelhead juvenile rearing habitat analyses suggest that Alternative 3 may have an adverse effect, as rearing habitat may decrease on average by 6% across all water year types in comparison to the No Action Alternative, and may increase and decrease throughout the year on a monthly scale. The steelhead juvenile rearing WUA analysis in Attachment O.1, *Clear Creek Weighted Usable Area Analysis* analyzed the period between July and December, but some juveniles may rear year-round in Clear Creek, up to four years before emigration to the ocean.

The greatest decrease in estimated juvenile rearing habitat may occur in August and the greatest increase in juvenile rearing habitat may occur in May.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperature range year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 186 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 194 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 55°F upper limit of successful smoltification during January through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 202 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-53. Table O-53, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 66.2°F upper limit of optimum temperature range for juvenile steelhead growth, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-53). For the 59.9°F juvenile pathogen virulence threshold, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 55°F upper limit of successful smoltification, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on juvenile steelhead rearing and emigration in Clear Creek.

Summary

There are expected adverse impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are expected to have a decrease in juvenile rearing habitat area across all water year types. Water temperatures above the three juvenile temperature criteria are not anticipated to change in frequency in Clear Creek below Whiskeytown Dam under Alternative 3.

Adult Upstream Migration and Holding

Adult steelhead enter the San Francisco Estuary from the Pacific Ocean and will either spawn within a few months of entering freshwater or stage in pools for more extended periods until the first high flows (Moyle 2002; Williams 2006). In Clear Creek, *O. mykiss* greater than 16 inches have been seen migrating upstream through video monitoring as early as August and throughout February (Killam 2022).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During the period of adult steelhead migration and holding in Clear Creek, the mean monthly flows under Alternative 3 compared to the No Action Alternative are on average reduced August through October and increased November through January (Table O-257). Throughout the full simulation period, flows on average will range from 17-33% reduction under Alternative 3. Flows are expected to generally be above 100 cfs throughout this period in Clear Creek, and unlikely to cause delays in migration and crowding for adult steelhead.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range for minimal migration impairment during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 116 for below Whiskeytown Dam. Results for the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 124 for below Whiskeytown Dam. Results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for adult migration and holding during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 32 for below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-54. Table O-54, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 41°F to 66.2°F range for minimal migration impairment, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-54). For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F pathogen virulence threshold for adult m, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on steelhead adult upstream migration and holding in Clear Creek.

Summary

There are expected negligible impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under Alternative 3 in comparison with the No Action Alternative. Under Alternative 3 compared to the No Action Alternative, Clear Creek flows are likely adequate for migrating adults. Water temperatures above the three adult temperature criteria are not anticipated to change in frequency in Clear Creek below Whiskeytown Dam under Alternative 3.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During the period of steelhead kelt emigration in Clear Creek, the mean monthly flows under Alternative 3 compared to the No Action Alternative will be reduced towards the tail ends of emigration and increased during peak emigration (Table O-257). Throughout the full simulation period, flows on average will have a 6% reduction in February and a 28% reduction in June under Alternative 3. Throughout the full simulation period, flows on average will have a 20-41% increase March through May under Alternative 3. Flows are above 100 cfs in Clear Creek throughout this period under Alternative 3. These results suggest there are negligible effects of flow to steelhead kelt emigration under Alternative 3.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F migration impairment limit during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 152 for below Whiskeytown Dam. Full results for the percent of months with water temperature above the 69.8°F lethal limit to kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 160 for below Whiskeytown Dam. Full results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 168 for below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-55. Table O-55, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 66.2°F kelt migration impairment limit, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-55). For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F pathogen virulence threshold for adult migration, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on steelhead kelt migration in Clear Creek.

Summary

There are expected negligible impacts of seasonal operations on steelhead kelts based on analyses of simulated flows and water temperature under Alternative 3 in comparison with the No Action Alternative. Under Alternative 3, flows are likely adequate for the small proportion of the population that emgirate as kelts in Clear Creek. Water temperatures above the three temperature criteria for kelts are not anticipated to change in frequency in Clear Creek below Whiskeytown Dam under Alternative 3 in comparison to the No Action Alternative

O.6.10.3 Lower American River

Spawning and Egg Incubation

In the lower American River, redd surveys have reported spawning January through mid-April, with peak spawning in February (Sweeney et al. 2021). The median months of spawning from 2002-2021 were from January through March. Redd surveys on the lower American River do not occur until the first week of January, and there are reports from the Sacramento Water Forum (2015) that indicate spawning starts in late December. Therefore, the timing window of spawning on the American River was analyzed from late December until March.

Steelhead egg incubation varies with water temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional two to four weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). On the lower American River, egg incubation starts in late December and ends in late May, with peak incubation between February and April (Hannon pers. comm. 2023; Sacramento Water Forum 2015).

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 3, lower American River steelhead mean spawning WUA under Alternative 3 is highest in critically dry water years and falls sharply with wetter water year types (Attachment M.3, *American River Weighted Usable Area Analysis*). This pattern of variation occurs because streamflows during the January through March spawning season of steelhead rise from dry to wetter water year types (Table O-259). The lower American River steelhead spawning WUA curve peaks at about 2,000 cfs (Attachment M.3, *American River Weighted Usable Area Analysis*) and flows under Alternative 3 are consistently well above this level in the wetter water years. February flows are especially high in all but critically dry water years and consequently February shows the lowest median spawning WUA for all alternatives (Attachment M.3, *American River Weighted Usable Area Analysis*). Differences in mean spawning WUA between Alternative 3 and the No Action Alternative are small, ranging from 2.7% lower under Alternative 3 for wet and above normal water years to 1.4% higher for critically dry water years (Attachment M.3, *American River Weighted Usable Area Analysis*). Median spawning WUA is higher under Alternative 3 than the No Action Alternative for January, is slightly lower for February, and is about the same for March (Attachment M.3, *American River Weighted Usable Area Analysis*).

The results of the SIT LCM model for Alternative 3 are generally the same as those described above, showing little difference in spawning WUA in comparison to the results for the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The SIT analysis results include a 9.1% reduction for Alternative 3 in April, but April was not included for the spawning WUA analysis above.

Overall, the results indicate that there is little difference in mean spawning WUA for steelhead between Alternative 3 and the No Action Alternative.

Redd Dewatering Analysis

The results of the analysis for redd dewatering potential for lower American River steelhead indicate that redd dewatering is much greater in wetter water years than in drier water years for Alternative 3 (Attachment M.1, *American River Redd Dewatering Analysis*). This difference reflects the greater frequency of larger flow fluctuations in wetter years. Mean steelhead redd dewatering potential is lower under Alternative 3 than under the No Action Alternative for all water year types except dry water years, which shows an 11.7% increase. Most of the reductions are large, including 34.1% lower in below normal water years, 21.9% lower in critically dry water years, and 13.5% lower in above normal water years (Attachment M.1, *American River Redd Dewatering Analysis*). In absolute terms, the large relative change for below normal water years results from an absolute change of reduction from 20.6% to 13.6%, which is still large. For the individual months of steelhead spawning in the lower American River, median redd dewatering potential is highest and variability is greatest in February for both the No Action Alternative and Alternative 3 (Attachment M.1, *American River Redd Dewatering Analysis*). The occurs because flows during the two-month incubation period following February spawning exhibit greater declines than those for January and March (Table O-259).

Overall, the results indicate that Alternative 3 produces substantial reductions in redd dewatering potential of steelhead relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 20 for Hazel Avenue and Table 22 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold for spawning adults during December through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 24 for Hazel Avenue and Table 26 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 40 for Hazel Avenue and Table 42 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold during December through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 44 for Hazel Avenue and Table 46 for Watt Avenue.

Results for the analysis are summarized in Table O-56. Table O-56 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 45°F to 55°F range for successful spawning there were zero and one month-water type combinations (0% and 5%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-56). There were zero and one month-water type combination (0% and 5%, respectively) with unfavorable results at both Hazel Avenue and Watt Avenue, respectively. For the 59.9°F spawning pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results at both Hazel Avenue and Watt Avenue. For the 45°F to 52°F range for optimal egg incubation there were there were one to two month-water type combinations (3.3% and 6.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were four and one month-water type combinations (13.3% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold, there were one and two month-water type combinations (3.3% to 6.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water type combinations (6.7% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results suggest that Alternative 3 would have positive (3.3% - 6.7% favorable) and negative (3.3% - 13.3% unfavorable) water temperature-related effects to steelhead spawning and egg incubation in the lower American River.

Summary

There are expected minor adverse and substantial beneficial impacts of seasonal operations on steelhead spawning and egg incubation in the lower American River based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows may have a minor increase and/or decrease on spawning habitat area but may substantially decrease redd dewatering potential. Water temperatures above the optimal range for egg incubation are expected to increase in frequency (6.7% favorable, 13.3% unfavorable) in the lower American River at Hazel Ave.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Yearling rearing is year-round in the lower American River. Young of the year fry rearing is from February through May (Sacramento Water Forum 2015). The timing of juvenile outmigration depends on the watershed and water year. The rotary screw trap monitoring station in the lower American River indicates outmigration into the Sacramento River with median passage starting in January and ending in May, with peak passage between March and May (Day 2022a).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During the period of steelhead rearing in the lower American River, the mean monthly flows under Alternative 3 compared to the No Action Alternative are increased and decreased depending on the month under critically dry water year types, which may alter their rearing habitat (Table O-260, Table O-259). Reductions under Alternative 3 are anticipated in October and November of critically dry years when flows are below 1,000 cfs, potentially impacting juvenile (yearling) habitat. The greatest increase in flows under Alternative 3 occur in April of a critically dry water year type (37% in the lower American River at H St) which may benefit young of the year steelhead fry rearing. Flows are expected to be either similar or increase during their other fry rearing months under Alternative 3. The greatest reduction occurs in June of a below normal water year type (43% in the lower American River at H St).

The CalSim 3 simulated flow results suggest that changes in flow in the lower American River under Alternative 3 compared to the No Action Alternative may have a minor adverse and a minor beneficial effect on juvenile habitat, and a minor beneficial effect for fry rearing during critically dry water year types. There are no reliable estimates for steelhead juvenile rearing habitat using weighted usable area analyses. USFWS 1985 derives spawning and rearing weighted usable area on fall-run Chinook salmon, but this study did not assess steelhead and has not been peer reviewed.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 48 for Hazel Avenue and Table 50 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F rearing and outmigration pathogen virulence threshold year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 52 for Hazel Avenue and Table 54 for Watt Avenue. Full results of the analysis assessing water temperatures above the percent of months with water temperature above the 55°F limit of successful smoltification during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 56 for Hazel Avenue and Table 58 for Watt Avenue.

Results for the three analyses are summarized in Table O-57. Table O-57 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels, there were one and two month-water combinations (1.7 and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-57). There were three and six month-water combinations (5.0% and 10%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F juvenile rearing and outmigration pathogen virulence threshold, there was one and three month-water combinations (1.7% and 5.0%, respectively) with favorable results at Hazel Avenue

and Watt Avenue, respectively. There were six and one month-water combinations (10% and 1.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 55°F limit of successful smoltification, there were zero and one month-water combinations (0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue. There were zero month-water combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results suggest that there would be positive (1.7% - 5% favorable) and negative (1.7% - 10% unfavorable) water temperature-related effects to steelhead juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There are expected adverse and beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration in the lower American River based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3 in critically dry water years, reductions in flows may decrease rearing habitat area (June, October, and November) and increases in flows may increase rearing habitat area (December, March, and April). Water temperatures above the optimum juvenile growth criteria have increases in frequency at Watt Avenue. Water temperatures above pathogens and disease criteria have increases in frequency at Hazel Avenue.

Adult Upstream Migration and Holding

Adult steelhead enter the San Francisco Estuary from the Pacific Ocean and will either spawn within a few months of entering freshwater or stage in pools for more extended periods until the first high flows (Moyle 2002; Williams 2006). In the lower American River, adult steelhead migration may occur as early as July and through early April, with peak abundance in January and February (Sacramento Water Forum 2015; Hallock 1989; Hallock et al. 1957).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Flows in the lower American River below Nimbus Dam are expected to be similar during peak adult migration and holding under Alternative 3 compared to the No Action Alternative (Table O-259 and Table O-260). Peak steelhead adult migration in the lower American River occurs between January and February (Sacramento Water Forum 2015), when flows are expected to be less than a 9% increase or decrease under Alternative 3 across all water year types (Table O-259 and Table O-260). The largest reductions in flow under Alternative 3 for peak adult migration occur in January of critically dry water year types, but flows are expected to be above 1,000 cfs during this period. The largest increases in flow under Alternative 3 throughout the migration period occur in March and April of all water year types. Throughout the adult migration period, November has the greatest reductions in flow under Alternative 3, with a 31% reduction in critically dry water year types. Flows in October and November of critically water year types are expected to be below 1,000 cfs under Alternative 3 but are likely still adequate for adult migration (Table O-260).

These results of the CalSim 3 simulated flows suggest that there may be a negligible effect of Alternative 3 compared to the No Action Alternative on steelhead adult migration and holding in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range of minimal migration impairment for adult steelhead during July through April are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 8 for Hazel Avenue and Table 10 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through April are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 12 for Hazel Avenue and Table 14 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult upstream migration and holding pathogen virulence threshold during July through April are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 16 for Hazel Avenue and Table 18 for Watt Avenue.

Results for the three analyses are summarized in Table O-58. Table O-58 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 41°F to 66.2°F range of minimal migration impairment for adult steelhead under Alternative 3, there were five and zero month-water combinations (10% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue (Table O-58). There were one to four month-water combinations (2.0% and 8.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F upper lethal limit to adult migrants, there were three and two month-water combinations (6.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two to four month-water combinations (4.0% and 8.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F adult upstream migration and holding pathogen virulence threshold, there were zero and one month-water combinations (0.0% and 2.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and five month-water combinations (4.0% and 10.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results suggest that there would be positive (4% - 6% favorable) and negative (2% - 8% unfavorable) water temperature-related effects to steelhead adult upstream migration and holding in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There are expected negligible impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under Alternative 3 in comparison with the No Action Alternative. Under Alternative 3 compared to the No Action Alternative, there are likely adequate flows during peak adult migration and holding. Water temperatures above all three temperature criteria both increase in frequency and decrease in frequency (2-6%) in the lower American River under Alternative 3 in comparison to the No Action Alternative, depending on the location (Hazel Ave or Watt Ave).

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Flows in the lower American River below Nimbus Dam are expected to be similar to or increased during peak kelt emigration under Alternative 3 compared to the No Action Alternative (Table O-259 and Table O-260). The largest reductions in flow under Alternative 3 during kelt emigration occur in June of below normal water year types, but flows are expected to be above 1,000 cfs during this period across all water year types. The largest increases in flow under Alternative 3 occur in March and April of all water year types, but flows are likely adequate for kelt emigration throughout the period.

These results of the CalSim 3 simulated flows suggest that there may be a negligible effect of Alternative 3 compared to the No Action Alternative on steelhead kelt emigration in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F limit of migration impairment for steelhead kelt emigration during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 28 for Hazel Avenue and Table 30 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F lethal limit for steelhead kelt emigration during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 32 for Hazel Avenue and Table 34 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F kelt emigration pathogen virulence threshold during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 36 for Hazel Avenue and Table 38 for Watt Avenue.

Results for the three analyses are summarized in Table O-59. Table O-59 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3, for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead, there were one and zero month-water combinations (4.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-59). There were zero and four month-water combinations (0.0% and 16%, respectively) with unfavorable results

at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F upper lethal limit to adult migrants, there were zero month-water combinations (0%) with favorable results at Hazel Avenue and Watt Avenue. There were zero and four month-water combinations (0.0% and 16.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F kelt emigration pathogen virulence threshold, there were one and two month-water combinations (4.0% and 8.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue. There were three and zero month-water combinations (12.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that there would be positive (4% - 8% favorable) and negative (12% - 16% unfavorable) water temperature-related effects to steelhead kelt emigration in the lower American River at Hazel Avenue and Watt Avenue. Negative effects are expected to be greater in magnitude than positive effects.

Summary

There are expected minor to moderate adverse and minor beneficial impacts of seasonal operations on steelhead kelt emigration based on analyses of simulated flows and water temperature under Alternative 3 in comparison with the No Action Alternative. Under Alternative 3 compared to the No Action Alternative, there are likely adequate flows for kelt emigration. Water temperatures above the three temperature criteria both increase in frequency (4-16%) and decrease in frequency (4-8%) in the lower American River under Alternative 3 in comparison to the No Action Alternative, depending on the location (Hazel or Watt Avenue).

O.6.10.4 Bay-Delta

Juvenile Rearing and Emigration

While juvenile steelhead can be found in all waterways of the Delta, they are seen more frequently in the main channels to their natal river systems (National Marine Fisheries Service 2009a). The San Francisco Estuary is used as a short-term outmigration corridor for juvenile steelhead but the propensity of rearing in the Delta is currently unknown (Hayes and Kocik 2014, Chapman et al. 2015, Buchanan et al. 2021). The USFWS monitoring programs (Sacramento beach seines, Sacramento trawl, and Knight's Landing RST) indicate outmigration timing from the Sacramento River with first median passage in January and last median passage in May (Columbia Basin Research, University of Washington 2024). Outmigration from the San Joaquin River is monitored through the Mossdale Trawl, and median passage is April through May (Columbia Basin Research, University of Washington 2024).

Potential Changes to Steelhead from Seasonal Operations

Zone of Influence

Differences in hydrology under Alternative 3 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions. With incremental decreases in OMR under Alternative 3 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under Alternative 3 may impact the proportional overlap at Turner Cut, San Joaquin

River at Jersey Point, and Old River at Middle River, see Alternative 3, Sacramento River Winter-run Chinook Salmon ESU (Section O.6.8.2, *Zone of Influence*).

Flow into Junctions

For a full description of Flow into Junctions model background, see Section O.4.8.2, *Sacramento River Winter-run Chinook Salmon ESU, Juvenile Rearing and Emigration in the Bay-Delta*. The following section covers discussion of the Central Valley Project and Head of Old River junctions. An expanded set of junction analysis results can be found in Attachment I.10, *Flow into Junctions*.

Under Alternative 3 in the -2,000 and -3,500 OMR bins, predicted proportion of flow entering the Central Valley Project (CVP) is greater than the No Action Alternative, and less than the No Action Alternative in the -5,000 and <-5,500 OMR bins. Changes in predicted proportion of flow entering the CVP when OMR was -2,000, -3,500, and -5,000 were less than ± 0.0406, indicating a negligible difference from the No Action Alternative. However, when OMR was <-5,500 the change in flow into CVP was -0.0933, indicating that slightly less flow will be routed into CVP under Alternative 3 than when compared to the No Action Alternative.

Under Alternative 3 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the Head of Old River (HOR) is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.0404, indicating a negligible difference between Alternative 3 and the No Action Alternative.

Summary

Alternative 3 relative to the No Action is expected to influence flow into the Head of Old River and CVP junctions. Under Alternative 3, no change to possibly less flow into CVP under OMR -3,500; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 3 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Steelhead

Salvage Density and Negative Binomial

Predictions from the salvage density and the negative binomial model for steelhead include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of steelhead at SWP Banks Pumping Plant for all the months December through April and all water years Alternative 3 was lower than predicted average monthly loss under the No Action Alternative, with up to a 49% decrease in predicted loss for dry water year types (Table O-60). Predicted average monthly loss of steelhead at CVP Jones Pumping Plant for all the months October through April for Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for all water year types, with up to a 58% decrease in predicted loss for dry water year types (Table O-61). For detailed

information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly salvage of juvenile steelhead at the Delta fish collection facilities for the months of December through June under Alternative 3 was lower than predicted loss under the No Action Alternative for all water year types except for above normal water year types which had a 3% increase in predicted loss. For all other water year types, predicted loss of steelhead at Jones was lower, with a reduction of up to 67% for wet water year types for Alternative 3 as compared to the No Action Alternative (Table O-62). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*, Table 8.

Summary

The results of the two entrainment models suggest diminished impacts of exports under Alternative 3 compared to the No Action Alternative, with substantial decreases in entrainment. Alternative 3 relative to the No Action Alternative is expected to have a moderate to substantial decreases (14-67%) in steelhead loss in wet, below normal, dry, and critically dry water year types in the Delta at both fish facilities under the Negative Binomial model. There is an expected increase (3%) in steelhead loss in above normal water year types under the Negative Binomial model. Alternative 3 relative to the No Action Alternative is expected to have moderate to substantial decreases (15-58%) in steelhead loss across all water year types in the Delta at both fish facilities under the Salvage Density model.

Potential Changes to Routing and Through Delta Survival of Steelhead

ECO-PTM

. For a detailed description of how flows under Alternative 3 may impact steelhead routing, see Alternative 3, Sacramento River Winter-run Chinook Salmon ESU (Section O. 6.8.2).

Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under Alternative 3 ranged from less than the No Action Alternative (up to 18% less under -5,000 cfs) to greater than the No Action Alternative (up to 5% greater under -3,500 cfs) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in Attachment I.7, *ECO-PTM*. The decrease in routing to the Interior Delta could have a large beneficial effect on outmigrating juveniles while the increase in routing could have an adverse effect on outmigrating juveniles.

Mean through-Delta percent survival December through March under Alternative 3 ranged from less than the No Action Alternative (up to 9% less under -3,500 cfs) to greater than the No Action Alternative (up to 16% more under <-2,000 cfs) (Attachment I.7, *ECO-PTM*). Survival through Delta-specific routes is discussed further in Attachment I.7, *ECO-PTM*. The increase in survival under some OMR conditions could have a large beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have a large adverse effect on outmigrating juveniles.

Summary

Alternative 3 relative to the No Action Alternative using ECO-PTM suggest an adverse or beneficial impact due to differences in flow, with a smaller proportion routed to Interior Delta between December and March, particularly under OMR -5,000. Alternative 3 relative to the No Action Alternative is expected to have a possible adverse or beneficial impact due to differences in flow on survival of outmigrating juvenile steelhead, under certain OMR conditions, according to the model.

O.6.10.5 San Joaquin River

Juvenile Emigration

The San Joaquin River is primarily documented as an outmigration corridor for juvenile steelhead (Buchanan et al. 2021). Outmigration from the San Joaquin River into the Delta is monitored through the Mossdale Trawl, and median passage is April through May (Columbia Basin Research, University of Washington 2024). RSTs in the lower Stanislaus River, a tributary to the San Joaquin River, suggests juvenile emigration into the San Joan Joaquin River starts in January and ends in June (Day 2022b).

Potential Changes to Steelhead from Seasonal Operations

Changes in flows from seasonal operations under Alternative 3 compared to the No Action Alternative may have a negligible effect on juvenile steelhead in the San Joaquin River. During the evaluated months in the juvenile emigration period, CalSim 3 estimates of mean monthly flows at Vernalis would generally be similar or decreased under Alternative 3 compared to the No Action Alternative across all water year types (Table O-263). Throughout the full simulation period, average flows will range from 3,364 to 6,507 cfs under Alternative 3 during juvenile emigration.

Changes in water temperature from seasonal operations Alternative 3 compared to the No Action Alternative are likely to have a negligible effect on juvenile steelhead in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile emigration period (Figure O-15).

Summary

The results of these two simulation models indicate there are expected negligible impacts of seasonal operations on juvenile steelhead in the San Joaquin River under Alternative 3 in comparison with the No Action Alternative.

Adult Upstream Migration and Holding

Steelhead/rainbow trout of anadromous parentage occur at low numbers in all three major San Joaquin River tributaries. These tributaries have a higher percentage of resident rainbow trout compared to the Sacramento River and its tributaries (Zimmerman et al. 2009). Estimates of migrating adults in the San Joaquin River are made from the CDFW angler report cards and suggest that migration starts in July, peaks in December and January, and ends in March (California Department of Fish and Wildlife 2007).

Potential Changes to Steelhead from Seasonal Operations

Changes in flows from seasonal operations under Alternative 3 compared to the No Action Alternative may have a minor adverse effect on adult steelhead migration and holding in the San Joaquin River in critically dry water year types. During the evaluated months in the adult migration period, CalSim 3 estimates of mean monthly flows at Vernalis would decrease from July through March of critically dry water year types under Alternative 3 compared to the No Action Alternative (Table O-263). Throughout the full simulation period, average flows will range from 466 to 2,065 cfs under Alternative 3.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible effect on adult steelhead migration and holding in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the adult migration period (Figure O-15).

Summary

There are likely negligible to minor adverse impacts of seasonal operations on adult steelhead migration and holding in the San Joaquin River based on analyses of simulated flows and water temperature under Alternative 3 in comparison with the No Action Alternative.

O.6.10.6 Stanislaus River

Spawning and Egg Incubation

Data on steelhead spawning in the Stanislaus River is limited, but adults appear to spawn primarily from January to April. In 2021, as part of the reasonable and prudent measure to accelerate steelhead monitoring and research in the NMFS (2019) Biological Opinion, CDFW initiated the Stanislaus River Life Cycle Monitoring Program. Based on the initial redd survey report, which had a late start due to COVID-19 restrictions, spawning appears to start in February and last until April (Kok and Keller 2023). Although few steelhead spawning surveys have been conducted in the Stanislaus River, spawning *O. mykiss* has been documented upstream of the Highway 120 Bridge in Oakdale, between Goodwin Dam and the Oakdale Recreation Area.

Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional 2-4 weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In the Stanislaus River, timing can only be estimated and would be January through late May.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

The spawning WUA results for Alternative 3 show a different pattern of variation in mean spawning WUA with water year type from the No Action Alternative and all the other alternatives (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the No Action Alternative and the other alternatives, the mean spawning WUA consistently increases from wet to critically dry water years, but for Alternative 3 mean spawning WUA is higher for above

normal water years than for below normal water years. The mean spawning WUA estimates for Alternative 3 are about the same or well below those for the No Action Alternative, depending on the water year type, including reductions of 24.0%, 21.5%, and 18.5% for wet, dry, and below normal water years, respectively (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). The spawning WUA results for individual months show much lower median spawning WUA under Alternative 3 relative to the No Action Alternative in December through March and higher median spawning WUA in April (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

The results of the SIT LCM model for Alternative 3 are generally consistent with those described above for spawning WUA, showing substantial reductions in spawning habitat in comparison to the results for the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

Overall, the results indicate that mean spawning WUA for steelhead is lower under Alternative 3 than under the No Action Alternative, including much lower in wet, dry, and below normal water year types.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 16 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold for spawning adults during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 18 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 32 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 54°F index value for egg incubation during December through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis,* Table 34 Full results of the analysis assessing the 59.9°F fry pathogen virulence threshold during December through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 36 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-63. Table O-63 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 45°F to 55°F range for successful spawning under Alternative 3, there were three month-water year type combinations (10.0%) with favorable results and zero month-water year type combination (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-63). For the 59.9°F spawning pathogen virulence threshold, there were zero month-water year type combinations (0%) with favorable and unfavorable results at Orange Blossom Bridge. For the 45°F to 52°F range for optimal egg incubation analysis, there were four month-water year type combination (10.0%) with favorable results and two month-water year type combinations (5.0%) with unfavorable results at Orange Blossom Bridge. For the 59.9°F fry pathogen virulence

threshold analysis, there was one month-water year type combinations (2.5%) with favorable results and zero month-water year type combinations (0%) with unfavorable results at Orange Blossom Bridge.

These results suggest that Alternative 3 would have beneficial effects on steelhead spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

There are expected adverse impacts of seasonal operations on steelhead spawning and egg incubation in the Stanislaus River based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are expected to have a decrease in spawning habitat area, particularly in wet, dry and below normal water year types. Water temperatures outside the successful spawning range and egg incubation range are expected to decrease in frequency the Stanislaus River at Orange Blossom Bridge.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in the Stanislaus River. The timing of juvenile outmigration depends on the watershed and water year. Rotary screw traps in the lower Stanislaus River suggests juvenile emigration into the San Joan Joaquin River starts in January and ends in June (Day 2022b).

Potential Changes to Steelhead from Seasonal Operations

Rearing Habitat—WUA Analyses

The results for mean fry rearing WUA under Alternative 3 show consistent reductions from drier to wetter water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the steelhead fry WUA curves (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which show moderately reduced WUA with increased flow, especially in the Orange Blossom Bridge and Riverbank reaches, which are the longest segments. Mean fry rearing WUA under Alternative 3 is lower to that for the No Action Alternative in all water year types except wet years, for which mean WUA is 1.0% higher under Alternative 3, but all differences are small. The largest reduction is 3.4% for dry water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fry rearing period, median rearing WUA is lower under Alternative 3 than under the No Action Alternative in April and May and the medians are similar in March and June (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

The results for juvenile rearing WUA under Alternative 3 show a minor increase in mean rearing WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in juvenile rearing WUA between Alternative 3 and the No Action Alternative are small, ranging from 0.3% lower for above normal water years to 1.7% higher for dry water years. Juveniles rear year-round and juvenile rearing WUA is highest in April and May (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For most months, median juvenile rearing WUA is similar between Alternative 3 and the No Action Alternative, but for February and March, the Alternative 3 medians are much higher.

The SIT LCM model provides rearing habitat results for all juveniles, not separating out the fry stage from older juveniles. The instream juvenile rearing habitat results for Alternative 3 are similar to those described above for fry and juvenile rearing WUA, showing little difference in rearing habitat acreages between Alternative 3 and the No Action Alternative in all months (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

Overall, the rearing WUA results indicate that mean fry and juvenile rearing WUA for steelhead is largely similar under Alternative 3 to means under the No Action Alternative.

Rearing Habitat—ASH Analyses

The results of the rearing ASH analysis for fry and juvenile rearing under Alternative 3 show more variation in the means with the water year type than that found in the rearing WUA results described above, with ASH means generally increasing from drier to wetter water year types, except for a minor reduction for juveniles from below normal to above normal water years. This pattern of variation reflects the overall relationship between streamflow and ASH for both life stages determined from modeling and field studies (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in fry and juvenile ASH between Alternative 3 and the No Action Alternative are small, which is consistent with the results of the rearing WUA analyses. For fry rearing, the differences range from 1.7% lower for above normal water years and to 1.3% higher for dry water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For juvenile rearing, the differences range from 0.8% lower for above normal water years and to 4.2% higher for dry water years. For the individual months of the rearing periods, the median fry rearing ASH is consistently higher under Alternative 3 than under the No Action Alternative, while the median juvenile rearing ASH is lower in December, higher in February and March, and roughly similar in the other months (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

Overall, the results indicate that steelhead fry and juvenile rearing ASH is largely similar under Alternative 3 relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimal growth without food limitation year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 38 for Orange Blossom Bridge and Table 40 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 42 for Orange Blossom Bridge and Table 44 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperatures above the 55°F limit of successful smoltification during January through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 48 for Orange Blossom Bridge and Table 50 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-64. Table O-64 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 66.2°F upper limit of optimal growth without food limitation under Alternative 3, there were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-64). There were zero and two month-water year type combinations (0.0% and 3.3%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 59.9°F juvenile pathogen virulence threshold, there were one and four month-water year type combinations (1.7% and 6.7%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. There were three month-water year type combinations (5.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River. For the 55°F limit of successful smoltification, there were three month-water year type combinations (12.0% and 20.0%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River.

These results suggest that Alternative 3 would have positive water temperature-related effects on steelhead juvenile rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

There are expected minor adverse and minor to moderate beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are expected to have a minor increase and/or decrease in fry and juvenile rearing habitat area across all water year types. Water temperatures above the smoltification criteria are expected to have decreases in frequency in the Stanislaus River under Alternative 3.

Adult Upstream Migration and Holding

In the Stanislaus River, *O. mykiss* greater than 16 inches have been seen migrating upstream through video monitoring as early as September and throughout March and can be recovered in the RST in Oakdale from November through April (Hellmair 2022; Eschenroeder et al. 2022).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Average flows in the Stanislaus River below Goodwin Dam are expected to generally decrease September through January and increase February through April during adult migration and holding under Alternative 3 compared to the No Action Alternative (Table O-261 and Table O-262). The largest reduction in flow is a 54% decrease under Alternative 3 in December of a below normal water year type (Table O-261). The largest increase in flow is a 63% increase

under Alternative 3 in March of a below normal water year type. Flows are lowest in September, November, and December of most water year types (except wet water year types) under both the No Action Alternative under Alternative 3. The largest decreases in low flow months under Alternative 3 compared to the No Action Alternative occur in December, with a 26%, 54%, and 27% decrease in above normal, below normal, and dry water year types respectively. Flows below Goodwin Dam are expected to be similar in critically dry water years but are expected to decrease at the Mouth under Alternative 3 compared to the No Action Alternative (Table O-261 and Table O-262).

These results of the CalSim 3 simulated flows suggest that there may be a minor adverse effect of Alternative 3 compared to the No Action Alternative on steelhead adult migration and holding in the Stanislaus River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range of minimal migration impairment for adult steelhead during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 4 for Orange Blossom Bridge and Table 6 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 8 for Orange Blossom Bridge and Table 10 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult upstream migration and holding pathogen virulence threshold during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 12 for Orange Blossom Bridge and Table 14 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-65. Table O-65 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 41°F to 66.2°F range of minimal migration impairment for adult steelhead under Alternative 3, there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River (Table O-65). There were zero and one month-water year type combinations (0.0% and 2.2%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence of the San Joaquin River, respectively. For the 69.8°F upper lethal limit to adult migrants there were zero and one month-water year type combination (0.0% and 2.2%, respectively) with favorable results at Orange Blossom Bridge and above the confluence of the San Joaquin River, respectively. There were zero and two month-water year type combinations (0.0% and 4.4%, respectively) with unfavorable results at both Orange Blossom Bridge, and above the confluence of the San Joaquin River, respectively. For the 59.9°F adult upstream migration and holding pathogen virulence threshold there was zero and one month-water year type combination (0.0% and 2.2%, respectively) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. There were three month-water year type combinations

(6.7%) with unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River.

These results suggest that Alternative 3 would have negligible water temperature-related effects on steelhead adult upstream migration and holding in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

There are expected minor adverse impacts of seasonal operations in the Stanislaus River on adult steelhead based on analyses of simulated flows and water temperature under Alternative 3 compared to the No Action Alternative. Under Alternative 3 compared to the No Action Alternative, there are potential minor adverse impacts of decreased flow in September, November, and December of drier water year types at the mouth of the Stanislaus River for adult migration and holding. Water temperatures outside the range or above the adult migration and holding criteria have negligible decreases in frequency under Alternative 3 compared to the No Action Alternative.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Average flows in the Stanislaus River below Goodwin Dam are expected to be generally increased during kelt emigration under Alternative 3 compared to the No Action Alternative, (Table O-261 and Table O-262). The largest reduction in flow is a 10% decrease under Alternative 3 in March of a critically water year type at the mouth of the Stanislaus River (Table O-262). The largest increase in flow is a 68% increase under Alternative 3 in February of a dry water year type below Goodwin Dam (Table O-261). Flows are expected to be lowest in February and March of drier water year types under the No Action Alternative and Alternative 3. The largest differences in these two months are 61-68% increases in February of dry water year types under Alternative 3. Throughout the full simulation period under Alternative 3 compared to the No Action Alternative, average flows increase throughout the kelt emigration period at both locations (Table O-261 and Table O-262).

These results of the CalSim 3 simulated flows suggest that there are anticipated minor beneficial effects of Alternative 3 compared to the No Action Alternative on steelhead kelt emigration in the Stanislaus River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F limit of migration impairment for steelhead kelt emigration during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 20 for Orange Blossom Bridge and Table 22 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F lethal limit for steelhead kelt emigration during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 24 for Orange Blossom Bridge and Table 26 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F kelt emigration pathogen virulence threshold during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 28 for Orange Blossom Bridge and Table 30 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-66. Table O-66 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 66.2°F limit of migration impairment for steelhead kelt emigration under Alternative 3, there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-66). There were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 69.8°F lethal limit for steelhead kelt emigration there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin Rive, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 59.9°F kelt emigration pathogen virulence threshold there were one and four month-water combinations (4.0% and 16.0%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. There were zero and one month-water combinations (0.0% and 4.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 3 would have positive water temperature-related effects to steelhead kelt emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

There are expected beneficial impacts of seasonal operations in the Stanislaus River on steelhead kelts based on analyses of simulated flows and water temperature under Alternative 3 compared to the No Action Alternative. Under Alternative 3 compared to the No Action Alternative, there are potential beneficial impacts of flow for kelt emigration. Water temperatures above the lethal limit for kelt emigration and pathogens and disease threshold are expected to decrease in frequency under Alternative 3 compared to the No Action Alternative.

O.6.11 Southern DPS Green Sturgeon

O.6.11.1 Sacramento River

Spawning and Egg Incubation

Southern DPS green sturgeon adults spawn primarily from April through July, although they periodically spawn in late summer and fall (as late as October). Northern DPS green sturgeon eggs hatch about a week after fertilization (at 60ºF), and incubation time of Southern DPS green sturgeon eggs is assumed to be similar (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). Because the incubation time for green sturgeon is so short, the effects analysis period for incubating eggs is considered to be the same as the spawning period, April through July, occasionally extending to October.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

<u>CalSim 3 Flows</u>

During the April through July green sturgeon spawning period, CalSim 3 estimates of mean monthly flows at RBDD under the No Action Alternative and Alternative 3 range from about 4,856 cfs for April of critically dry water years to about 15,277 cfs in April of wet water years (Table O-249). Mean flows during most of this period are moderate (~7,000 cfs to ~12,000 cfs) and likely to be suitable for spawning and egg incubation. Differences in flows at RBDD between Alternative 3 and the No Action Alternative are moderate in most months of the spawning period. Flows are moderately lower for Alternative 3 in April of below normal and dry water years (up to 11%), May of critically dry water years (up to 15%), June of all except dry water years (up to 18%), and July of above normal and below normal water years (up to 15%). Flows substantially increase under Alternative 3 in May of wet and above normal water years (up to 27%) (Table O-249). During the August through October period, when green sturgeon spawning occurs in occasional years, the flows under both alternatives tend to be lower than those in April through July, but the mean flows would be close to or above 5,000 cfs for all water year types in all four months, which is expected to be adequate for green sturgeon spawning and egg incubation. Moderate reductions in mean flows from the No Action Alternative to Alternative 3 are predicted for September of wet and above normal water years (up to 9%). Increased flows are predicted in August of below normal and dry water years (up to 23%) and October of critically dry water years (9%) under Alternative 3 (Table O-249). However, September spawning occurs only sporadically so any effect on the green sturgeon population would be minor (NMFS 2018b). Increases in mean flow from No Action Alternative to Alternative 3 in May, August, or October may or may not be substantial enough to have a positive effect on larval green sturgeon. Flow reductions at RBDD in summer and fall months under Alternative 3 could result in reduced habitat quality in spawning pool and egg incubation habitats, adversely affecting green sturgeon.

CalSim modeling for the Sacramento River at Hamilton City indicates that mean monthly flows during the period of spawning and egg incubation, April through July, are moderately to substantially different between the No Action Alternative and Alternative 3 (Table O-251). Reductions occur in April of below normal and dry water years (up to 9%), May of dry and critically dry years (up to 7%), June of wet, above normal, below normal, and dry water years

(up to 22%), and July of wet, above normal, and below normal water years (up to 19%). Substantial flow increases occur in May of wet and above normal water years (up to 29%) (Table O-251). During the August to October spawning period under Alternative 3, reductions in flows occur in August of wet water years (6%) and September of wet and above normal water years (up to 10%). Moderate to substantial flow increases occur in August of below normal, dry, and critically dry water years (up to 29%) and October of critically dry water years (12%). Moderate increases in mean flow from No Action Alternative to Alternative 3 in May, August, or October may or may not be substantial enough to have a positive effect on larval green sturgeon. Flow reductions at Hamilton City in summer and fall months under Alternative 3 could result in reduced habitat quality in spawning and egg incubation habitats, adversely affecting green sturgeon.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 49.3°F to 63.7°F range for spawning initiation during April through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 208 for Bend Bridge and Table 210 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 52.3°F to 60.8°F range supporting egg incubation during April through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 216 for Bend Bridge and Table 218 for Hamilton City.

Results for the three analyses are summarized in Table O-67. Table O-67, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 49.3°F to 63.7°F spawning initiation range, there were zero and five month-water year type combinations (0% and 25.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-67). There were zero and one combinations (0% and 5.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. For the 52.3°F to 60.8°F range for egg incubation, there were two and one combinations (10.0% and 5.0%, respectively) with favorable results at Bend Bridge and Hamilton City, respectively. There were zero and five combinations (0% and 25.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive and negative water temperature-related effects of Alternative 3 on green sturgeon spawning and egg incubation.

Summary

Alternative 3 relative to the No Action Alternative is expected to have possible beneficial impacts and adverse impacts on spawning habitats due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have beneficial and adverse impacts on spawning depending on location, month, and water year type due to differences in water temperature.

Larval and Juvenile Rearing and Emigration

The green sturgeon spawning period is from April through July, so the larval period is considered to be April through September. The green sturgeon juvenile stage begins when metamorphosis of the larva is complete, typically at about 45 days post hatch. The juveniles rear in the Sacramento River from about May through December. During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near the Cow Creek confluence to the Delta (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). Effects of flow and water temperature on green sturgeon larvae and juveniles may occur from April through December in the Sacramento River when analyzing the two life stages together.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

CalSim 3 Flows

CalSim 3 modeling for the Sacramento River at RBDD indicates that mean monthly flow differences during the April through September period of larval rearing are generally moderate between the No Action Alternative and Alternative 3. Under Alternative 3, reduced flows are predicted for April of below normal and dry water years (up to 11%), May of critically dry water years (15%), June of all except dry water years (up to 18%), July of above normal and below normal water years (up to 15%), and September of wet and above normal water years (up to 9%) (Table O-249). The April, May, June, July, and September reductions in flow from the No Action Alternative to Alternative 3 during various water years would potentially have a minor adverse effect on green sturgeon larvae because, as discussed in Section O.1.3.2.5, *Green Sturgeon, Southern DPS*, there appears to be a positive relationship between annual outflow and abundance of white sturgeon larvae and juveniles, but the applicability of the relationship to green sturgeon is uncertain.

CalSim 3 modeling for the Sacramento River at Hamilton City indicates that mean monthly flow difference during the period of juvenile rearing and emigration, are generally moderate between the No Action Alternative and Alternative 3. Under Alternative 3, reduced flows are predicted for April of below normal and dry water years (up to 9%), May of dry and critically dry water years (up to 7%), June of all except critically dry water years (up to 22%), July of wet, above normal and below normal water years (up to 19%), August of wet water years (6%), and September of wet and above normal water years (up to 10%) (Table O-251). The April, May, June, July, August, and September reductions in flow from the No Action Alternative to Alternative 3 during various water years would potentially have a minor adverse effect on green sturgeon larvae because, as discussed in Section O.1.3.2.5, *Green Sturgeon, Southern DPS*, there appears to be a positive relationship between annual outflow and abundance of white sturgeon larvae and juveniles, but the applicability of the relationship to green sturgeon is uncertain.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 64.4°F upper threshold for larvae from May through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 220 for Bend Bridge and Table 222 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 66.2°F range of optimal juvenile bioenergetic performance

during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 224 for Bend Bridge and Table 226 for Hamilton City.

Results for the three analyses are summarized in Table O-68. Table O-68, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 64.4°F upper water temperature limit for newly hatched larvae, there were one and seven month-water year type combinations (5% and 35.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-68). There were zero and four combinations (0% and 20.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. For the 59°F to 66.2°F range of optimal juvenile bioenergetic performance, there was one combination (6.7%) with favorable results at both locations. There were six and two combinations (40.0% and 13.3%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive and negative water temperature-related effects of Alternative 3 on green sturgeon larval and juvenile rearing and emigration.

Summary

Alternative 3 relative to the No Action Alternative is expected to have possible adverse impacts on rearing and emigration due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have beneficial and adverse impacts on rearing and emigration depending on location, month, and water year type due to differences in water temperature.

Adult Upstream Migration and Holding

Green sturgeon adults enter the Sacramento River from the Delta as early as February to make their way upstream to spawn in deep pools from the GCID oxbow (near Hamilton City) to the Cow Creek confluence. After spawning, the adults hold in the river for varying amounts of time, but typically emigrate back to the San Francisco Estuary and the ocean from about October through December (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). With the extended adult holding period, effects of flow and water temperature on adult upstream migration and holding may occur from February through December.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

CalSim 3 Flows

Flow differences during the February through December period of green sturgeon upstream migration and holding would generally be moderate between Alternative 3 and the No Action Alternative at RBDD, Hamilton City, and Wilkins Slough (Table O-249 through Table O-251). CalSim 3 model results predict substantially higher mean monthly flows under Alternative 3 at all locations during May of wetter years (up to 37%) and August (up to 43%) of drier years. Substantially lower flows under Alternative 3 occur during June and July of wetter water years (up to 28% and 26%, respectively) at Hamilton City and Wilkins Slough. September and November are predicted to have moderately reduced flows at all locations during wet and above normal water years. Substantial increases in mean flow from No Action Alternative to Alternative 3 in May and August may be enough to have a beneficial effect on migrating and

holding adult green sturgeon. All of the more notable flow differences occur within a range of river flows (~3,500 cfs to 12,000 cfs) that are not expected to substantially affect upstream passage of migrating green sturgeon, but the June and July flow reductions under Alternative 3 at all locations could result in reduced habitat quality in holding pool habitats, adversely affecting holding adults.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52°F to 69.4°F range for adult migration during April through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 204 for Bend Bridge and Table 206 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 52°F to 73.4°F range for adult holding year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 212 for Bend Bridge and Table 214 for Hamilton City.

Results for the two analyses are summarized in Table O-69. Table O-69 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%. If the exceedance or occurrence value was >10% lower under the alternative relative to the No Action Alternative, the result is termed "Favorable". If the exceedance or occurrence value was >10% higher under the alternative relative to the No Action Alternative, the result is termed "Unfavorable". The 10% value was chosen to represent a level of difference between the alternative and the No Action Alternative that could have a biologically meaningful effect on the species but considers the coarse definition in the data (e.g., a difference in just one of the 14 above normal water years represents a 7% difference). This value should not be interpreted as a significance threshold.

Under Alternative 3 for the 52°F to 69.4°F range for adult migration, there were no month-water year type combinations (0% of total combinations during the period, respectively) with favorable or unfavorable results at both Bend Bridge and Hamilton City, respectively (Table O-69). For the 59°F to 73.4°F range for adult holding, there was one combination (1.7%) with favorable results at both Bend Bridge and Hamilton City. There were 15 and one combinations (25.0% and 1.7%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be negative effects and negligible positive water temperature-related effects of Alternative 3 on green sturgeon adult upstream migration and holding.

Summary

Alternative 3 relative to the No Action Alternative is expected to have potential beneficial impacts and adverse impacts on migration and holding habitat due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have adverse impacts and negligible beneficial impacts on migration and holding depending on location, month, and water year type due to differences in water temperature.

O.6.11.2 San Joaquin River

Green sturgeon are also present in the San Joaquin River, but at considerably lower numbers than white sturgeon. Anglers have reported catching green sturgeon in the San Joaquin River and one adult green sturgeon was captured by Reclamation in April of 2020 (Root et al., 2020 [research note]). Although the reported presence of green sturgeon in the San Joaquin River coincides with the spawning migration period of green sturgeon within the Sacramento River, no evidence of spawning has been detected (Section O.1.8.2.3, *Green Sturgeon, Southern DPS*).

Potential Changes to Green Sturgeon from Seasonal Operations

CalSim 3 Flows

Since green sturgeon spawning has not been confirmed in the San Joaquin River, life stage analyses were not performed. It is assumed that adult green sturgeon could be in the San Joaquin River during all months of the year.

During the evaluated months, CalSim 3 estimates of mean monthly flows at Vernalis under Alternative 3 range from about 466 cfs for July of critically dry water years to about 13,336 cfs for February of wet water years (Table O-263). CalSim 3 results predict moderately to substantially decreased flows under Alternative 3 compared to the No Action Alternative during all months except February and May of various water year types. Substantially decreased flows are predicted for April and July through September of all water years (up to 22% in July of wetter water years). Moderate decreases in flows are predicted for January of above normal water years (7%), March of critically dry water years (10%), June of above normal, below normal, and critically dry water years (up to 6%), October of all water years (up to 7%), and November and December of above normal, below normal, and dry water years (up to 10%) (Table O-263). Because green sturgeon are uncommon in the San Joaquin River and can easily relocate to other parts of the Bay Delta system that have adequate flow, it is not anticipated that flow reductions under Alternative 3 would have an effect on green sturgeon compared to the No Action Alternative.

Summary

Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on adult green sturgeon due to differences in flow. Due to the lack of information about green sturgeon life stages in the San Joaquin River, a temperature analysis was not done for this species in this geography.

O.6.11.3 Bay-Delta

Larval and Juvenile Rearing and Emigration

After hatching, larvae and juveniles migrate downstream toward the Delta. Juveniles are believed to use the Delta for rearing for the first one to three years of their lives before moving out to the ocean and are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, especially within the central Delta and Suisun Bay/Marsh (Section O.1.9.1.5, *Green Sturgeon, Southern DPS*).

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

Zone of Influence

Differences in hydrology under Alternative 3 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions. With incremental decreases in OMR under Alternative 3 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under Alternative 3 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 3, Sacramento River Winter-run Chinook Salmon ESU (Section O.6.8.2, *Zone of Influence*).

Flow into Junctions

For a full description of Flow into Junctions model background, see Section O.4.8.2, *Sacramento River Winter-run Chinook Salmon ESU, Juvenile Rearing and Emigration in the Bay-Delta*. The following section covers discussion of the Central Valley Project and Head of Old River junctions. An expanded set of junction analysis results can be found in Attachment I.10, *Flow into Junctions*.

Under Alternative 3 in the -2,000 and -3,500 OMR bins, predicted proportion of flow entering the Central Valley Project (CVP) is greater than the No Action Alternative, and less than the No Action Alternative in the -5,000 and <-5,500 OMR bins. Changes in predicted proportion of flow entering the CVP when OMR was -2,000, -3,500, and -5,000 were less than ± 0.0406, indicating a negligible difference from the No Action Alternative. However, when OMR was <-5,500 the change in flow into CVP was -0.0933, indicating that slightly less flow will be routed into CVP under Alternative 3 than when compared to the No Action Alternative.

Under Alternative 3 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the Head of Old River (HOR) is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.0404, indicating a negligible difference between Alternative 3 and the No Action Alternative.

Delta Outflow vs. Sturgeon YCI

There are currently no tools available to directly evaluate the effect of spring outflow on green sturgeon thus white sturgeon are used as a proxy species for green sturgeon. To evaluate the effect of spring outflow on green sturgeon a Delta Outflow vs Year-Class Strength[1] regression analysis was done. This analysis is a response to the NMFS Green Sturgeon Recovery Plan that suggested larval abundance and distribution may be influenced by spring and summer outflow. The recovery plan also suggested that recruitment may be highest in wet years, making water flow an influential habitat parameter (National Marine Fisheries Service 2018a:12). As noted by

[1] Year-class strength in this case is an index of year-class abundance based on age-0 and age-1 white sturgeon abundance indices from otter trawling by the San Francisco Bay Study (Fish 2010).

NMFS (2018b:12), there are correlations between white sturgeon and Delta outflow, which have previously been used to infer potential effects on green sturgeon (ICF International 2016).

In contrast to white sturgeon, there are currently no quantitative relationships established between green sturgeon and Delta flows. There appears to be a positive relationship between annual outflow and abundance in rotary screw traps at Red Bluff Diversion Dam of green sturgeon larvae and juveniles (Heublein et al. 2017a). More recently, CDFW found that catch per unit effort of yearling juvenile green sturgeon sampled in the Delta was about 10 times as high in years following wet water years as in years following dry and critically dry water years (Beccio 2021). These factors are generally suggestive of a positive relationship with flow, but it is uncertain the extent to which such effects may reflect water operations.

The Delta Outflow Year-Class Strength regression analysis found statistically significant positive correlations between white sturgeon year-class strength and Delta outflow for April-May and March-July. The analysis is used as a surrogate for green sturgeon. For the April-May Delta outflow, the average overall YCI values would be substantially increased under Alternative 3 (18) relative to the No Action Alternative (11.2), a 59.9% relative increase (Table O-70). The same is true for the March-July Delta outflow, with the average overall YCI value for Alternative 3 being 22.4 compared to 16.7 for the No Action Alternative, a 34.2% relative increase (Table O-71). Effects of Alternative 3 on green sturgeon relative to the No Action Alternative are expected to be positive given the substantial increases in average Delta flow conditions between the two alternatives over all water year types during the specified months. For more detailed information see summaries presented in Attachment J.2, *Sturgeon Year Class Index and Delta Outflow*.

<u>Summary</u>

Alternative 3 relative to the No Action is expected to influence flow into the Head of Old River and CVP junctions. Under Alternative 3, no change to possibly less flow into CVP under OMR -3,500; no change in flow into HOR under OMR groupings. Impacts of pumping under both Alternative 3 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI). Alternative 3 relative to the No Action Alternative is expected to have minor beneficial impacts on green sturgeon year class strength using white sturgeon as a proxy for green sturgeon due to differences in flow.

Potential Changes to Entrainment of Southern DPS Green Sturgeon

<u>Salvage Density</u>

Predictions from the salvage density model for green sturgeon include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of green sturgeon at SWP Banks Pumping Plant for the months January, and March of all water year types Alternative 3 was less than or equal to predicted average monthly loss under the No Action Alternative for all water year types except for the below normal year type that had an increase of 1%. For all other water year types Alternative 3 had a lower or equal predicted loss of green sturgeon at Banks compared to the No Action Alternative with up to a 58% reduction in loss for wet water year types (Table O-72). Predicted average monthly loss of green sturgeon at CVP Jones Pumping Plant for all the months June through July Alternative 3 had equal or lower predicted average monthly loss compared to the No Action Alternative for all water year types, with up to a 89% reduction in predicted loss for dry water year types (Table O-73). It should be noted that loss of green sturgeon at both facilities is rare and infrequent, with such low values of predicted loss the percent differences may not be representative. For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Summary

Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on the entrainment of juvenile green sturgeon at both facilities due to differences in flow. Modeled results from the quantitative model shows possible beneficial impacts, but since green sturgeon are salvaged so rarely, the numbers may not be representative.

Adult Upstream Migration and Holding

Adult green sturgeon move through the Delta from February through April to get to spawning locations in the upper Sacramento River. Following their initial spawning run upriver, adults split into two out migration groups, the "early" out migration group may migrate immediately back downstream through the Delta during May and June, or the "late" out migration group may hold for a few weeks to months in the upper river before moving back downstream during November through January (Section O.1.9.1.5, *Green Sturgeon, Southern DPS*).

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

Delta Outflow vs. Sturgeon YCI

The Delta outflow vs Sturgeon YCI regression analysis results apply to all life stages of green sturgeon found in the Bay Delta. The regression analysis, used as a surrogate for green sturgeon, found statistically significant positive correlations between white sturgeon year-class strength and Delta outflow for April-May and March-July. Under Alternative 3, April-May Delta outflow average overall YCI values would be 59.9% higher (Table O-70) and the March-July Delta outflow values would be 34.2% higher (Table O-71) compared to the No Action Alternative. Refer to the analysis in Section O.6.11.3.1, *Larval and Juvenile Rearing and Emigration* and Attachment J.2, *Sturgeon Year Class Index and Delta Outflow*, for additional details.

Summary

Alternative 3 relative to the No Action Alternative is expected to have beneficial impacts on green sturgeon year class strength due to differences in flow.

O.6.12 Delta Smelt

O.6.12.1 Bay-Delta

Adult Migration and Spawning

During winter, adult Delta smelt initiate upstream spawning migration in association with "first flush" flow events (Sommer et al. 2011). Others report this seasonal change as a multi-directional and more circumscribed dispersal movement to freshwater areas throughout the Delta region (Murphy and Hamilton 2013). By late winter-spring, after arriving in freshwater staging habitats, adult Delta smelt hold until spawning commences during favorable water temperatures (Bennett 2005; Grimaldo et al. 2009; Sommer et al. 2011; Damon et al. 2016). Delta smelt spawn over a wide area throughout much of the Delta, including the Sacramento River and San Joaquin River confluence, the upper Sacramento River, and Cache Slough as well as into Suisun Marsh and the Napa River as conditions allow (Brown et al. 2014; Murphy and Hamilton 2013). Spawning of Delta smelt has not been observed in the wild (Moyle et al. 2016).

Potential Changes to Delta Smelt from Seasonal Operations

<u>CalSim 3 X2 Modeled X2 Position</u>

The position of X2 under Alternative 3 ranged from similar to further seaward when compared to the No Action Alternative (Table O-252) during the adult Delta smelt migration and spawning period, varying 0-7 km from the No Action Alternative, likely having beneficial effects on adult Delta smelt in the winter and spring.

<u>USFWS Delta Smelt Life Cycle Model</u>

The geometric mean of the expected rate of change in abundance across years (1995-2015), λ, for Alternative 3 was 1.16 (Attachment F.4., *Delta Smelt Life Cycle Model with Entrainment*). This is substantially higher than the λ values for all other Alternatives. Like other Alternatives, the geometric means of the expected population growth rate under Alternative 3 varied between water year types, from λ equal to 0.90 (-10% decline on average) for below normal, dry and critically dry water years, to λ equal to 1.53 (53% increase in abundance on average) for wet and above normal years. Compared to the No Action Alternative, the results under Alternative 3 were more positive and ranged from 20% to 29% higher than the No Action Alternative in terms of population growth rates, depending on the water year type (Attachment F.4., *Delta Smelt Life Cycle Model with Entrainment*).

<u>Revised Maunder and Deriso Life Cycle Model</u>

Based on life cycle analysis with the revised Maunder and Deriso in R (MDR) model, relative to the No Action Model, model projections under Alternative 3 indicate a substantial beneficial impact, with Delta smelt population growth rate larger than for the No Action Alternative in all modeled years (1995-2015; Attachment F.1, *Maunder and Deriso in R Model*). The geometric mean of λ was 0.97 under Alternative 3 across all water year types, 28% higher than for the No Action Alternative (λ = 0.75), and the magnitude of this difference remained similar for both drier and wetter water years.

Because the MDR is an integrated life cycle model, the effects of each Alternative were evaluated quantitatively primarily based on year-to-year changes in the population growth rate metric. However, as a statistical model fitted to abundance data for multiple life-stages, it is possible to gain a qualitative understanding of the season-specific covariates with a statistically significant influence on each life-stage. Also, because the covariates are standardized prior to model fitting, their coefficients can be directly compared.

In the MDR model, survival from the sub-adult to adult stage can be influenced by winter covariates which are averaged across the December to February period. Model selection retained combined Old and Middle River flow (OMR) and mean Secchi depth at South Delta monitoring stations as significant covariates of sub-adult survival, with coefficients of 0.477 and 0.542, respectively. Although differences in hydrology between the Alternatives would be expected to influence turbidity, the relationship is complex and was not able to be addressed for this analysis. Within the MDR, impacts on sub-adult survival are therefore related only to differences in OMR between the Alternatives. Winter OMR was 65% higher (i.e. less negative), on average, for Alternative 3 than under the No Action Alternative, a difference which likely accounts for the majority of the beneficial impact on population growth relative to the No Action Alternative.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the winter in the low salinity zone showed significant relationships for five zooplankton taxa; *Daphnia* adults, decapod larvae, *Eurytemora affinis* adults, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 3, when compared to the No Action Alternative, *Daphnia* adults had the largest expected CPUE increase of 22% during the below normal water year and the smallest expected CPUE increase of 4% during the wet water year type. Results for decapod larvae were negligible when rounded to the nearest whole integer (values were 0) across all WYT and scenarios. *E. affinis* adults had the largest expected CPUE increase of 13% during the dry water year type and the smallest expected CPUE increase of 5% during the wet water year type. Other calanoid copepod adults had the largest expected CPUE increase of 33% during the below normal and dry water year type and the smallest expected CPUE increase of 12% during the wet water year type. Other calanoid copepodites had the largest expected CPUE increase of 21% during dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 3 are generally higher than the No Action Alternative for winter months and water year types (Table O-254) resulting in higher zooplankton CPUE.

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for five zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 3, when compared to the No Action Alternative, cladocearns (except *Daphnia*) had the largest expected CPUE increase of 20% during the critically dry water year type and the smallest expected CPUE increase of 10% during the wet water year type. *E. affinis* adults had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Harpacticoids had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE

increase of 7% during the wet water year type. Other calanoid copepod adults had the largest expected CPUE increase of 15% during the critically dry water year type and the smallest expected CPUE increase of 9% during the wet water year type. Other calanoid copepod copepodites had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 6% during the wet water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 3 are generally higher than the No Action Alternative for spring months and water year types (Table O-254) resulting in higher zooplankton CPUE.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a beneficial impact on adult Delta smelt migration and spawning due to differences in flow. Compared to the No Action Alternative, CPUE of Delta Smelt prey species is expected to be higher under Alternative 3. Results from the revised and Deriso life cycle model indicate that under Alternative 3 there would be a substantially higher population growth rate. These results generally agreed with the results from the USFWS life cycle models which found population increases under Alternative 3 ranging from 21 -23% higher when compared to the No Action Alternative depending on the water year type. CalSim 3 results indicate that the position of X2 ranged from no different to further seaward when compared to the No Action Alternative during the winter and spring depending on the water year type, which is expected to have no impact to beneficial impacts on adult Delta smelt migration and spawning.

Potential Changes to Entrainment of Delta Smelt

Alternative 3 relative to the No Action Alternative may affect the entrainment of adult Delta smelt. Entrainment varies annually and depends on a combination of hydrology, turbidity, and export rates (see Smith et al. 2021). Historic salvage shows adult Delta smelt are entrained in the Delta Fish Collection Facilities, however in more recent years fewer fish have been entrained likely due to a combination of changes to operations and the continued decline of the Delta smelt population. While the USFWS life cycle model does incorporate entrainment, it was not used to evaluate entrainment of adult Delta smelt. Instead, OMR flows were used to evaluate changes between Alternative 3 and the No Action Alternative.

CalSim 3 OMR Values

OMR combined flows was less negative under Alternative 3 when compared to the No Action Alternative from January to June which would have substantial positive effects on entrainment of adult Delta smelt (Table O-255). The largest difference in OMR flows were in April during the wet water year type (375% less negative), while the smallest difference was June during the critically dry water year type (28% less negative). In general, during the January to June period, OMR was less negative under Alternative 3 compared to No Action Alternative which would be beneficial for adult Delta smelt entrainment.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a beneficial impact on the entrainment of adult Delta smelt due to differences in flow. Differences in OMR flow between Alternative 3 and the No Action Alternative are in general less negative from January to June, which can lead to decreased entrainment of adult Delta smelt.

Eggs and Larvae

Eggs hatch after an average of 10 days in the spring and planktonic larvae are transported (advected) from freshwater regions by the Sacramento River and tidal flows from March through May. The larval stage lasts for an average of 30 days. The nonpelagic habitats used by larval Delta smelt before they move into the pelagic areas are not known (Swanson et al. 1998; Sommer et al. 2011).

Potential Changes to Delta Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

While Delta smelt can occupy a wide range of habitats and salinities, historically a majority of Delta smelt reside in or near the LSZ (Merz et al. 2011, Moyle et al. 1992). X2 has been used as a proxy for the LSZ (MacWilliams et al. 2015, Kimmerer et al. 2013, Jassby et al. 1995). The position of X2 responds to CVP and SWP operations, the more freshwater outflow into the Bay-Delta results in a more seaward X2 position; saltwater is unable to intrude further landward while less outflow results in a more landward X2 position. The size of the LSZ is largest when X2 is below 50 km in San Pablo Bay and second largest between 60 and 75 km, when the LSZ is in Suisun Bay (Kimmerer et al. 2013). The size of the LSZ is smallest when X2 is located near the Carquinez Strait (X2 ~ 50-60 km) and at the confluence of the Sacramento and San Joaquin Rivers (X2 ~ 80-85 km).

The position of X2 under Alternative 3 was further seaward compared to the No Action Alternative (Table O-252) during the larval Delta smelt period, varying 1-5 km from the No Action Alternative depending on water year type, likely having no to beneficial effects on larval Delta smelt in the spring.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for 5 zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 3, when compared to the No Action Alternative, cladocearns (except *Daphnia*) had the largest expected CPUE increase of 20% during the critically dry water year type and the smallest expected CPUE increase of 10% during the wet water year type. *E. affinis* adults had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Harpacticoids had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Other calanoid copepod adults had the largest expected CPUE increase of 15% during the critically dry water year type and the smallest expected CPUE increase of 9% during the wet water year type. Other calanoid copepod copepodites had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 6% during the wet water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 3 are generally higher than the No Action Alternative for spring months and water year types (Table O-254) resulting in higher zooplankton CPUE.

Revised Maunder and Deriso Life Cycle Model

Life cycle analysis with the revised Maunder and Deriso Model in R (MDR) did not identify any significant covariates of recruitment, and so did not evaluate effects on eggs or early larval stages.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a beneficial impact on Delta smelt larvae due to differences in flow. Compared to the No Action Alternative, CPUE of Delta Smelt prey species is expected to be higher under Alternative 3. Results from the Maunder and Deriso life cycle model indicate that under Alternative 3 there would be a slight beneficial impact on the survival of post-larval Delta smelt under Alternative 3. CalSim 3 results indicate that the position of X2 was further seaward (1–5 km) from the No Action Alternative during the spring which are expected to have no to beneficial impacts on larval Delta smelt.

Potential Changes to Entrainment of Delta Smelt

Alternative 3 relative to the No Action Alternative may affect the entrainment of Delta Smelt larvae due to differences in flow. This possible difference was evaluated using a quantitative model.

Particle Tracking Model (PTM)

The CalSim 3 model simulated operational conditions under a range of OMR and inflow conditions from the Sacramento and San Joaquin rivers, with the DSM2 PTM module allowing for an assessment of entrainment of neutrally buoyant passive particles (a proxy for larval Delta smelt, generally distributed throughout the water column) at export facilities (Attachment I.8, *Particle Tracking Fate Modeling of Larval Smelt Entrainment*). PTM analysis was only considered for the larval Delta smelt life stage since modeling suggests later Delta smelt life stages are likely not neutrally buoyant and have a behavioral response to maintain horizontal position in the estuary (Gross et al. 2021, Kimmerer and Nobriga 2008). Results discussed here are expressed as percent of particles with a fate of *Entrained at Exports*. Please refer to Attachment I.3, *Delta Export Zone of Influence Analysis*, for keys to inflow and OMR bins codes, including corresponding Sacramento and San Joaquin rivers flow ranges and mean OMR and Exports flow ranges. While a complete set of detailed results is presented in Attachment I.8, *Particle Tracking Fate Modeling of Larval Smelt Entrainment*, the following narrative focuses on three injection regions when assessing potential entrainment effects from the perspective of varying inflows (Inflow bins: *Sacramento River, San Joaquin River,* and *Yolo Bypass Region*) and one injection region when assessing potential effects from the perspective of OMR net flows (OMR bins: *San Joaquin River Region*).

Inflow Bins.

Depending on inflow conditions, an average of 0 to 3% of particles injected within the Sacramento River region ended up entrained at export facilities under Alternative 3, compared to 0 to 14% under the No Action Alternative. Regardless of inflow conditions, Alternative 3 would always lead to reductions in the average percentage of particles entrained at export facilities, ranging from -87% under “medmed” inflow conditions to 0% under “hilo” inflow conditions.

Depending on inflow conditions, an average of 21 to 82% of particles injected within the San Joaquin River region ended up entrained at export facilities under Alternative 3, compared to 45 to 87% under the No Action Alternative. Regardless of inflow conditions, Alternative 3 would always lead to reductions in the average percentage of particles entrained at export facilities, ranging from -6% under "hilo" inflow conditions to -59% under "medhi" inflow conditions. Although not discussed here in detail, a similar pattern was observed for other injection regions with moderate potential for particles entrainment. Alternative 3 would generally lead to reductions in the average percentage of particles entrained compared to the No Action Alternative under all inflow conditions excluding "hilo" inflow conditions which ranged from 5% increase for the Mokelumne River injection region to 6% increase for the Central Delta injection region.

Depending on inflow conditions, an average of 0 to 1% of particles injected within the Yolo Bypass region would end up entrained at export facilities under Alternative 3, compared to 0 to 5% under the No Action Alternative. Based on inflow conditions, Alternative 3 would almost always lead to reductions in the average percentage of particles entrained at export facilities, ranging from -30% under "himed" inflow conditions to -94% under "medhi" inflow conditions. The 23% increase in particles related to "hilo" inflow conditions is associated with the percent difference calculation, however there was a negligible difference in entrained particles between the NAA and Alternative 3 under these conditions.

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), there was a difference between the average percentage of particles entrained under Alternative 1 and under the No Action Alternative (-1 to -69%).

OMR Bins.

Depending on OMR flow conditions, an average of 51 to 80% of particles injected within the San Joaquin River region would be entrained at export facilities under Alternative 3, compared to 57 to 87% under the No Action Alternative. Potential entrainment ranged from 11% lower under Alternative 3 than under the No Action Alternative for the -2000 OMR bin (51% *vs* 57%) to little or no difference for the -3500 bin between the No Action Alternative and Alternative 3 (68% vs 59%, respectively). Although not discussed here in detail, a similar pattern of slight reductions or similar entrainment rates under -2000 and -5000 OMR Bins, and a slight increase in entrained particles under -3500 OMR Bin was observed for Mokelumne River, Sacramento River, Central Delta export facilities. Alternative 3 would generally lead to substantial reductions in the average percentage of particles entrained compared to the No Action Alternative for the most negative OMR index (-5000: -37 to -75%), negligible reductions under the less negative OMR index (-2000: -5% to 11%) and increases under intermediate OMR index (-3500: +20 to +97%).

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), regardless of OMR flow conditions, there was generally little difference between the average percentage of particles entrained under Alternative 3 and under the No Action Alternative (-3 to +1%).

Summary

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), Alternative 3 relative to the No Action Alternative, is expected to have a negligible to beneficial impact on the entrainment of Delta smelt for all inflow groupings. For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta) Alternative 3 relative to the No Action Alternative is expected to have a negligible impact on the entrainment of Delta smelt, depending on OMR grouping.

Juveniles

During and after larval rearing in freshwater, many young Delta smelt move with river and tidal currents during the early summer to remain in favorable rearing habitats, often moving into low salinity (≤ 6 psu) areas to avoid seasonally warm and highly transparent waters that typify many areas in the central Delta (Nobriga et al. 2008). Juvenile Delta smelt rearing habitat is correlated with salinity, particularly the position of the LSZ, and other habitat attributes such as turbidity and temperature. Delta smelt also rear in upstream areas such as the Cache Slough complex and Sacramento Deep Water Ship Channel, depending on habitat conditions (Sommer and Mejia 2013). Studies indicate that in fall, prior to spawning, juvenile and sub-adult Delta smelt tend to remain in the LSZ (Sommer et al. 2011), though they can be found in the lower San Joaquin River, Suisun and San Pablo bays, the Sacramento River and San Joaquin River confluence, Cache Slough, and the lower Sacramento River (Murphy and Hamilton 2013).

Potential Changes to Delta Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 3 ranged from similar to the No Action Alternative to further seaward (Table O-252) during the juvenile Delta smelt period, varying 0–5 km from the No Action Alternative, likely having no to beneficial effects on juvenile Delta smelt in the summer depending on water year type. During the fall period, CalSim 3 modeling indicates that the estimated X2 position under Alternative 3 when compared to the No Action Alternative ranged from no different to further seaward (0–5 km), which would have no to beneficial effects for juvenile Delta smelt.

Habitat Suitability Index

Juvenile Delta smelt summer and fall habitat was estimated for different water year types (wet, above normal, below normal, dry, and critical) using the Bever et al. (2016) habitat suitability index (Bever HSI) and the Bever HSI with a water temperature threshold of 22° Celsius (22C HSI), where the Bever HSI value is multiplied by 0 when water temperature is greater than 22° C and by 1 when water temperature is less than or equal to 22° C. The temperature threshold of 22ºC was used based on sub-lethal physiological and behavioral effects observed in multiple studies (Davis et al. 2022, Hammock et al. 2022; Komoroske et al. 2021; Lewis et al. 2021; Davis et al. 2019; Komoroske et al. 2015). Under Alternative 3, mean Bever HSI for subregions targeted by the summer fall habitat action (Yolo Bypass, which includes Cache Slough and Sacramento Deepwater Shipping Channel; Lower Sacramento River; Confluence; Suisun Marsh; northwest Suisun Bay) was 5% lower to almost 6% higher than under the No Action Alternative, depending on water year type. Under Alternative 3, the mean 22C HSI for the summer fall habitat action subregions was 10% lower to almost 6% higher than under the No Action

Alternative, depending on water year type. The largest differences under Alternative 3 are predicted during the dry water year for mean Bever HSI (6% higher) and during the above normal water year for mean 22C HSI (10% lower). The smallest differences are predicted during the below normal water year for mean Bever HSI (< 1% higher) and for mean 22C HSI (2% lower).

The results of the HSI analyses suggest that Alternative 3 may result in minor increases (1%–6%) and minor decreases (2%–10%) in suitable habitat depending on water year type and the application of a temperature threshold in comparison to the No Action Alternative and would likely have minor beneficial to minor adverse impacts on juvenile Delta smelt summer and fall habitat.

Revised Maunder and Deriso Life Cycle Model

Summer outflow, the only variable within the revised Maunder and Deriso Model in R (MDR) with influence on the larval life-stage, varied little between alternatives (Attachment F.1, *Maunder and Deriso in R Model*). However, Alternative 3 was the only alternative under which outflow increased relative to the No Action Alternative (approximately 6% higher outflow than No Action Alternative), indicating that, on average, a slight, beneficial impact on the survival of post-larval Delta smelt would result under Alternative 3.

The preferred set of covariates identified through extensive model selection did not include parameters that differed between alternatives (Attachment F.1, *Maunder and Deriso in R Model*). Mean Delta water temperature and Secchi depth were the selected parameters for the fall period, which correspond to juvenile survival in the MDR model. Although hydrological differences between the alternatives would potentially impact these variables, the relationships between flow, temperature and turbidity are complex, and were not able to be modeled for this exercise. As such, juvenile Delta smelt survival under Alternative 3 was the same as under the No Action Alternative.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the fall showed significant relationships for two taxa; *E. affinis* adults and mysids. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 3, when compared to the No Action Alternative, *E. affinis* had the largest expected CPUE increase of 33% for the wet water year type and no expected change in CPUE for the above normal, below normal, dry, and critically dry water year type. However, the expected CPUE for *E. affinis* during the fall was very low (1–3 individuals per cubic meter) and unlikely to impact Delta smelt juveniles. Mysids had the largest expected CPUE increase of 25% during the above normal water year type and no expected change in CPUE for the critically dry water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 3 are generally higher than the No Action Alternative for November for most water year types (Table O-254) resulting in higher zooplankton CPUE.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a beneficial impacts and adverse impacts on juvenile Delta smelt due to differences in flow. CalSim 3 results indicate that the position of X2 ranged from no different to further seaward, depending on water year type, compared to No Action Alternative during the summer and fall which are expected to have beneficial impacts on juvenile Delta smelt. The results of the HSI analyses suggest that Alternative 3, depending on water year type and the application of a temperature threshold, in comparison to the No Action Alternative would likely have minor beneficial to adverse impacts on juvenile Delta smelt summer and fall habitat. Results from the revised Maunder and Deriso life cycle model did not include parameters that differed between alternatives therefore juvenile survival under Alternative 3 was the same as under the No Action Alternative. Compared to the No Action Alternative, CPUE of Delta smelt prey species was not related to outflow in the summer and is expected to be higher than the No Action Alternative during the fall.

Potential Changes to Entrainment of Delta Smelt

Alternative 3 relative to the No Action Alternative may affect the entrainment of juvenile Delta smelt due to differences in flow. Entrainment varies annually and depends on a combination of hydrology, turbidity, and export rates (see Smith et al. 2021). Historic salvage shows juvenile Delta smelt are entrained in the Delta Fish Collection Facilities, however in more recent years fewer fish have been entrained likely due to a combination of changes to operations and the continued decline of the Delta smelt population. While the USFWS life cycle model does incorporate entrainment, it was not used to evaluate entrainment of adult Delta Smelt. Instead, OMR flows were used to evaluate changes between Alternative 3 and the No Action Alternative.

CalSim 3 OMR Values

OMR combined flows generally was less negative under Alternative 3 when compared to the No Action Alternative from June to November, which would have positive effects on entrainment of juvenile Delta smelt (Table O-255). The largest difference in OMR flows under Alternative 3 compared with the No Action Alternative was in August during the wet water year type (65% less negative), while OMR flows were more negative in October during the dry year type (13% more negative) compared to the No Action Alternative. In general, during the June to November period, OMR was less negative under Alternative 3 compared to No Action Alternative, which would have beneficial effects on juvenile Delta smelt entrainment.

O.6.13 Longfin Smelt

O.6.13.1 Bay Delta

Adult Migration and Spawning

Longfin smelt are anadromous and spawn in fresh or low-salinity water in the Bay-Delta (Grimaldo et al. 2017), generally at two years of age (Moyle 2002). A portion of the population migrate from the ocean into the San Francisco Estuary and move upstream to spawn during late fall through winter, with most spawning occurring from November through April (California Department of Fish and Wildlife 2009a). Spawning locations have been estimated using field observations of gravid females and yolk-sac larvae (Grimaldo et al. 2017, Lewis et al. 2019) and through particle-tracking modeling (Gross et al. 2022) to suggest spawning extends farther

seaward than previously thought (Moyle 2002). Based on these studies, longfin smelt appear to spawn in the low-salinity zone where brackish and freshwaters meet (Grimaldo et al. 2017), and in tidal wetlands of south San Francisco Bay and San Pablo Bay when hydrological conditions favor spawning in more seaward regions (Lewis et al. 2020, Grimaldo et al. 2020). These regions include marshes of the Petaluma watershed, Napa-Sonoma watershed, Sacramento-San Joaquin watershed, and Coyote Creek watershed (Lewis et al. 2020, Hobbs et al. 2015).

Potential Changes to Longfin Smelt from Seasonal Operations

CalSim 3 Modeled X2 Position

The position of X2 under Alternative 3 ranged from similar to further seaward compared to the No Action Alternative (Table O-252) during the adult longfin smelt migration and spawning period, varying 0-7 km from the No Action Alternative, likely having negligible to beneficial impacts on adult longfin smelt in the fall, winter and spring.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the winter in the low salinity zone showed significant relationships for 5 zooplankton taxa; *Daphnia* adults, decapod larvae, *Eurytemora affinis* adults, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 3, when compared to the No Action Alternative, *Daphnia* adults had the largest expected CPUE increase of 22% during the below normal water year and the smallest expected CPUE increase of 4% during the wet water year type. Results for decapod larvae were negligible when rounded to the nearest whole integer (values were 0) across all WYT and scenarios. *E. affinis* adults had the largest expected CPUE increase of 13% during the dry water year type and the smallest expected CPUE increase of 5% during the wet water year type. Other calanoid copepod adults had the largest expected CPUE increase of 33% during the below normal and dry water year type and the smallest expected CPUE increase of 12% during the wet water year type. Other calanoid copepodites had the largest expected CPUE increase of 21% during dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 3 are generally higher than the No Action Alternative for winter months and water year types (Table O-254) resulting in higher zooplankton CPUE.

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for 5 zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 3, when compared to the No Action Alternative, cladocearns (except *Daphnia*) had the largest expected CPUE increase of 20% during the critically dry water year type and the smallest expected CPUE increase of 10% during the wet water year type. *E. affinis* adults had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Harpacticoids had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Other calanoid copepod adults had the largest expected CPUE increase of 15% during the critically dry water year type and the smallest expected CPUE increase of 9% during the wet water year type. Other calanoid copepod

copepodites had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 6% during the wet water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflow under Alternative 3 are generally higher than the No Action Alternative for spring months and water year types (Table O-254) resulting in higher zooplankton CPUE.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a beneficial impact on adult longfin smelt migration and spawning due to differences in flow. Compared to the No Action Alternative, CPUE of longfin smelt prey species is expected to increase under Alternative 3 during the fall, winter and spring. The position of X2 under Alternative 3 ranged from similar to further seaward when compared to the No Action Alternative likely resulting in negligible to beneficial impacts on adult longfin smelt migration and spawning.

Potential Changes to Entrainment of Longfin Smelt

Alternative 3 relative to the No Action Alternative may affect the entrainment of adult longfin smelt due to differences in flow. Entrainment varies annually and depends on a combination of hydrology and export rates.

CalSim 3 Modeled X2 Position

The position of X2 under Alternative 3 was further seaward (lower) compared to the No Action Alternative (Table O-252) during the adult longfin smelt migration and spawning period, varying 0 to -7 km (further seaward) from the No Action Alternative depending on the month and water year type.

CalSim 3 Total Exports and OMR Values

Total exports during the adult longfin smelt migration and spawning period under Alternative 3 decreased when compared to the No Action Alternative across the entire longfin smelt migration and spawning period. OMR flow values were less negative compared to the No Action Alternative across the entire longfin smelt migration and spawning period (Table O-255). Compared to the No Action Alternative, under Alternative 3, there is likely a beneficial effect on adult longfin smelt during the spawning and migration period when compared to the No Action Alternative since total exports were lower and OMR values were less negative and under the -5000 cfs threshold.

Summary

Alternative 3 relative to the No Action Alternative may have negligible to beneficial impacts on entrainment of adult longfin smelt during migration and spawning, due to differences in flow. Compared to the No Action Alternative, the position of X2 varied 0-7 km further seaward under Alternative 3, likely having a beneficial impact on entrainment of adult longfin smelt. Exports were lower and OMR values were less negative under Alternative 3 when compared to the No Action Alternative likely having a beneficial impact on adult longfin smelt migration and spawning.

Eggs and Larvae

In the San Francisco Estuary, most longfin smelt larvae hatch between December and May, and rarely outside of this range (Baxter 1999). Longfin smelt larvae are most abundant in the water column usually from January through April (Bureau of Reclamation 2008). Larval longfin smelt rear in low salinity to brackish water (2–12 ppt; Grimaldo et al. 2017) and in tidal wetlands of San Pablo Bay (Sonoma Creek, Napa River, and Petaluma River) and south San Francisco Bay (Alviso Marsh Complex and salt pond restoration areas) (Hobbs et al. 2015, Lewis et al. 2020). The spatial distribution of these larvae reflects the year-to-year variation in freshwater outflow which affects the geographic location of the low-salinity zone during the winter and spring (Dege and Brown 2004, Grimaldo et al. 2020). During high outflow years, the low salinity zone can extend into San Pablo Bay. Within the low-salinity zone and adjacent waters, larvae have been commonly collected in both littoral (nearshore) and pelagic (offshore) habitats.

Potential Changes to Longfin Smelt from Seasonal Operations

<u>CalSim 3 Modeled X2 Position</u>

The position of X2 under Alternative 3 ranged from similar to further seaward when compared to the No Action Alternative (Table O-252) during the larval longfin smelt period, varying 0-5 km from the No Action Alternative, likely having negligible to beneficial impacts on larval longfin smelt in the spring.

<u>Zooplankton CPUE-Outflow Analysis</u>

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for 5 zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 3, when compared to the No Action Alternative, cladocearns (except *Daphnia*) had the largest expected CPUE increase of 20% during the critically dry water year type and the smallest expected CPUE increase of 10% during the wet water year type. *E. affinis* adults had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Harpacticoids had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Other calanoid copepod adults had the largest expected CPUE increase of 15% during the critically dry water year type and the smallest expected CPUE increase of 9% during the wet water year type. Other calanoid copepod copepodites had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 6% during the wet water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 3 are generally higher than the No Action Alternative for spring months and water year types (Table O-254) resulting in higher zooplankton CPUE.

<u>Summary</u>

Alternative 3 relative to the No Action Alternative is expected to have beneficial impacts on longfin smelt larvae due to differences in flow. Compared to the No Action Alternative, CPUE of longfin smelt prey species under Alternative 3 is expected to increase during the spring. The

position of X2 under Alternative 3 ranged from similar to further seaward when compared to the No Action Alternative likely resulting in negligible to beneficial impacts on larval longfin smelt.

Potential Changes to Entrainment of Longfin Smelt

Particle Tracking Model (PTM)

Inflow Bins.

Depending on inflow conditions, an average of 0 to 7% of SO particles and 0 to 6% of NB particles injected within the Sacramento River region would be entrained at export facilities under Alternative 3, compared to 1 to 16% (SO) and 1 to 13% (NB) particles under the No Action Alternative. Regardless of inflow conditions, the average percentage of particles entrained at exports under Alternative 3 was always lower than under the No Action Alternative, ranging from -27% under "hihi" conditions to -96% under "medhi" conditions for both SO and NB particles.

Depending on inflow conditions, an average of 0 to 2% (SO) or 0 to 1% (NB) of particles injected within the Western Delta region would be entrained at export facilities under Alternative 3, compared to 0 to 4% (SO) and 0 to 3% (NB) under the No Action Alternative. Regardless of inflow conditions, the average percentage of particles entrained at exports under Alternative 3 was always lower than under the No Action Alternative, ranging from -27% under "lomed" conditions (SO) and -1% under "hihi" conditions (NB) to -96% (SO) and -99% (NB) under "medhi" conditions.

Depending on inflow conditions, an average of 0 to 3% (SO) or 0 to 2% (NB) of particles injected within the Yolo Bypass region would be entrained at export facilities under Alternative 3, compared to 0 to 8% (SO) and 0 to 5% (NB), under the No Action Alternative. Regardless of inflow conditions, the average percentage of particles entrained at exports for Alternative 3 was always lower than for the No Action Alternative, ranging from -31% (SO) and -21% (NB) under "hihi" conditions to -96% (SO) and -97% (NB) under "medhi" conditions.

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), regardless of inflow conditions, there was a lower average percentage of particles entrained under Alternative 3 compared to the No Action Alternative (-58% to 0% NB and SO).

OMR bins.

Depending on OMR flow conditions, an average of 18 to 72% (SO) or 17 to 71% (NB) of particles injected within the Central Delta region would be entrained at export facilities under Alternative 3, compared to 24 to 81% (SO) and 22 to 79% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 31% lower for both SO and NB particles under Alternative 3 than under the No Action Alternative for the -5000 OMR bin to 26% (SO) and 27% (NB) higher for the -3500 OMR bin.

Depending on OMR flow conditions, an average of 20 to 73% (SO) or 17 to 70% (NB) of particles injected within the Mokelumne River region would be entrained at export facilities under Alternative 3, compared to 23 to 78% (SO) and 24 to 72% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 23% (SO) and 24% (NB) lower under Alternative 3 than under the No Action Alternative for the -5000 OMR bin to 20% higher for the -3500 OMR bin for both SO and NB particles.

Depending on OMR flow conditions, an average of 1 to 11% (SO) or 1 to 9% (NB) of particles injected within the Yolo Bypass region would be entrained at export facilities under Alternative 3, compared to 2 to 16% (SO) and 1 to 13% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 66% lower (SO) and 67% lower (NB) under Alternative 3 than under the No Action Alternative for the -5000 OMR bin to 54% (SO) and 55% (NB) higher for the -3500 OMR bin.

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), regardless of OMR flow conditions, there was generally little difference between the average percentage of particles entrained under Alternative 3 and under the No Action Alternative (-3 to +1% NB and SO).

Summary

The percentage of particles entrained at exports were generally similar between surface-oriented particles representative of yolk-sac larval longfin smelt and neutrally buoyant particles representative of >10mm larval longfin smelt. For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta) Alternative 3 relative to the No Action Alternative is expected to have a beneficial impact on the entrainment of larval longfin smelt for all inflow groupings. For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), Alternative 3 would generally have a minor positive to similar impact on entrainment of larval longfin smelt compared to the No Action Alternative for all OMR grouping.

Juveniles

Juveniles have been detected throughout the San Francisco Estuary and rarely in some Delta tributaries (Merz et al. 2013). Juveniles gradually move seaward as they grow and as water temperatures increase in the late spring and early summer (Rosenfield and Baxter 2007; Tobias and Baxter 2021). Seasonal patterns in abundance and occurrence in the nearshore ocean suggest that the population is at least partially anadromous (Rosenfield and Baxter 2007; Garwood 2017). The detection of longfin smelt within the estuary throughout the year and geochemical analysis of otoliths suggests longfin smelt in the San Francisco Estuary utilize several life history strategies (Lewis et al. 2019).

Potential Changes to Longfin Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 3 ranged from similar to further seaward when compared to the No Action Alternative (Table O-252) during the juvenile longfin smelt period, varying 0-5 km from the No Action Alternative, likely having negligible to beneficial impacts on juvenile longfin smelt in the summer.

Longfin Smelt Abundance-Outflow Analysis

Juvenile Longfin Smelt abundance as represented by the Fall Midwater Trawl index of abundance is predicted to be higher under Alternative 3 than the No Action Alternative, regardless of water year type (Attachment J.1, *Longfin Smelt Outflow*, Table 3). The extent to which the predicted abundance for Alternative 3 is larger than the No Action Alternative increases incrementally as water year types become more wet, ranging from 19% higher during critically dry water years, to 40% higher during wet water years.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for five zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 3, when compared to the No Action Alternative, cladocearns (except *Daphnia*) had the largest expected CPUE increase of 20% during the critically dry water year type and the smallest expected CPUE increase of 10% during the wet water year type. *E. affinis* adults had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Harpacticoids had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 7% during the wet water year type. Other calanoid copepod adults had the largest expected CPUE increase of 15% during the critically dry water year type and the smallest expected CPUE increase of 9% during the wet water year type. Other calanoid copepod copepodites had the largest expected CPUE increase of 11% during the critically dry water year type and the smallest expected CPUE increase of 6% during the wet water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 3 are generally higher than the No Action Alternative for spring months and water year types (Table O-254) resulting in higher zooplankton CPUE.

During the summer months (May to August), the zooplankton-outflow analysis showed no significant relationships between outflow and zooplankton CPUE. Several studies have previously found relationships between abundance of zooplankton taxa and outflow during the summer (e.g. Kimmerer 2002, Kimmerer et al. 2018) while other studies have found mixed effects (Frantzich et al. 2021) or no effects (Sommer et al. 2020) of increased flow on zooplankton abundance. Evaluating possible benefits of increased outflow and flow pulses during summer may be difficult given sampling frequency and the effect size of increases to zooplankton abundances (Brandon et al. 2021).

Summary

Alternative 3 relative to the No Action Alternative is expected to have beneficial impacts on juvenile longfin smelt due to differences in flow. Juvenile longfin smelt abundance as represented by the Fall Midwater Trawl index of abundance is predicted to be higher under Alternative 3 than it is for the No Action Alternative. Compared to the No Action Alternative, CPUE of longfin smelt prey species is expected to increase under Alternative 3 during the spring. The position of X2 under Alternative 3 ranged from similar to further seaward when compared to the No Action Alternative likely resulting in negligible to beneficial impacts on juvenile longfin smelt.

Potential Changes to Entrainment of Longfin Smelt

Longfin Smelt Outflow Entrainment

The regression from Grimaldo et al. (2009) between April-May juvenile longfin smelt entrainment and Old and Middle River flows was used to assess potential differences in salvage between modeled alternatives. The analysis does not account for changes in operations since the USFWS 2008 and NMFS 2009 Biological Opinion, changes in population size over time, turbidity, juvenile behavior, and geographic shifts in distribution during higher outflow years.

Changes in OMR flows under Alternative 3 compared with the No Action Alternative may have an impact on LFS salvage. Compared to the No Action Alternative, predicted salvage decreases ranged from 47% during the critically dry water year type to 92% during the wet water year type. Alternative 3 had the least negative mean April-May OMR values during drier water year types and positive OMR flows during wetter years compared to the No Action Alternative and therefore lowest predicted salvage. Overall modeling for Alternative 3 suggests that longfin smelt salvage would decrease substantially when compared to the No Action Alternative. (Attachment I.4, *Longfin Smelt Salvage-OMR Relationship*).

Summary

Alternative 3 relative to the No Action Alternative is expected to have a substantial beneficial impact on the entrainment of longfin smelt due to differences in flow. Overall modeling for Alternative 3 suggests that longfin smelt salvage would decrease substantially when compared to the No Action Alternative.

O.6.14 Fall-run and Late Fall-run Chinook Salmon ESU

O.6.14.1 Sacramento River

Spawning and Egg/Alevin Incubation

Fall-run Chinook salmon typically spawn in the Sacramento River, primarily between Keswick Dam and RBDD from October through December, with incubation occurring from October through April. Peak spawning time for late fall-run Chinook salmon generally is from January through April (National Marine Fisheries Service 2009a), with incubation typically lasting for approximately two to four months between April and June (Moyle 2002). See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under Alternative 3, differences in mean spawning WUA are higher in wet, above normal, and critically dry water year types, and lower in below normal and dry water year types when compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 3 and the No Action Alternative is a 2.5% increase in above normal water years. The largest reduction in estimated spawning habitat is a -2.5% decrease in below normal water year types.

The monthly median value of spawning WUA under Alternative 3 is slightly higher than the No Action Alternative September through December (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are relatively similar in September and October, and slightly lower in November and December. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently highest in December when compared to other spawning months (Table O-248). This results in lower spawning WUA results because the fall-run Chinook salmon spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 3,000 to 6,000 cfs).

The results of the spawning habitat analysis based on CalSim 3 simulated flows suggest that Alternative 3 may have a minor (less than 3%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. Out of the four months of potential fall-run Chinook salmon spawning, September and October have the highest estimated spawning WUA across all alternatives.

Fall-run Chinook Salmon: Redd Dewatering Analysis

Fall-run Chinook salmon mean redd dewatering potential under Alternative 3 increases from drier to wetter water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). Most egg incubation of fall-run occurs during fall and winter, when periodic storms and high runoff in wetter years result in increased flow fluctuations, increasing risk of redd dewatering. In drier winters, flow fluctuations are reduced and fewer redds are dewatered. Differences in mean redd dewatering potential between Alternative 3 and the No Action Alternative are large for most water year types, including reductions of 9.6%, 11.2%, and 7.3% for wet, above normal, and below normal water year types, respectively, and an increase of 12.7% for critically dry years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). The apparent magnitude of these relative differences may be misleading because all absolute differences are less than 2%.

Overall, the results indicate that fall-run Chinook salmon redd dewatering potential under Alternative 3 is lower or higher than that under the No Action Alternative, depending on the water year type.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 235 for Keswick Dam and Table 236 for RBDD. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 238 for Keswick Dam and Table 239 for RBDD. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during December through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 241 for Keswick Dam and Table 242 for RBDD.

Results for the three analyses are summarized in Table O-74. Table O-74, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 42.1°F to 55°F spawning initiation range analysis, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at both Keswick Dam and RBDD (Table O-74). There were zero and one combinations (0% and 5.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there was one combination (5.0%) with favorable results at both Keswick Dam and RBDD and no combinations (0%) with unfavorable results at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero and one combinations (0% and 5.0%, respectively) with favorable results at Keswick Dam and RBDD, respectively and no combination (0%) with unfavorable results at both locations. These results suggest that there would be negligible positive and negative effects of Alternative 3 on fall-run Chinook salmon spawning and egg/alevin incubation.

Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on redd dewatering from sudden drops in flow. However, redd surveys occur during the pulse flow period and redd dewatering has not been observed.

Fall-run Chinook Salmon: Summary

The change in seasonal operations in the Sacramento River between Alternative 3 and the No Action Alternative are expected to have minor impacts on fall-run Chinook salmon spawning habitat and incubation. Under Alternative 3, changes in flows cause minor increases and decreases in spawning habitat area in all water year types. Changes in flows would result largely in minor decreases of redd dewatering potential for fall-run Chinook salmon compared to the No Action Alternative. There may be redd dewatering following spring pulse flow events, though this has not been observed during redd surveys. Water temperatures under Alternative 3 would result in similar conditions to the No Action Alternative for spawning initiation, egg incubation and fry emergence, and pathogen virulence.

Late Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under Alternative 3, differences in mean spawning WUA are lower in all water year types when compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). There are no increases in mean estimated spawning habitat between Alternative 3 and the No Action Alternative. The largest reduction in estimated spawning habitat is a -5.9% decrease in above normal water year types.

The monthly median values of spawning WUA under Alternative 3 are similar to the No Action Alternative throughout the three spawning months (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are also relatively similar across all three spawning months. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are highest in February but all three months are above 8,000 cfs (Table O-248). This results in spawning WUA results that are approximately the same

across all three months because the late fall-run Chinook salmon spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) peak at relatively low flows (approximately 3,000 to 6,000 cfs).

Overall, the spawning habitat analysis based on CalSim 3 simulated flows indicate that Alternative 3 may have a minor (5.9%) decrease in estimated spawning habitat during above normal water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. The three months of potential late fall-run Chinook salmon spawning have similar estimated spawning WUA across all alternatives.

Late Fall-run Chinook Salmon: Redd Dewatering Analysis

The results for Alternative 3 show substantial increases in percentage of late fall-run Chinook salmon redds dewatered with water year type, varying from high redd dewatering in wet water years to low redd dewatering in critically dry water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation reflects flow conditions for the winter and spring months when late fall-run Chinook salmon spawning and incubation occurs (Table O-248). During wet winters and springs, periodic storms and high runoff increase flow and flow variability, which tends to result in greater redd dewatering. In drier years, flow fluctuations are reduced and fewer redds are dewatered. Mean redd dewatering potential increases from Alternative 3 to the No Action Alternative under all water year types, and several of the increases are large (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). The largest increase is 35.5% for the redd dewatering means in critically dry years. Other large increases are 10.2% and 13.1% for below normal and above normal water years, respectively. Note that the 35.5% increase for critically dry years represents an absolute difference in redd dewatering of 0.9%.

Overall, the results indicate that redd dewatering potential under would be higher Alternative 3 then under the No Action Alternative.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 267 for Keswick Dam and Table 268 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 270 for Keswick Dam and Table 271 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 273 for Keswick Dam and Table 274 for below Clear Creek.

Results for the three analyses are summarized in Table O-75. Table O-75, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 42.1°F to 55°F spawning initiation range analysis, there were three and two month-water year type combinations (15.0% and 10.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and Clear Creek, respectively (Table O-75). There were no combinations (0%) with unfavorable results at either location. For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were four and seven combinations (20.0% and 35.0%, respectively) with favorable results at Keswick Dam and Clear Creek, respectively. There were no combinations (0%) with unfavorable results at both locations. These results suggest that there would be positive water temperature effects of Alternative 3 on late fall-run Chinook salmon spawning initiation, egg incubation, and fry emergence, and negligible negative effects to these life stages.

Late Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on spawning behavior and redd dewatering from sudden drops in flow. However, redd surveys occur during the pulse flow period and redd dewatering has not been observed.

Late Fall-run Chinook Salmon: Summary

The change in seasonal operations in the Sacramento River between Alternative 3 and the No Action Alternative are expected to have minor impact on fall-run Chinook salmon spawning habitat and incubation. Under Alternative 3, changes in flows may cause a minor decrease in spawning habitat area in above normal water years, but redd dewatering would experience an minor increase to the conditions under the No Action Alternative. Water temperatures would be more favorable for spawning initiation, and egg incubation and fry emergence, but similar for pathogen virulence compared to the No Action Alternative. There may be changes to spawning behavior and redd dewatering with spring pulse flow events, but redd dewatering has not been observed during the pulse flow period. Water temperatures are expected to have minimal impacts on late fall-run Chinook salmon spawning and incubation or the frequency of pathogen virulence under Alternative 3.

Juvenile Rearing and Emigration

The majority of young fall-run Chinook salmon migrate to the ocean during the first few months following emergence, mostly between January through June. Late fall-run Chinook salmon juveniles typically enter the ocean after 7 to 13 months of rearing in freshwater, generally between October and February. See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Fry Rearing Habitat Analysis

Under Alternative 3, mean fry rearing WUA decreases in all water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). There are no anticipated increases in mean fry rearing WUA in comparison to the No Action Alternative. The largest reduction in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 2.3% decrease in above normal water year types.

The monthly median value of fry rearing WUA under Alternative 3 has a 5% reduction in February and December below the No Action Alternative but is similar throughout the other fry rearing months (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The results during January and March show little variation in the third quartile of the WUA distributions. This occurs because the fry rearing WUA curves peak at the lowest flows encountered in the river (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and Keswick Dam flow releases are frequently low during these months in critically dry years when Shasta Reservoir is operated to rebuild storage volume (Table O-248). The first quartile is much wider because a greater range of flows affect the fry rearing WUA values below the median.

The results of the fall-run Chinook salmon fry rearing habitat analysis suggest that Alternative 3 in comparison to the No Action Alternative may have a minor (up to 2.3%) decrease in estimated fry rearing habitat across all water year types and the greatest reduction in estimated habitat may occur in February and December (5%) in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Fall-run Chinook Salmon: Juvenile Rearing Habitat Analysis

Under Alternative 3, mean juvenile rearing WUA increases in below normal, dry, and critically dry water year types and reductions in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 3.5% increase in critically dry water year types. The largest reduction in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 1.6% decrease in wet water year types.

The monthly median value of juvenile rearing WUA under Alternative 3 is 7% higher than the No Action Alternative in June but similar February through May (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The juvenile rearing WUA values under the modeled alternatives are similar across the months of February and March, and gradually decrease until the lowest estimated values in June. As discussed previously for fry rearing WUA, the high WUA values with low variability in the third quartile for February and March result from the peaking of the WUA curve at the lowest flows and frequent low Keswick Dam flow releases during these months to build Shasta Reservoir storage (Table O-248). The wide range of values in the first quartile of these months reflects the high frequency and variability of higher flows in these wet months. The lowest juvenile rearing WUA values in June result from releases in the summer months above 10,000 cfs and estimated peak juvenile rearing at flows below 5,000 cfs.

The results of the fall-run Chinook salmon juvenile rearing habitat analysis suggest that Alternative 3 in comparison to the No Action Alternative may have a minor (less than 4%) increases and/or decrease in estimated juvenile rearing habitat across all water year types and the greatest increase in estimated habitat may occur in June (7%) in the mainstem upper Sacramento River.

Fall-run Chinook Salmon: Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. Alternative 3 shows a substantial but variable increase in stranding of fall-run Chinook salmon fry from critically dry to wet water year types, with a minor reduction in stranding from dry to below normal water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Fall-run fry rearing occurs primarily during winter and early spring. Alternative 3 shows the highest stranding in February and similar stranding levels in December, January, and March (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The higher mean stranding levels for fall-run fry during February and wet water years likely results from periodic storms and high runoff that produce increased variability of flow. Mean fall-run fry stranding under Alternative 3 is similar to that under the No Action Alternative in most water year types but is 12.5% higher in above normal water years and 6.0% lower in critically dry water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Other differences are less than 4%.

Overall, fall-run juvenile stranding for fry is similar under Alternative 3 to that under the No Action Alternative, but the Alternative 3 has higher stranding in above normal water years and lower stranding in critically dry years.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 247 for Keswick Dam, Table 248 for Red Bluff Diversion Dam, and Table 249 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 251 for Keswick Dam, Table 251 for Red Bluff Diversion Dam, and Table 253 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 255 for Keswick Dam, Table 256 for Red Bluff Diversion Dam, and Table 257 for Hamilton City.

Results for the three analyses are summarized in Table O-76. Table O-76, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to one month-water year type combinations (0% to 5.0% of total combinations during the period) with favorable results depending on location (Table O-76). There were zero to six combinations (0% to 30.0%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations with either favorable or unfavorable results For the 59.9°F juvenile pathogen virulence threshold, there were zero to five combinations (0% to 25.0%) with favorable results depending on location. There would be zero to two combinations (0% to 10.0%) with unfavorable results depending on location. These

results suggest that there would be positive and negative water temperature-related effects of Alternative 3 on fall-run Chinook salmon juvenile rearing and emigration.

Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

Fall-run Chinook Salmon: Summary

Under Alternative 3, differences in seasonal operations in the Sacramento River are expected to have largely minor impacts on fall-run Chinook salmon fry and juvenile rearing habitat and behavior. There would be minor decreases in WUA for fall-run Chinook salmon fry rearing habitat in all water year types relative to the No Action Alternative, while juvenile rearing habitat would have minor increases and decreases in all water year types. Fry stranding in the Sacramento River would be similar to stranding of fall-run Chinook salmon except some increases in fry stranding in above normal water year types. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. Water temperatures in the Sacramento River would result in more unfavorable conditions below Keswick Dam for growth, smoltification and predation, but more favorable conditions for fall-run Chinook salmon juveniles, particularly at RBDD, regarding pathogen virulence.

Late Fall-run Chinook Salmon: Fry Rearing Habitat Analysis

Under Alternative 3, mean fry rearing WUA increase in below normal, dry, and critically dry water year types and decrease in all other water year types in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 5.6% increase in critically dry water year types. The largest reduction in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 1.0% decrease in wet water year types.

The monthly median value of fry rearing WUA under Alternative 3 is 5% higher than the No Action Alternative in April but similar during the other fry rearing months (Attachment O.3, *Sacramento River Weighted Usable Area Analysis s*). The fry rearing WUA median values under the modeled alternatives are similar across the months of May and June, and highest in March. The lower fry rearing WUA values in May and June result from releases in the summer months above 7,000 cfs (Table O-248) and estimated peak fry rearing at flows below 5,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The results of the late fall-run Chinook salmon fry rearing habitat analysis suggest that Alternative 3 in comparison to the No Action Alternative may have a minor (less than 6%) increase and/or decrease in estimated fry rearing habitat across all water year types and the greatest increase in estimated habitat may occur in April (5%) in the mainstem upper Sacramento River.

Late Fall-run Chinook Salmon: Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. Mean stranding of late fall-run Chinook salmon fry under Alternative 3 shows minor and inconsistent variation with water year type; wet years have the highest stranding and dry years the lowest, while stranding is similar in critically dry, below normal, and above normal water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Late fall-run Chinook salmon fry rearing occurs primarily during spring. Alternative 3 shows the highest median stranding in March, the lowest stranding in May, and similar stranding in April and June (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Mean fry stranding of late fall-run Chinook salmon is greater for all water year types under Alternative 3 than under the No Action Alternative. The increases range from 5.0% for dry water years to 29.0% for above normal water years. The increase for critically dry water years, 15.3%, is also notable (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*).

Overall, late fall-run Chinook salmon juvenile stranding for fry is higher under Alternative 3 as compared to the No Action Alternative for all water year types and is much higher for above normal and critically dry water years.

Late Fall-run Chinook Salmon: Juvenile Rearing Habitat Analysis

Under Alternative 3, mean juvenile rearing WUA constitute increases in wet, above normal, below normal, and critically dry water year types and a reduction in dry water year types in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 3 and the No Action Alternative is a 4.4% increase in critically dry water year types. The largest reduction in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 1.2% decrease in dry water year types.

The monthly median value of juvenile rearing WUA under Alternative 3 is 7% higher than the No Action Alternative in June and 6% lower in August (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). During the juvenile rearing period, the median WUA values steadily decline from May to the lowest median WUA values in July. The lower juvenile rearing WUA values in June and July result from releases in the summer months above 7,000 cfs (Table O-248) and estimated peak juvenile rearing at flows below 5,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The results of the late fall-run Chinook salmon juvenile rearing habitat analysis suggest that Alternative 3 in comparison to the No Action Alternative may have a minor (less than 5%) increase and/or decrease in estimated juvenile rearing habitat across all water year types. The greatest increase in estimated habitat may occur in June (7%) and the greatest decrease in estimated habitat may occur in August (6%) in the mainstem upper Sacramento River.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during April through February are presented in Attachment L.1, *Sacramento River*

Water Temperature Analysis, Table 279 for Keswick Dam, Table 280 for Red Bluff Diversion Dam, and Table 281 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 283for Keswick Dam, Table 284 for Red Bluff Diversion Dam, and Table 285 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 287 for Keswick Dam, Table 288 for Red Bluff Diversion Dam, and Table 289 for Hamilton City.

Results for the three analyses are summarized in Table O-77. Table O-77, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to three month-water year type combinations (0% to 5.5% of total combinations during the period) with favorable results depending on location (Table O-77). There were zero to eight combinations (0% to 14.5%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were one to 11 combinations (1.8% to 20.0%) with favorable results depending on location. There would be zero to three combinations (0% to 5.5%) with unfavorable results depending on location. These results suggest that there would be positive and negative water temperature-related effects of Alternative 3 on late fall-run Chinook salmon juvenile rearing and emigration.

Late Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

Late Fall-run Chinook Salmon: Summary

Under Alternative 3, differences in seasonal operations in the Sacramento River are expected to have largely minor impacts on late fall-run Chinook salmon fry and juvenile rearing habitat and behavior. There would be minor increases and decreases in WUA for fall-run Chinook salmon fry and juvenile rearing habitat in all water year types relative to the No Action Alternative. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. Late fall-run Chinook salmon fry stranding in the Sacramento River would be higher under Alternative 3 for all water year types, with higher stranding risks under above normal and critically dry water years. Water temperatures in the Sacramento River under Alternative 3 would result in more unfavorable conditions below Keswick Dam for growth, smoltification and predation, but more favorable conditions at Hamilton City. There would be more favorable conditions for juvenile late fall-run Chinook salmon at Keswick Dam and RBDD with regards to pathogen virulence, but there are more unfavorable conditions at Hamilton City.

Adult Upstream Migration and Holding

Fall-run Chinook salmon migrate upstream past RBDD on the Sacramento River from July to December, and late fall-run Chinook salmon migrate upstream past RBDD from October through December (National Marine Fisheries Service 2009a). Adult late fall-run Chinook salmon typically hold in the river for one to three months before spawning, while fall-run Chinook salmon generally spawn shortly after entering freshwater. See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

During the July through December period of fall-run and late fall-run Chinook salmon adult migration and holding, the mean monthly flows under Alternative 3 at Sacramento River below Keswick Dam, below RBDD, Hamilton City, and Wilkins Slough would vary from less than to greater than flows under the No Action Alternative. Flows in July at all locations are mostly lower (4 to 23% reduction in flows) than under the No Action Alternative. An exception to this is in dry and critically dry water years when flows have minor to moderate increases (1% to 15%). Flows in August are typically lower in wet and above normal water years (-4% to -9%), but typically increase in flows in below normal, dry and critically dry water years (6% to 43%). September flows, except in below normal water years, are generally lower (-3% to 14%) under Alternative 3 compared to the No Action Alternative. Generally, flows in October and November are similar, but with the greatest increases in flow occurring in dry and critically dry water years (1% to 19%). Except at Wilkins Slough, average flows in December typically increase at minor to moderate levels (1% to 23%), with average flows for all water years combined increased between 4% and 8%. Wet water years at all locations are mostly lower than flows under the No Action Alternative, however, there is a negligible increase in flows in December at RBDD and Hamilton City.

The average monthly flows across all water year types under Alternative 3 between July and December would be greater than 8,000 cfs below Keswick Dam, 9,250 cfs below RBDD, nearly 8,800 cfs at Hamilton City, and nearly 6,300 cfs at Wilkins Slough (Table O-248, Table O-249, Table O-251, Table O-250). Flows at in the Sacramento River under Alternative 3 would be high enough (> 3,250 cfs) to allow upstream passage.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 227 for Keswick Dam, Table 228 for Red Bluff Diversion Dam, and Table 229 for Hamilton City. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 231 for Keswick Dam, Table 232 for Red Bluff Diversion Dam, and Table 233 for Hamilton City.

Results are summarized in Table O-78. Table O-78, as described in Section O.4.8.1 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 37.9°F to 68°F successful adult migration range analysis, there were zero to two month-water year type combinations (0% to 6.7% of total combinations during the period) with favorable results depending on location (Table O-78). There were no combinations (0%) with unfavorable results at all locations. For the 59.9°F adult pathogen virulence threshold analysis, there would be zero to six combinations (0% to 20.0%) with favorable results and zero to two combinations (0% to 6.7%) with unfavorable results depending on location. These results suggest that there would be positive effects of Alternative 3 on water temperature conditions for fall-run Chinook salmon in the Sacramento River.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 259 for Keswick Dam, Table 260 for Red Bluff Diversion Dam, and Table 261 for Hamilton City. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 262 for Keswick Dam, Table 263 for Red Bluff Diversion Dam, and Table 264 for Hamilton City.

Results are summarized in Table O-79. Table O-79 as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 37.9°F to 68°F successful adult migration range analysis, there were zero to two month-water year type combinations (0% to 5.0% of total combinations during the period) with favorable results depending on location (Table O-79). There were no combinations (0%) with unfavorable results at all locations. For the 59.9°F adult pathogen virulence threshold analysis, there would be zero to five month-water year type combinations (0% to 12.5%) with favorable results and zero to one month-water year type combinations (0% to 2.5%) with unfavorable results depending on location. These results suggest that there would be positive effects of Alternative 3 on water temperature conditions for late fall-run Chinook salmon adult migration and holding in the Sacramento River.

Sacramento River Pulse Flows

Fall-run and late fall-run adult migration is outside the spring pulse flow period.

Summary

Under Alternative 3, fall-run and late fall-run Chinook salmon would be impacted by differences in seasonal operations in the Sacramento River. Flows in the Sacramento River would result in both increases and decreases, affecting adult migration and holding conditions. Conditions for adult fall-run and late fall-run Chinook salmon successful migration are expected to be similar to

the No Action Alternative, but with some more favorable conditions at Hamilton City. Below Keswick Dam and RBDD, fall-run and late fall-run Chinook salmon migrating adults would be exposed to more favorable conditions with respect to pathogen virulence. Migrating adult fall-run and late fall-run Chinook salmon would be experience both adverse and beneficial impacts under Alternative 3 compared to the No Action Alternative.

O.6.14.2 Clear Creek

Spawning and Egg Incubation

Fall-run Chinook salmon typically spawn in Clear Creek from late September through early December, (Earley et al. 2013). Fall-run typically emerge from the gravel in December through March. Timing of peak late-fall spawning in the Sacramento River, January through April, was used as a proxy for Clear Creek. Late fall-run incubation and emergence is estimated to occur from March through June.

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under Alternative 3, mean spawning WUA increases in below normal and critically dry water year types and decreases in all other water year types compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat is a 13.3% increase in critically dry water year types. The largest reduction in estimated spawning habitat is a 0.5% decrease in dry, wet, and above normal water year types.

The mean values of spawning WUA by month are lower in October and higher in November and December under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). December is expected to have the highest spawning WUA values under Alternative 3 throughout the spawning period.

The spawning habitat analysis suggests that Alternative 3 may have a beneficial effect (up to a 13.3% increase) in fall-run Chinook salmon estimated spawning habitat in Clear Creek in critically dry years when compared to the No Action Alternative, and a beneficial effect in below normal years, and a negligible effect in all other water year types.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 237 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 240 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during December through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 243 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-80. Table O-80, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 42.1°F to 55°F spawning initiation range analysis, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-80). For the 59.9°F pathogen virulence threshold, there were zero (0%) combinations with either favorable or unfavorable results below Whiskeytown Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero (0%) combinations with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on fall-run Chinook salmon spawning and egg incubation in Clear Creek.

Fall-run Chinook Salmon: Summary

Overall, there may be a beneficial impact from seasonal operations on fall-run Chinook salmon spawning and egg incubation in Clear Creek based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows may have a beneficial impact on spawning habitat with an increase in critically dry and below normal years, and a negligible impact in all other water year types with similar impacts to water temperature conditions.

Late Fall-run Chinook Salmon: CalSim 3 Flows

For the period of late-fall run Chinook salmon spawning and egg incubation (January through June), seasonal operations may result in both negative and positive impacts below Whiskeytown Dam under Alternative 3 compared to the No Action Alternative. Average annual flow during this period would substantially increase in January (35%), March (33%), April (20%) and May (41), but have a minor decrease in February (6%), and a substantial decrease in June (28%) (Table O-257). In February, flows would decrease in wet, above normal, and below normal water years but increase during dry and critically dry years.

Using peak spawning flows of 300-350 cfs from the fall-run Chinook salmon WUA curves as a proxy for potential late-fall-run Chinook salmon spawning habitat, changes under Alternative 3 suggest that, when averaged across all water year types, flows would increase favorable spawning habitat except in June. However, flows do not exceed the 300 cfs peak spawning flows except in February, which does experience a slight decrease in average flows of 6% compared to the No Action Alternative.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperatures outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 282 for Clear Creek below Whiskeytown. Full results of the analysis assessing the percent of months with water temperatures above the 75.2°F juvenile UILT during April through February are presented in Attachment L.1, *Sacramento River Water*

Temperature Analysis, Table 286 for Clear Creek below Whiskeytown. Full results of the analysis assessing the percent of months with water temperatures above the 59.9°F juvenile pathogen virulence threshold during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 290 for Clear Creek below Whiskeytown.

Results for the three analyses are summarized in Table O-81. Table O-81, described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown (Table O-81). For the 75.2°F UILT for rearing and migrating juveniles, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown. For the 59.9°F juvenile pathogen virulence threshold, there were no month-water year type combinations (0%) with either favorable or unfavorable results below Whiskeytown. These results suggest that there would be water temperature-related negligible effects of Alternative 3 on late fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

Juvenile Rearing and Emigration

The majority of young fall-run Chinook salmon migrate to the ocean during the first few months following emergence, mostly between January through June. Late fall-run Chinook salmon juveniles typically enter the ocean after 7 to 13 months of rearing in freshwater, generally between October and February (Moyle 2002).

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

<u>Fall-run Chinook Salmon: Fry Rearing Habitat Analysis</u>

Under Alternative 3, mean fry rearing WUA decreases in all water year types compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean fry rearing WUA under Alternative 3 in comparison to the No Action Alternative. The greatest reduction in estimated fry rearing habitat is a 2.6% decrease in dry water year types under Alternative 3 in comparison to the No Action Alternative.

The mean values of fry rearing WUA are similar across all months under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*).

The results of the fry rearing habitat analysis suggest that Alternative 3 compared to the No Action Alternative may have a minor adverse effect (less than 3% decrease) in estimated fall-run Chinook salmon fry rearing habitat across all water year types in Clear Creek.

<u>Fall-run Chinook Salmon: Juvenile Rearing Habitat Analyses</u>

Under Alternative 3, mean juvenile rearing WUA decreases in all water year types compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under Alternative 3 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between Alternative 3 and the No Action Alternative is a 6.2% decrease in critically dry water year types.

On average across all water year types, there is a 4.1% reduction in estimated juvenile rearing habitat under Alternative 3.

The mean values of juvenile rearing WUA by month are lower June through September and higher in May under Alternative 3 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). May is expected to have the highest juvenile rearing WUA values under Alternative 3 throughout the juvenile rearing period.

The results of the juvenile rearing habitat analysis suggests that Alternative 3 compared to the No Action Alternative may have a minor adverse effect (up to 6.2% decrease) in fall-run Chinook salmon juvenile rearing habitat across all water year types.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 250 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 254 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 258 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-82. Table O-82, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-82). For the 75.2°F UILT for rearing and migrating juveniles, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F juvenile pathogen virulence threshold, there were no month-water year type combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be water temperature-related negligible effects of Alternative 3 on fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

Fall-run Chinook Salmon: Summary

There may be minor adverse impacts of seasonal operations on fall-run Chinook salmon fry rearing and emigration habitat in Clear Creek based on analyses of simulated flows and water temperature under Alternative 3 in comparison with the No Action Alternative. Under Alternative 3, changes in flows are expected to have a minor decrease (less than 3%) in estimated fall-run Chinook salmon fry rearing habitat across all water year types in Clear Creek. Additionally, the results of the juvenile rearing habitat analysis indicates that Alternative 3 in comparison to the

No Action Alternative may have up to 6.2% decrease in habitat. Potential water temperature-related impacts (growth, smoltification, predation, and pathogen virulence) results suggest that there would be negligible impacts of Alternative 3 on fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

Late Fall-run Chinook Salmon: CalSim 3 Flows

For the period late-fall juvenile rearing and emigration (October through February), there would be both negative and beneficial impacts below Whiskeytown Dam under Alternative 3 compared to the No Action Alternative. Average annual flow released would increase by minor level in November and substantial amounts in December and January (Table O-257). Flows would substantially decrease in October and have a minor decrease in February (Table O-257).

The largest flow decreases in October and February occur in wet, above normal, and below normal water years, though October also shows substantial decreased flows in dry water years. December and January experience substantial increased flows in all water year types, while October, November, and February primarily experience substantial increased flows in critically dry water years. There would generally be a substantial increase in fry and juvenile rearing habitat available for late fall-run Chinook salmon caused by increased flows in Clear Creek in November through January, but a minor to substantial decrease in fry and juvenile rearing habitat in October and February caused by decreased flows.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 282 for Clear Creek below Whiskeytown. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 286 for Clear Creek below Whiskeytown. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 290 for Clear Creek below Whiskeytown.

Results for the three analyses are summarized in Table O-83. Table O-83, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown (Table O-83). For the 75.2°F UILT for rearing and migrating juveniles, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown. For the 59.9°F juvenile pathogen virulence threshold, there were no month-water year type combinations (0%) with either favorable or unfavorable results below Whiskeytown. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on late fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

Late Fall-run Chinook Salmon: Summary

The change in seasonal operations in Clear Creek between Alternative 3 and the No Action Alternative is expected to have both positive and negative impacts on late fall-run Chinook salmon rearing and emigration. Increased flows in November through January would provide substantially beneficial conditions for late fall-run Chinook salmon rearing and emigration, but decreased flows in October and February would result in adverse impacts. Under Alternative 3, there would be negligible water temperature-related impacts on late fall-run Chinook salmon rearing and emigration in Clear Creek compared to the No Action Alternative.

Adult Upstream Migration and Holding

Fall-run Chinook salmon may arrive at Clear Creek before spawning from July through early December. Adult late fall-run Chinook salmon migrate and arrive slightly later and do not need to hold and mature before spawning from November into January.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: CalSim 3 Flows

For the period of fall and late-fall adult migration and holding (July through January), there would be both negative and beneficial impacts below Whiskeytown Dam under Alternative 3 compared to the No Action Alternative. Average flow released would increase November through January and decrease July through October. The exception is during a critically dry water year during October with an increase of 20% (Table O-257). The largest decrease under Alternative 3 compared to the No Action Alternative occur July and August. There would be a substantial reduction in suitable adult migration conditions for adult fall-run Chinook salmon as a result of flows in Clear Creek.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 230 for Clear Creek below Whiskeytown Dam. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 234 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-84. Table O-84, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 37.9°F to 68°F successful adult migration range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-84). For the 59.9°F adult pathogen virulence threshold, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown

Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on fall-run Chinook salmon adult upstream migration and holding in Clear Creek.

Fall-run Chinook Salmon: Summary

Overall, there may be both moderate negative and beneficial impacts of seasonal operations on fall-run Chinook salmon adult upstream migration and holding in Clear Creek based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows may decrease during the months of July through October and increase in November and January. Water temperature results suggest that there would be negligible impacts of Alternative 3 on fall-run Chinook salmon adult upstream migration and pathogen virulence in Clear Creek.

Late Fall-run Chinook Salmon: CalSim 3 Flows

During the periods of late-fall run Chinook salmon adult migration (November through January), flows would be increased by 23% on average among all water year types when compared to the No Action Alternative. The largest increase is in January with a 35% increase in average flows (222 cfs to 299 cfs). There would also be an increase of 31% in November during critically dry years providing an additional beneficial impact to late fall-run Chinook salmon adult migration and holding (Table O-257).

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature above the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 262 for Clear Creek below Whiskeytown Dam. Full results of the percent of months with water temperature outside the 59.9°F adult pathogen virulence threshold analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 266 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-85. Table O-85, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 37.9°F to 68°F successful adult migration range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-85). For the 59.9°F adult pathogen virulence threshold, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on late fall-run Chinook salmon adult upstream migration and holding in Clear Creek.

Late Fall-run Chinook Salmon: Summary

The change in seasonal operations in Clear Creek between Alternative 3 and the No Action Alternative is expected to have moderate to substantial benefits adult fall-run Chinook salmon upstream migration and holding. Under Alternative 3, flows would be increased from November through January so there may be a beneficial impact on late-fall-run Chinook salmon adult migration in Clear Creek. Water temperature results suggest that there would be negligible water temperature-related effects of Alternative 3 on late fall-run Chinook salmon adult upstream migration and holding in Clear Creek.

O.6.14.3 Lower American River

Spawning and Egg Incubation

Spawning occurs from about mid-October through early February, with peak spawning from mid-October through December. Chinook salmon spawning occurs within an 18-mile stretch from Paradise Beach to Nimbus Dam; however, most spawning occurs in the uppermost 3 miles (California Department of Fish and Wildlife 2012a). Chinook salmon egg and alevin incubation occurs in the lower American River from about mid-October through April. There is high variability from year to year; however, most incubation occurs from about mid-October through February.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Spawning Habitat—Flow Analysis

Under Alternative 3, fall-run Chinook salmon mean spawning WUA varies among water year types, with no evident trend (Attachment M.3, *American River Weighted Usable Area Analysis*). The highest means are for above normal and below normal water year types and the lowest is for wet water years. Mean spawning WUA differs little between Alternative 3 and the No Action Alternative for all water year types, ranging from 2.5% lower for above normal water year types to 1.4% higher for dry water years (Attachment M.3, *American River Weighted Usable Area Analysis*). For the individual months of the fall-run spawning season, estimated median spawning WUA under Alternative 3 is similar to than the No Action Alternative October and November, but is moderately higher in December (Attachment M.3, *American River Weighted Usable Area Analysis*). October has a higher median spawning WUA than November of December because flows, on average, are lower in October (Table O-259). The fall-run spawning WUA curve (Attachment M.3, *American River Weighted Usable Area Analysis*) peaks at relatively low flows (below 3,000 cfs).

As noted previously, the lower American River WUA curve peaks at about 2,000 cfs (Attachment M.3, *American River Weighted Usable Area Analysis*) and flows under Alternative 3 are consistently well above this level in the wetter water years. Overall, fall-run spawning WUA is similar under Alternative 3 to that under the No Action Alternative.

Redd Dewatering

The results of the analysis for fall-run Chinook salmon under Alternative 3 indicate that mean redd dewatering potential is greatest in wet water years and lowest in critically dry years (Attachment M.1, *American River Redd Dewatering Analysis*). The higher redd dewatering potential in wetter years reflects a greater frequency of large flow fluctuations in those water year types. Redd dewatering is similar under Alternative 3 and the No Action Alternative for most water year types but is much lower (53.1%) for critically dry water years (Attachment M.1, *American River Redd Dewatering Analysis*). It should be noted, however, that the absolute difference in percent of redds dewatered between Alternative 3 and the No Action Alternative in critically dry years is only 2.3%. For the individual months of fall-run spawning in the lower American River, redd dewatering potential increases from October spawning to that in December, reflecting the somewhat higher flows and likelihood of flow fluctuations over this period (Table O-259).

Overall, fall-run Chinook salmon redd dewatering under Alternative 3 is similar to that under No Action Alternative, except for critically dry water years when redd dewatering is much lower on a relative scale, although only modestly lower on an absolute scale.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 42.1°F to 55°F range for spawning initiation during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 63 for Hazel Avenue and Table 64 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult spawning pathogen virulence threshold during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 65 for Hazel Avenue and Table 66 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence during October through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 67 for Hazel Avenue and Table 68 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F fry pathogen virulence threshold during October through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 69 for Hazel Avenue and Table 70 for Watt Avenue.

Results for the four analyses are summarized in Table O-86. Table O-86, as described in Section O.4.12.3.1 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 42.1°F to 55°F range for spawning initiation, there were six and zero month-water combinations (17.1 and 0%, respectively) with favorable results at both Hazel and Watt Avenue (Table O-86). There was one month-water combination (2.9%) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for spawning adults, there was zero and one month-water combinations (0% and 2.9%, respectively) with favorable results at both Hazel and Watt Avenue, respectively. There were zero and two combinations (0% and 10.0% respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 42.8°F to 56°F range for egg incubation and fry

emergence analysis, there were two and zero month-water type combinations (6.7% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. Similarly, there were two and zero month-water type combinations (6.7% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold analysis, there were zero to one month-water combinations (0% and 3.3% respectively) with favorable results at Hazel Avenue and Watts Avenue, respectively. There were three and one month-water combinations (10.0% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results suggest that there would be positive (2.9% - 3.3% favorable) and negative (2.9% - 11.4% unfavorable) effects of Alternative 3 on fall-run Chinook salmon spawning and egg incubation in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Overall, seasonal operations on fall-run Chinook salmon spawning in the lower American River based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative are similar. Fall-run Chinook salmon spawning habitat area is similar under Alternative 3 to that under the No Action Alternative. For redd dewatering, there are also minimal differences with the exception of a potential slight negative impact in redd dewatering in a critically dry year, but this difference is only 2.4 % larger than the No Action Alternative. Temperature models under Alternative 3, suggest that there could be both beneficial and adverse impacts of Alternative 3 on fall-run Chinook salmon spawning and egg incubation in the lower American River at Hazel Avenue and Watt Avenue. There would be similar to minor changes to water temperatures for favorable and unfavorable conditions for spawning initiation, pathogen virulence, and egg incubation and fry emergence.

Juvenile Rearing and Emigration

Fall-run Chinook salmon fry emergence occurs from January through mid-April, and juvenile rearing extends from January to about mid-July (Williams 2001). Most Chinook salmon out-migrate from the lower American River as fry from December to July; out-migration peaks in February and March (Snider and Titus 2002; Pacific States Marine Fisheries Commission 2014).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

For the period of juvenile rearing and emigration (December through July), CalSim 3 modeling indicates that flow released from Folsom Reservoir storage under Alternative 3 compared to the No Action Alternative would have both beneficial and adverse predicted effects on flows (Table O-259). Under Alternative 3 compared to the No Action Alternative, the largest decreases were in June and July with an average across all water year types of 29% and 13% decreases respectively, resulting in a potentially negative effect. Beneficial increases in flow are predicted to occur in a dry year in March and April with an average across all water types of an increase of 6% in March and 16% in April, a minor to moderate beneficial effect.

For the period of juvenile rearing and emigration (December through July), CalSim 3 modeling indicates that the average flow released at H street under Alternative 3 compared to the No Action Alternative would have both beneficial and negative predicted effects on flows (Table O-260). Under Alternative 3 compared to the No Action Alternative, the largest decreases were in June and July with an average across all water year types of 27% and 12% decreases respectively, resulting in a potentially negative effect. Beneficial increases in flow are predicted to occur in a dry year in March and April with an average across all water types of an increase of 6% in March and 16% in April.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 71 for Hazel Avenue and Table 72 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F upper incipient lethal temperature (UILT) for juveniles during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 73 for Hazel Avenue and Table 74 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 75 for Hazel Avenue and Table 76 for Watt Avenue.

Results for the three analyses are summarized in Table O-87. Table O-87 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability, there were zero and one water-month combinations (0% and 4.0%, respectively) with favorable results at both Hazel and Watt Avenue (Table O-87). There were zero and three combinations (0% and 12.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 75.2°F upper incipient lethal temperature (UILT) for juveniles, there were zero combinations (0%) with favorable results at both Hazel and Watt avenues. There were also zero (0%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration, there were one and two month-water type combinations (4.0% and 8.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water type combinations (8.0% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results suggest that Alternative 3 would have positive (4% - 8% favorable) and negative (8% - 12% unfavorable) water temperature-related effects on fall-run Chinook salmon juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There may be both beneficial and adverse impacts of seasonal operations on fall-run Chinook salmon fry rearing and emigration in the lower American River based on analyses of simulated flows and water temperatures under Alternative 3 in comparison with the No Action Alternative. Under Alternative 3, changes in flows are expected to slightly increase in March and April on average among all water year types and would have decreases in June and July.. There would be negligible water temperature-related impacts of Alternative 3 on fall-run Chinook salmon juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue. There would be similar to minor changes to water temperatures for spawning initiation, pathogen virulence, and egg incubation and fry emergence.

Adult Upstream Migration

Adult fall-run Chinook salmon enter the lower American River from about mid-September through January, with peak migration from approximately mid-October through December (Williams 2001).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

For the period of adult migration (September through January), CalSim 3 modeling indicates that the average flow below Nimbus Dam under Alternative 3 compared to the No Action Alternative would have both beneficial and adverse predicted effects on flows (Table O-259). While the average of all water year types suggests overall negligible potential effects there are notable fluctuations in the critically dry years with a predicted decrease in flows of 29% in November, and an increase in flows of 62% in December, a significantly beneficial effect.

For the period of adult migration (September through January), CalSim 3 modeling indicates that the average flow released at H street under Alternative 3 compared to the No Action Alternative would have be very similar to that below Nimbus Dam with both beneficial and adverse predicted effects on flows (Table O-260). While the average of all water year types suggests overall negligible potential effects there are notable fluctuations in the critically dry years with a predicted decrease in flows of 31% in November, and an increase in flows of 62% in December, a significantly beneficial effect.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 59 for Hazel Avenue and Table 60 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 61 for Hazel Avenue and Table 62 for Watt Avenue.

Results for the two analyses are summarized in Table O-88. Table O-88, as described in Section O.4.12.3.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 37.9°F to 68°F successful migration range for adult fall-run Chinook salmon under, there were six and zero month-water combinations (17.1% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-88). There were one and seven month-water combinations (2.9% and 20.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for adult migration, there were zero and one month-water combinations (0.0% and 2.9%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were four and one month-water combinations (11.4% and 2.9%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results indicate that Alternative 3 would have positive (2.9% - 17.1% favorable) and negative (2.9% - 20% unfavorable) water temperature-related effects to fall-run Chinook salmon adult upstream migration and holding in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There may be both beneficial and adverse impacts of seasonal operations on fall-run Chinook salmon adult migration in the lower American River based on analyses of simulated flows and water temperatures under Alternative 3 in comparison with the No Action Alternative. The largest differences are in the critically dry years with a predicted decrease in flows below Nimbus Dam of 29% in November, a moderately negative impact and an increase in flows of 62% in December, a significantly beneficial impact, similar flows are predicted at H street. Temperature models suggest that similar negligible beneficial and adverse water temperature-related impacts to fall-run Chinook salmon adult upstream migration and holding in the lower American River at Hazel Avenue and Watt Avenue. There would be changes to water temperatures for favorable and unfavorable conditions for successful migration, and increases in unfavorable conditions for pathogen virulence.

O.6.14.4 San Joaquin River

Fall-run Chinook salmon adults migrate upstream through the San Joaquin River past Vernalis between September and November. Juvenile fall-run Chinook salmon migrate downstream past Vernalis primarily January through May. See Section O.1.8.1 for additional information.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Under Alternative 3, flows in the San Joaquin River at Vernalis, as shown by CalSim 3 model simulations, would decrease in October and April in all water year types, and in November in above normal, below normal, and dry water year types compared to the No Action Alternative. Flows decrease in October between 6% to 7%, with average flows at 1,925 cfs. Flows decrease in April between 11% and 20%, with average monthly flows at 1,862 cfs. Flows in January through March, and in May are generally similar to the flows under the No Action Alternative, though with a minor decrease in flows in above normal water years in January (7%), and in critically dry water years in March (10%). Table O-263 provides the monthly average flows in the San Joaquin River at Vernalis.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on fall-run Chinook salmon in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Changes in flows from seasonal operations under Alternative 3 compared to the No Action Alternative may have a minor to moderate impacts on migrating adult and juvenile fall-run Chinook salmon. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.6.14.5 Bay-Delta

Juvenile Rearing and Emigration

Most fall-run Chinook salmon fry rear in freshwater from December through June, with out-migration as smolts occurring primarily from January through June, with presence in the Delta in December through July. In general, fall-run Chinook salmon fry abundance in the Delta increases following high winter flows. Smolts that arrive in the estuary after rearing upstream migrate quickly through the Delta and Suisun and San Pablo Bays. Late fall-run Chinook salmon migrate may be found in the Delta between December and April. See Section O.1.9.1 for additional information.

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

Zone of Influence

Differences in hydrology under Alternative 3 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions. With incremental decreases in OMR under Alternative 3 and the No Action Alternative, proportional overlap at these three locations decreases. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under Alternative 3 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 3, Sacramento River Winter-run Chinook Salmon ESU (Section O.6.8.2, *Zone of Influence*).

Flow into Junctions

For a full description of Flow into Junctions model background, see Section O.4.8.2, *Sacramento River Winter-run Chinook Salmon ESU, Juvenile Rearing and Emigration in the Bay-Delta*. The following section covers discussion of the Central Valley Project and Head of Old River junctions. An expanded set of junction analysis results can be found in Attachment I.10, *Flow into Junctions*.

Under Alternative 3 in the -2,000 and -3,500 OMR bins, predicted proportion of flow entering the Central Valley Project (CVP) is greater than the No Action Alternative, and less than the No Action Alternative in the -5,000 and <-5,500 OMR bins. Changes in predicted proportion of flow entering the CVP when OMR was -2,000, -3,500, and -5,000 were less than ± 0.0406, indicating

a negligible difference from the No Action Alternative. However, when OMR was <-5,500 the change in flow into CVP was -0.0933, indicating that slightly less flow will be routed into CVP under Alternative 3 than when compared to the No Action Alternative.

Under Alternative 3 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the Head of Old River (HOR) is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.0404, indicating a negligible difference between Alternative 3 and the No Action Alternative.

Summary

Alternative 3 relative to the No Action Alternative is expected to influence flow into the Head of Old River and CVP junctions, due to differences in flow. Under Alternative 3, no change to possibly less flow into CVP under OMR -3,500; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 3 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Fall-run / Late Fall-run Chinook Salmon ESU

Fall-run Chinook Salmon: Salvage Density

Predictions from the salvage density model for Fall-run Chinook salmon include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through July Alternative 3 was greater than predicted average monthly loss under the No Action Alternative for dry and critically dry water year types, predicted loss was lower for wet, above normal, and below normal water year types. Predicted average monthly loss at Banks under Alternative 3 had a range from 11% higher for critically dry water year types to 41% lower for wet water year types (Table O-89). Predicted average monthly loss of fall-run Chinook salmon at CVP Jones Pumping Plant for the months of November through August Alternative 3 was less than predicted average monthly loss under the No Action Alternative for all water year types. The range of predicted loss for fall-run Chinook salmon at Jones under Alternative 3 compared to the No Action Alternative was from 81% lower in dry water year types to 59% lower for wet water year types (Table O-90). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Late Fall-run Chinook Salmon: Salvage Density

Predictions from the salvage density model for late fall-run Chinook salmon include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of late fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through April and all water year types Alternative 3 was lower than

predicted average monthly loss under the No Action Alternative. Predicted average monthly loss at Banks under Alternative 3 had a range from 15% lower for below normal water year types to 49% lower for dry water year types (Table O-91). Predicted average monthly loss of late fall-run Chinook salmon at CVP Jones Pumping Plant for the months of October through April and all water year types Alternative 3 was less than predicted average monthly loss under the No Action Alternative. The range of predicted loss for late fall-run Chinook salmon at Jones under Alternative 3 compared to the No Action Alternative was from 25% lower in wet water year types to 58% lower for dry water year types (Table O-92). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Summary

The predicted monthly entrainment of fall-run Chinook salmon at Banks Pumping Plant is expected to be substantially increased under Alternative 3 compared to the No Action Alternative in wet and above normal water years causing substantial impacts to fall-run Chinook salmon, however entrainment would be similar to the No Action Alternative in below normal, dry water years and moderate in critically dry water years. The predicted monthly entrainment of fall-run Chinook salmon at the Jones Pumping Plant would be increased compared to the No Action Alternative in all water year types. Late fall-run Chinook salmon entrainment at both Banks and Jones Pumping Plants would be increased under Alternative 3 compared with the No Action Alternative.

Potential Changes to Through Delta Survival of Fall-run / Late Fall-run Chinook Salmon ESU

Fall-run Chinook Salmon: Delta Passage Model

Under Alternative 3, in all water year types, predicted mean survival of fall-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to 0.022. There is not a substantial difference in predicted proportion of fall-run Chinook salmon surviving to Chipps Island between Alternative 3 and the No Action Alternative.

Late Fall-run Chinook Salmon: Delta Passage Model

Under Alternative 3, in all water year types, predicted mean survival of late-fall-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). However, the change in mean predicted survival to Chipps Island in all water year types less than or equal to 0.008. There is not a substantial difference in predicted proportion of late-fall-run Chinook salmon surviving to Chipps Island between Alternative 3 and the No Action Alternative.

Summary

Under Alternative 3, there would be negligible changes in through Delta survival of both fall-run and late fall-run Chinook salmon through the Delta to Chipps Island compared to the No Action Alternative.

O.6.14.6 Stanislaus River

Spawning and Egg Incubation

Peak spawning for fall-run Chinook salmon in the Stanislaus River typically occurs in November with roughly 7% of spawning occurring prior to November 1, and 2% prior to October 15. The few redds created during late September and early October are typically in the reach just below Goodwin Dam with spawning typically ending in December.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Spawning Habitat—Flow Analyses

The results for Alternative 3 show a consistent trend of reduction in mean spawning WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the shape of the fall-run spawning WUA curves (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which show reduced WUA with increased flow, except at the lowest and highest flows (less than about 200 cfs to 500 cfs and greater than about 1,000 cfs, respectively). CalSim 3 mean monthly flows below Goodwin Dam, which is immediately upstream of the WUA study reach, are 200 cfs or above in all water year types, with flow generally increasing from critically dry to wet water years during months of the October through December fall-run spawning period, except December (Table O-261). The mean spawning WUA estimates for Alternative 3 are similar to or moderately higher than those under the No Action Alternative, ranging from 0.2% higher in dry water to 5.9% higher in above normal water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fall-run Chinook salmon spawning period, median spawning WUA under Alternative 3 is higher than the median under the No Action Alternative in November and December and is about the same in October (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

Overall, the results indicate that mean spawning WUA for fall-run Chinook salmon are about the same for Alternative 3 and the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 55 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult spawning pathogen virulence threshold during October through January are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 56 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 57 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F fry pathogen virulence threshold during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 58 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-93. Table O-93 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 42.1°F to 55°F range for spawning initiation there were zero month-water year type combinations (0.0%) with favorable results and one month-water year type combinations (5.0%) with unfavorable results at Orange Blossom Bridge (Table O-93). For the 59.9°F adult spawning pathogen virulence threshold there were no month-water year type combinations (0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence there was one month-water year type combinations (5.0%) with favorable and zero combinations (0.0%) with unfavorable results at Orange Blossom Bridge. For the 59.9°F fry pathogen virulence threshold there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge. These results suggest that Alternative 3 would have negligible water temperature-related effects on fall-run Chinook salmon spawning and egg incubation.

Summary

There may be both adverse and beneficial impacts of seasonal operations in the Stanislaus River on fall-run Chinook salmon spawning and egg incubation based on analyses of simulated flows under Alternative 3 in comparison with the No Action Alternative. Spawning habitat area would be generally similar under Alternative 3 compared to the No Action Alternative. Modeled water temperature results were variable but suggests only negligible beneficial and adverse water temperature-related impacts on fall-run Chinook salmon spawning and egg incubation. There would be similar conditions affecting spawning initiation, egg incubation and fry emergence, and pathogen virulence.

Juvenile Rearing and Emigration

Fall-run juvenile rearing in the Stanislaus River typically occurs from January through May (Stanislaus River Fish Group 2004). Fry migration generally occurs from January through March, followed by smolt migration from April through May (Bureau of Reclamation 2012).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Rearing Habitat—WUA Flow Analyses

The results for fall-run fry rearing WUA under Alternative 3 show little variation among water year types in mean rearing fry WUA, except for lower means in above normal and wet water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the fall-run fry WUA curves, which show reduced WUA with increased flow, especially in the Orange Blossom Bridge and Riverbank reaches (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which are the longest segments of the study. Mean fry rearing WUAs under Alternative 3 is lower than under the No Action Alternative in all water year types, but the reductions are small, ranging from 0.9% lower for critically dry water years to 2.4% lower for above normal water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fry rearing period, fry rearing WUA is similar under Alternative 3

and the No Action Alternative in February, March and May, and is higher under Alternative 3 in April (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

The results for juvenile rearing WUA under Alternative 3 show no consistent change with water year type (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in juvenile rearing WUA between Alternative 3 and the No Action Alternative are small, ranging from a 1.0% reduction for above normal water years to a 3.4% increase for dry water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the juvenile rearing period, differences in the median WUAs between Alternative 3 and the No Action Alternative are small, except for a much higher medias under Alternative 3 in March and October (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

Overall, the results indicate that fry and juvenile rearing WUA for fall-run Chinook salmon under Alternative 3 is similar to that under the No Action Alternative.

Rearing Habitat—ASH Flow Analyses

The results of the Area of Suitable Habitat (ASH) analysis for fall-run fry and juvenile rearing are quite different from the rearing WUA results described above. The mean ASH estimates vary more strongly with water year type than the rearing WUA estimates for both fry and juvenile fall-run, consistently increasing from critically dry to wet years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the overall relationship between flow and ASH for both life stages as determined from modeling and field studies (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in fry and juvenile ASH between Alternative 3 and the No Action Alternative are highly variable, including large increase in mean ASH under Alternative 3 for both wet and dry water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). The increases for fry are 10.2% for wet years and 17.5% for dry years, while those for juveniles are 10.5% and 33.0% for wet and dry water years, respectively. The other differences for fry range from a reduction of 1.4% for above normal water years to an increase of 8.4% for below normal water years, while the other differences for juveniles range from 0.7% higher for above normal water years to 7.2% higher for below normal water years. For the individual months of the fall-run fry rearing period, median ASH under Alternative 3 relative to the No Action Alternative is higher in February and March and similar in April and May.

Overall, the results indicate that fry and juvenile rearing ASH for fall-run Chinook salmon are higher or similar under Alternative 3 relative to the No Action Alternative, depending on water year type.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 59 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F upper incipient lethal temperature (UILT) for juveniles during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 60 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F

pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 61 for Orange Blossom Bridge.

Results for the three analyses are summarized in Table O-94. Table O-94, as described in Section O.4.14.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 3 for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability there were zero month-water year type combinations (0.0%) with favorable results and three month-water year type combinations (15.0%) with unfavorable results at Orange Blossom Bridge (Table O-94). For the 75.2°F upper incipient lethal temperature (UILT) for juvenile fall-run Chinook salmon there were no month-water year type combinations (0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration there was one month-water year type combination (5.0%) with favorable results and zero combination (0.0%) with unfavorable results at Orange Blossom Bridge.

These results suggest that there would be negative water temperature-related effects of Alternative 3 on fall-run Chinook salmon juvenile rearing and emigration.

Summary

There are expected adverse and beneficial impacts of seasonal operations on fall-run chinook salmon juvenile rearing and emigration based on analyses of simulated flows and water temperature under Alternative 3, in comparison to the No Action Alternative. Under Alternative 3, changes in flows are expected to have similar increases and decreases in rearing habitat in the WUA analysis and minor to moderate increases in rearing habitat area in the ASH analysis. Modeled water temperature results were variable but suggest only negligible beneficial and adverse water temperature-related impacts on fall-run Chinook salmon rearing. There would be changes in unfavorable conditions for growth, smoltification, predation vulnerability and pathogen virulence.

Adult Upstream Migration and Holding

Fall-run Chinook salmon adults generally migrate upstream from late September through December with peak migration from late October through early November in the Stanislaus River.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

For the period of adult upstream migration and holding of fall-run Chinook salmon (September through December), CalSim 3 modeling under Alternative 3 compared to No Action Alternative indicates that there may be negative effects as a result of decreases in flows in all water year types. Overall flows are similar with the exception of December with an average 19% decrease in flows among all water year types. This effect in December does not occur during a critically dry year with no difference predicted during this time.

For the period of adult upstream migration and holding of fall-run Chinook salmon (September-December), CalSim 3 modeling under Alternative 3 compared to No Action Alternative indicates that average flow released at the mouth of the Stanislaus River would be similar to that modeled at Goodwin Dam where overall flows are similar to the No Action Alternative with the exception of December with an average 15% decrease in flows among all water year types (Tables O-261 and O-262).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during July through December are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 51 for Orange Blossom Bridge and Table 52 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration during July through December are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 53 for Orange Blossom Bridge and 54 for above the confluence with the San Joaquin River.

Results for the two analyses are summarized in Table O-95. Table O-95, as described in Section O.4.14.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 3 for the 37.9°F to 68°F successful migration range there were no month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River (Table O-95). There were zero and two month-water year type combinations (0.0% and 6.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence of the San Joaquin River. For the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration there were no month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River. There were three and two month-water year type combinations (10.0% and 6.7%, respectively) with unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River, respectively.

These results suggest that Alternative 3 would have negative water temperature-related effects on fall-run Chinook salmon upstream holding and migration in the Stanislaus River at Orange Blossom Bridge and above the confluence of the San Joaquin River.

Summary

For the period of adult upstream migration and holding of fall-run Chinook salmon (September-December), CalSim 3 modeling under Alternative 3 compared to the No Action Alternative predicts that there may be adverse impacts as a result of a decrease in flows in December with a 19% average decrease among all water year types at Goodwin Dam and 15% reduction at the mouth. Water temperature model results also suggest that Alternative 3 would have adverse water temperature-related impacts on fall-run Chinook salmon upstream migration and holding. There would be changes in unfavorable conditions for successful migration and pathogen virulence.

O.6.15 White Sturgeon

O.6.15.1 Sacramento River

Spawning and Egg Incubation

Spawning occurs in deep water in the middle and lower Sacramento River from near Verona (~RM 80) to just upstream of Colusa (~RM 156) from late February to early June, peaking during March and April, (Section O.1.3.2.6, *White Sturgeon*). Because the incubation time for white sturgeon is so short, the peak impacts analysis period for incubating eggs is also considered to be March and April.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

During the March and April spawning and egg incubation period for white sturgeon, CalSim 3 estimates of mean monthly flows at Wilkins Slough under Alternative 3 range from about 4,400 cfs for April of critically dry water years to about 18,100 cfs for March of wet water years (Table O-250). Because white sturgeon spawn in deep pools, these flow levels are likely to be adequate for spawning and egg incubation, so no adverse effects are expected to result. Alternative 3 relative to the No Action Alternative has differences in flow that are small in both months (up to 2%), but flows are higher (11%) for Alternative 3 in April of critically dry water years and lower (up to 7%) in April of below normal and dry water years (Table O-250).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 61°F upper limit for optimal egg incubation during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 291 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 68°F upper limit for embryo hatching during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 292 for Hamilton City.

Results for the two analyses are summarized in Table O-96. Table O-96, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 61°F upper limit for optimal egg incubation, there was one month-water year type combination (5.0% of total combinations during the period) with favorable results and three combinations (15.0%) with unfavorable results at Hamilton City (Table O-96). For the 68°F upper limit for embryo hatching, there were no combinations (0%) with favorable or unfavorable results at Hamilton City. These results suggest that there would be negative water temperature-related effects of Alternative 3 on white sturgeon spawning and egg incubation in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minimal beneficial impacts on spawning habitats due to differences in flow. Differences in water temperature between the two alternatives are expected to have possible adverse impacts on spawning in the Sacramento River.

Larval and Juvenile Rearing and Emigration

The white sturgeon juvenile stage begins when metamorphosis of the larva is complete, typically at about 45 days post hatch (Heublein et al. 2017a, Deng et.al 2002). Therefore, since white sturgeon spawn from late February to early June, peaking in March and April, the larval period is considered to be March through June. Juvenile white sturgeon are believed to initiate a secondary dispersal (the primary dispersal occurring at the larval stage) in spring by actively swimming downstream during the night (Heublein et al. 2017a). The juvenile emigration period is considered to be April through July. Therefore, the effects analysis period for larvae and juvenile rearing and emigration is considered to be March through July.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

During the white sturgeon larval and juvenile rearing and emigration period, approximately April to July, CalSim 3 estimates of mean monthly flows at Wilkins Slough under Alternative 3 range from about 3,200 cfs for May of critically dry water years to about 14,600 cfs for April of wet water years (Table O-250). CalSim 3 results indicate that flows during April through July would generally decrease (up to 28%) with Alternative 3 compared to the No Action Alternative. However, under Alternative 3 compared to the No Action Alternative, flows would increase in May of wet and above normal years (up to 37%) and increase (up to 15%) in April, June, and July of critically dry years (Table O-250). These flow levels are likely to be adequate for white sturgeon rearing and emigration; therefore, Alternative 3 would likely have a potential adverse effect on larval and juvenile white sturgeon relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66°F limit above which stress is observed in juvenile white sturgeon year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 293 for Hamilton City.

Results for the analysis are summarized in Table O-97. Table O-97, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 66°F stress limit for juvenile white sturgeon, there were four month-water year type combinations (6.7% of total combinations during the period, respectively) with favorable results and two combinations (3.3%) with unfavorable results at Hamilton City (Table O-97). These results suggest that there would be negligible water temperature-related effects of Alternative 3 on white sturgeon larval and juvenile rearing and emigration in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have negligible impacts or possible adverse impacts on rearing and emigration due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on rearing and emigration in the Sacramento River due to differences in water temperature.

Adult Upstream Migration and Holding

Adults ready for spawning likely move into the lower reaches of the Sacramento River during early winter to begin their upstream migration (Section O.1.3.2.6, *White Sturgeon*). Upstream migration appears to be rapid, with minimal holding time (Schaffter 1997, Heublein et al. 2017a). Based on rapid upstream migration, short egg incubation period, and larval presence in the Sacramento River; the adult upstream migration and holding period is considered to be December to February for this effects analysis.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

During the white sturgeon adult upstream migration and holding period, approximately December to February, CalSim 3 estimates of mean monthly flows at Wilkins Slough under Alternative 3 range from about 6,700 cfs for January of critically dry water years to about 20,000 cfs for February of wet water years (Table O-250). CalSim 3 results indicate that flows during December through February would generally remain similar (up to 5%) with Alternative 3 compared to the No Action Alternative, with the exception of increased flows in December of above normal water years (7%) and January of critically dry water years (Table O-250). Alternative 3 would have a similar effect on upmigrating and holding adult white sturgeon relative to the No Action Alternative.

Water Temperature Analysis

Potential water temperature-related effects to adult white sturgeon upstream migration and holding in the Sacramento River were evaluated by assessing the percent of months with water temperature above the 77°F upper limit of suitable water temperature for adult white sturgeon (Israel et al. 2009) at Hamilton City (Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 2).

Full results of the analysis assessing the percent of months with water temperature above the 77°F upper limit of suitable water temperature for adult white sturgeon during November through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 294 for Hamilton City.

Results for the analysis are summarized in Table O-98. Table O-98, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 77°F upper limit of suitable water temperature for adult white sturgeon, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results (Table O-98). These results suggest that there would be negligible water temperature-related effects of Alternative 3 on adult white sturgeon upstream migration and holding in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on migration and holding habitat due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on migration and holding in the Sacramento River due to differences in water temperature.

O.6.15.2 Lower American River

Limited quantitative information is available on the distribution and status of white sturgeon in the lower American River; however, small numbers of adults apparently use the lower American River, as evidenced by sturgeon report cards submitted to the CDFW by anglers in recent years (Section O.1.6.2.1, *Fish Evaluated in the Lower American River*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

Adult white sturgeon have been reported by anglers in the lower American River during all months of the year, peaking in March-April and November-December (California Department of Fish and Wildlife 2023i). During all months, CalSim 3 estimates of mean monthly flows below Nimbus Dam under Alternative 3 range from about 719 cfs for October of critically dry water years to about 12,311 cfs for February of wet water years (Table O-259). For all water year types, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 5%) under Alternative 3 compared to the No Action Alternative, with a few exceptions. Flows under Alternative 3 for all water years would decrease in June and July (up to 27%) and increase in March, April, and August (up to 16%) (Table O-259).

During all months, CalSim 3 estimates of mean monthly flows at H Street under Alternative 3 range from about 603 cfs for October of critically dry water years to about 12,332 cfs for February of wet water years (Table O-260). For all water year types, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 5%) under Alternative 3 compared to the No Action Alternative, with a few exceptions. Flows under Alternative 3 for all water years would decrease in June and July (up to 29%) and increase in March, April, and August (up to 16%) compared to the No Action Alternative (Table O-260).

White sturgeon are not likely to be affected by changes in flow under Alternative 3 compared to the No Action Alternative due to their limited distribution in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 77°F upper limit of suitable water temperatures for adult white sturgeon year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 77 for Hazel Avenue and Table 78 for Watt Avenue.

Results for the analysis are summarized in Table O-99. Table O-99, as described in Section O.4.15.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 77°F upper limit of suitable water temperatures for adult white sturgeon, there were zero month-water combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-99). There were also zero month-water combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue.

These results suggest that Alternative 3 would have negligible water temperature-related effects to non-spawning white sturgeon in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on white sturgeon habitat due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible water temperature-related impacts on white sturgeon habitat in the lower American River due to their limited distribution in this geography.

O.6.15.3 San Joaquin River

Little is known about white sturgeon populations inhabiting the San Joaquin River. White sturgeon spawning in the San Joaquin River was documented for the first time in 2011 and confirmed in 2012. Although the majority of sturgeon likely spawn in the Sacramento River, the results of these surveys confirm that white sturgeon do spawn in the San Joaquin River in both wet- and dry-year conditions and may be an important source of production for the white sturgeon population in the Sacramento–San Joaquin River system (Section O.1.8.2.4, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

Using the Sacramento River as a surrogate, it can be inferred that the spawning period for white sturgeon in the San Joaquin River also occurs in deep water from late February to early June, peaking during March and April, (Section O.1.8.2.4, *White Sturgeon*). Because the incubation time for white sturgeon is so short, the peak impacts analysis period for incubating eggs is also considered to be March and April. Since confirmed spawning events took place in the San Joaquin River, it is reasonable to assume that rearing larvae, emigrating juveniles, and migrating adults are also present in the San Joaquin River, but due to the lack of information on these life stages they are not part of this analysis.

During the evaluated months in the spawning period, CalSim 3 estimates of mean monthly flows at Vernalis under Alternative 3 range from about 1,832 cfs for March of critically dry water years to about 12,558 cfs for March of wet water years (Table O-263). CalSim 3 results indicate that there would be minimal differences in flows during March (up to 4%) except in critically dry years when flows would moderately decrease (10%) under Alternative 3. Flows would also moderately decrease in April of all water year types (up to 20%) under Alternative 3 compared to the No Action Alternative (Table O-263). Due to spawning occurring in deep pools, it is not anticipated that flows under Alternative 3 would have an effect on white sturgeon spawning compared to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on white sturgeon in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 3 relative to the No Action Alternative is expected to have negligible impacts to possible adverse impacts on spawning white sturgeon due to differences in flow. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.6.15.4 Bay-Delta

Juvenile Rearing and Emigration

White sturgeon are believed to be most abundant within the Bay-Delta region. Juveniles can be found throughout the Delta year-round. Additionally, white sturgeon larvae have been observed to be flushed farther downstream in the Delta and Suisun Bay in high outflow years, but otherwise rear higher in the system (Section O.1.9.1.6, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

<u>CalSim 3 Flows</u>

During all months, CalSim 3 estimates of mean monthly flows in the Sacramento River at Rio Vista under Alternative 3 range from about 3,626 cfs for September of critically dry water years to about 105,899 cfs for February of wet water years (Table O-256). For all water year types, CalSim 3 results indicate that differences in flows would generally increase in winter and spring months and decrease in summer and fall months under Alternative 3 compared to the No Action Alternative. Flows under Alternative 3 for wet water years would substantially decrease in June through September (up to 39%) and moderately increase in May and December (up to 23%). Flows in above normal water years would decrease in September and October (up to 19%), substantially decrease in June, July, and August (up to 53%) and increase in January, April, and December (up to 15%), and substantially increase in May (30%). Flows in below normal water years would substantially decrease in June and July (up to 49%), moderately decrease in August (23%), and moderately increase in February, March, April, and December (up to 20%). Flows in dry water years would moderately decrease in June and July (up to 26%) and moderately increase in March, April, August, and December (up to 26%). Flows in critically dry water years would moderately decrease in September (6%) and moderately increase in March, April, June,

July, August, and December (up to 28%) (Table O-256). It is not anticipated that flows under Alternative 3 would have an effect on white sturgeon juveniles compared to the No Action Alternative and may have a positive effect on juveniles during critically dry years.

CalSim 3 estimates of mean monthly total exports of SWP and CVP under Alternative 3 range from 966 cfs for August of critically dry water years to about 7,612 cfs for January of wet water years (Table O-253). For all water year types, CalSim 3 results indicate that differences in exports during January through December would substantially decrease (up to 79%) under Alternative 3 compared to the No Action Alternative with a couple exceptions. Exports would moderately increase in October of dry water years (11%), and August of critically dry water years (24%) (Table O-253). Changes in exports under Alternative 3 may have a positive effect on white sturgeon juveniles compared to the No Action Alternative due to increased Delta outflow.

Delta Outflow vs Sturgeon YCI

Differences in year class strength between Alternative 3 and the No Action Alternative are expected to be minorly beneficial. For additional effects of spring Delta outflow vs white sturgeon YCI under Alternative 3, refer to the analysis in Section O.6.11.3.1, *[Green Sturgeon] Larval and Juvenile Rearing and Emigration* and Attachment J.2, *Sturgeon Year Class Index and Delta Outflow*, for additional details.

Summary

Alternative 3 relative to the No Action Alternative are expected to have potential beneficial impacts on white sturgeon year class strength due to differences in flow.

Potential Changes to Entrainment of White Sturgeon

Salvage Density

Differences in exports under Alternative 3 compared with the No Action Alternative may have effects on white sturgeon entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model.

Predictions from the salvage density model for white sturgeon include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of white sturgeon under Alternative 3 compared to the No Action Alternative at the SWP Banks Pumping Plant and CVP Jones Pumping Plant was lower in nearly all water year types, except dry water years at SWP Banks Pumping Plant when it would be similar; no loss is anticipated in critically dry year types at either facility (Tables O-100 and O-101). The SWP Banks Pumping Plant predicted average monthly loss was up to 47% lower for December through March and May through August (Table O-100). At the CVP Jones Pumping Plant predicted average monthly loss was up to 80% lower for May through November of above normal water year types (Table O-101). Historical loss of white sturgeon at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Summary

Differences in export between Alternative 3 and the No Action Alternative are expected to have negligible impacts on the entrainment of juvenile white sturgeon at both facilities. Modeled results from the quantitative model show possible beneficial impacts, but since white sturgeon are salvaged so rarely, the numbers may not be representative.

Subadult and Adult Residency

White sturgeon are believed to be most abundant within the Bay-Delta region. Non-spawning adults can be found throughout the Delta year-round. When not undergoing spawning or ocean migrations, adults and subadults are usually most abundant in brackish portions of the Bay-Delta (Section O.1.9.1.6, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

Juveniles, subadults and non-spawning adults are in the Bay Delta year-round, refer to the CalSim 3 flow analysis in the juvenile life stage (Section O.6.15.5.1, *Juvenile Rearing and Emigration*) for changes in flow under Alternative 3 compared to the No Action Alternative.

Summary

Alternative 3 relative to the No Action Alternative is expected to have possible beneficial impacts on white sturgeon year class strength due to differences in flow.

O.6.16 Native Minnows

O.6.16.1 Sacramento River

Sacramento Splittail, Hardhead, and Sacramento Hitch

- **Sacramento Splittail:** Historically, Sacramento splittail was widespread in the Sacramento River from Redding to the Delta (Rutter 1908, as cited in Moyle et al. 2004). This distribution has become somewhat reduced in recent years (Sommer et al. 1997, 2007b). During drier years there is evidence that spawning occurs farther upstream (Feyrer et al. 2005). Adult splittail migrate upstream in the lower Sacramento River to above the mouth of the Feather River and into the Sutter and Yolo Bypasses (Sommer et al. 1997; Feyrer et al. 2005; Sommer et al. 2007b). Each year, mainly during the spring spawning season, a small number of individuals have been documented at the Red Bluff Pumping Plant and the entrance to the GCID intake (Moyle et al. 2004).

  Most juvenile Sacramento splittail move from upstream areas downstream into the Delta from April through August (Meng and Moyle 1995; Sommer et al. 2007b). The production and recruitment of YOY Sacramento splittail is largely influenced by extent and duration of inundation of floodplain spawning habitats, with abundance spiking following wet years and declining after dry years (Sommer et al. 1997; Moyle et al. 2004; Feyrer et al. 2006).

- **Hardhead:** Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986). They migrate upstream and into tributary streams as far as 45 miles (72.4 km) to spawning sites. Spawning behavior has not been documented, but it is assumed to be similar to that of the pikeminnow, which deposit their eggs over gravel-bottomed riffles, runs, and at the head of pools (Moyle et al. 1995). Hardhead larvae and juveniles likely inhabit stream margins with abundant cover and move into deeper habitats as they grow larger. Adults occupy the deepest part of pools. Juvenile and adult hardhead are present in the Sacramento River year-round. Thompson et al. (2012) found that adults tend to prefer water temperatures near 67°F (19.4°C), but were frequently observed between 57.2-78.8°F (14°C-26°C), and individuals have been captured at RBDD, where water temperatures are generally much cooler (Tucker et al. 1998).
- **Sacramento Hitch:** Sacramento hitch historically occurred in low-elevation streams throughout the Sacramento and San Joaquin Valleys and in the Delta (Moyle et al. 2015). Sacramento hitch were not known to occur in high abundance in the Sacramento watershed, but they are known to prefer shallow backwater areas and historically were observed in the upper and lower Sacramento River and north Delta (Brown & May, 2006; Robinson & Safran, 2014).

  Moyle et al. (2015) summarized habitat and distribution: Spawning takes place mainly in riffles of streams tributary to lakes, river, and sloughs after flows increase in response to spring rains, but spawning requirements are in need of further documentation. Moyle et al. (2015) indicate that YOY hitch spend the next two months after hatching shoaling in shallow water or staying close to aquatic plants before moving out into more open water at around 50-mm fork length.

Potential Changes to Sacramento Splittail, Hardhead, and Sacramento Hitch from Seasonal Operations

<u>CalSim 3 Flows</u>

The greatest factor in determining native minnow spawning success and recruitment is the amount and duration that crucial floodplain spawning areas are inundated during the period of native minnow migration and spawning. In wet years flows over 22,500 cfs at Tisdale, the first flood control gate, would cause the Tisdale weir to begin spilling into the Sutter Bypass (DWR 2010b). Adult migration generally occurs during the late winter with juvenile outmigration into the Delta occurring in spring/early summer. Exact migration, spawning and outmigration timing are not well understood for native minnows, so flows were examined for the months of December through May.

CalSim 3 modeling indicates that average flow released at Keswick Dam under Alternative 3 would generally be similar to flows under No Action Alternative December through May, the range of average flows for the full simulation period are from 5,942 cfs (April) to 11,919 cfs (February) (Table O-248). Differences in average flows at Keswick Dam under Alternative 3 are from a 5% reduction (April) to a 8% increase (December) (Table O-248). Native minnows need adequate flows to allow access to upstream spawning/rearing habitat, with minimal differences in flows under Alternative 3 the effect on flow to native minnow is likely negligible as compared to the No Action Alternative.

For the full simulation period, the difference in average CalSim 3 flow estimates under Alternative 3 compared to the No Action Alternative at Wilkins Slough are minimal, with a range of 1% decrease in flows for April to a 16% increase in May (Table O-250). Under Alternative 3 CalSim 3 flow estimates at Wilkins Slough would have a negligible effect on native minnow spawning and migration as compared to the No Action Alternative. Slight increases in flows at Wilkins during the month of May could have a positive effect on native minnows allowing for more successful outmigration and higher levels of recruitment in the Delta.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 75°F observed range of suitable water temperatures for Sacramento splittail during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 307 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 84.2°F range of preferred temperatures in lab and field observations for Sacramento hitch non-spawning adults year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Tables 308 for Keswick Dam, 309 for Red Bluff Diversion Dam, and 310 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 64°F optimal water temperature range for hardhead spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Tables 311 for Keswick Dam and 312 for Red Bluff Diversion Dam. Full results of the analysis assessing the percent of months with water temperature outside the 57.2°F to 78.8°F commonly observed range of temperatures for non-spawning adult hardhead year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Tables 314 for Keswick Dam and 315 for Red Bluff Diversion Dam.

Results for the four analyses are summarized in Table O-102. Table O-102, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 45°F to 75°F observed range for suitable Sacramento splittail spawning, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at Hamilton City (Table O-102). For the 77°F to 84.2°F preferred range for non-spawning Sacramento hitch, there were no combinations (0%) with favorable or unfavorable results at any location analyzed. For the 59°F to 64°F optimal hardhead spawning range, there were zero and three combinations (0% and 20.0%, respectively) with favorable results at both locations analyzed. There were 0 and 5 combinations (0% and 33.3%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there were one and four combinations (1.7% and 6.7%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were three and three combinations (5.0% and 5.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be positive and negative water temperature-related effects of Alternative 3 on native minnows in the Sacramento River.

Summary

Seasonal operations impacts on native minnows would likely be negligible or slightly beneficial based on the CalSim 3 and water temperature analysis with a few exceptions. Alternative 3 relative to the No Action Alternative is expected to have a minor beneficial impact due to differences in flow, with slight increases in the month of May for the lower river, possibly allowing for higher levels of outmigration. Adverse and beneficial water temperatures are shown in the temperature analysis for hardhead spawning under Alternative 3. Water temperature related impacts on Sacramento splittail and hitch are likely negligible below Keswick Dam and at RBDD.

O.6.16.2 Clear Creek

Hardhead

According to Moyle et al. 2015, hardhead mainly occupy canyon reaches and deep pools in Clear Creek. Hardhead are one of the non-target species regularly caught in the rotary screw traps in lower Clear Creek (Schraml and Chamberlain 2019a, 2019b, 2020, and 2021). Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986). They migrate upstream and into tributary streams as far as 45 miles (72.4 km) to spawning sites.

Potential Changes to Hardhead from Seasonal Operations

CalSim 3 Flows

During the December through May period for adult migration and spawning, the CalSim 3 modeling results show that throughout the full simulation period, average flows in Clear Creek are higher under Alternative 3 with the exception of a 6% reduction in February. Under Alternative 3 average flows in Clear Creek ranged from 230 cfs (April) to 312 cfs (February) (Table O-257). Even with a 6% reduction in February flows would remain generally high during the period of hardhead spawning and migration so the effect of seasonal operations under Alternative 3 compared to the No Action Alternative would likely be negligible.

Hardhead are present in Clear Creek all months of the year. During the full simulation period and for all months utilizing the CalSim 3 modeling results, average flows under Alternative 3 had a range from 99 cfs (August) to 312 cfs (February) (Table O-257). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from 33% lower (August) to 41% higher (May) (Table O-257). With the decrease in flows in February, flows would still remain relatively high during the winter and spring, but during the fall a substantial reduction in flows would likely have a negative effect on hardhead occupying Clear Creek by limiting suitable habitat, and prey availability.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 64°F optimal water temperature range for hardhead spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 304 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 57.2°F to 78.8°F commonly observed range of

temperatures for hardhead spawning year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 307 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-103. Table O-103, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 59°F to 64°F optimal hardhead spawning range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results (Table O-103). For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on native minnows in Clear Creek.

Summary

There are likely negligible impacts of seasonal operations on migrating and spawning adult Hardhead in Clear Creek based on temperature and simulated flow analysis for Alternative 3 as compared to the No Action Alternative. However, a reduction in flows during the fall would likely have a negative impact on juvenile and non-spawning adults occupying Clear Creek.

O.6.16.3 Lower American River

Hardhead and Sacramento Splittail

- **Hardhead:** The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are fairly common in the lower reaches of the lower American River. Hardhead are fairly common year-round in the lower reaches of the lower American River (Moyle 2002). Although migratory behavior of hardhead in the lower American River individuals is unknown, individuals from other large rivers, such as the Sacramento River, migrate into tributary streams during April and May. Hardhead typically spawn between April and May (Moyle 2002). Although hardhead early life history is largely unknown, young individuals likely remain along stream edges with dense cover and move into deeper water as they grow, which allows migrants to move back downstream in the current (Moyle 2002).

- **Sacramento Splittail:** Splittail likely spawn in the lower reaches of the lower American River (Sommer et al. 2008; Moyle et al. 2004). Because upstream migration is more directed and fish tend to swim farther upstream during wet years (Moyle 2002), more individuals are expected to use the lower American River in wet years. Although juvenile splittail are known to rear in upstream areas for a year or more (Baxter 1999), most move to the Delta after only a few weeks of rearing on floodplain habitat (Bureau of Reclamation 2008). Most juveniles move downstream into the Delta from April to August (Meng and Moyle 1995). The primary factor potentially limiting the lower American River population of Sacramento splittail is availability of inundated floodplains for spawning and rearing habitats (Moyle et al. 2004).

Potential Changes to Hardhead and Sacramento Splittail from Seasonal Operations

CalSim 3 Flows

During the December through May period for adult migration and spawning for flows in the lower American River below Nimbus the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are minimal. Under Alternative 3 average flows in the lower American River below Nimbus ranged from 3,541 cfs (May) to 6,398 cfs (February) (Table O-259). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 1% reduction (May) to a 16% increase (April) (Table O-259). With minimal differences in flows native minnow migration and spawning would likely have a negligible affect under Alternative 3 compared to the No Action Alternative.

During the full simulation period, and all months, CalSim 3 estimates of mean monthly flows below Nimbus Dam under Alternative 3 are from 1,461 cfs (October) to 6,398 cfs (February) (Table O-259). The difference in average flows under Alternative 3 as compared to the No Action Alternative for the full simulation period range from a 27% reduction (June) to a 16% increase (April) (Table O-259). With a slight increase in flows during March/April native minnows would likely benefit albeit slightly in the lower American River. However, a substantial reduction in flows in June may have a negative effect on native minnows. Given these two mechanisms, the effect on native minnows in the lower American River under Alternative 3 would likely be negligible as compared to the No Action Alternative.

During the December through May period for adult migration and spawning for flows in the lower American River at H street the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are minimal, with all but the month of May having an increase in flows. Under Alternative 3 average flows in the lower American River at H street ranged from 3,411 cfs (May) to 6,386 cfs (February) (Table O-260). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 1% reduction (May) to a 16% increase (April) for the full simulation period (Table O-260). With minimal differences in flows native minnow migration and spawning would likely have a negligible affect under Alternative 3 compared to the No Action Alternative. With a slight increase during the spawning period (March/April) native minnows spawning success may have a slight positive effect under Alternative 3.

During all months, and for the full simulation period, CalSim 3 estimates of mean monthly flows at H Street under Alternative 3 range from 1,353 (October) to 6,386 cfs (February) (Table O-260). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 29% reduction (June) to a 16% increase (April) for the full simulation period (Table O-260). With a slight increase in flows during March/April native minnows would likely benefit albeit slightly in the lower American River. However, a substantial reduction in flows in June/July may have a negative effect on native minnows. Given these two mechanisms, the effect on native minnows in the lower American River under Alternative 3 would likely be negligible as compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 75°F water temperature range observed for Sacramento splittail suitable spawning during February through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 87 for Hazel Avenue and Table 88 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the outside the 59°F to 64°F water temperature optimal range for hardhead spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 89 for Hazel Avenue and Table 90 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the outside the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 91 for Hazel Avenue and Table 92 for Watt Avenue.

Results for these three analyses are summarized in Table O-104. Table O-104, as described in Section O.4.16.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 45°F to 75°F temperature range observed for suitable spawning for Sacramento splittail under Alternative 3, there were zero month-water combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-104). There were also zero month-water combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue. For the 59°F to 64°F water temperature optimal range for hardhead spawning under Alternative 3, there were four and zero month-water combinations (26.7% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and five month-water combinations (6.7% and 33.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were three and two month-water combinations (5.0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were one and five month-water combinations (1.7% and 8.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

Overall, these results suggest that there would be positive and negative water temperature-related effects on native minnows in the lower American River.

Summary

There are likely negligible impacts of seasonal operations on native minnow in the lower American River based on the difference in simulated flows and the temperature analysis for Alternative 3 compared to the No Action Alternative. The temperature analysis for the lower American River at Hazel and Watt Avenue results suggest both beneficial and adverse impacts of water temperature on hardhead spawning, depending on the location. Water temperature related impacts on Sacramento splittail are likely negligible in the lower American River at Watt Ave and Hazel Ave. Similarly, the flow analysis in the lower American River shows an increase in flows during the spawning period for native minnows with a decrease during the period of outmigration. Native minnow spawning adults would likely benefit from Alternative 3, but outmigration success would likely be negatively impacted. Overall, given the flow and

temperature analysis the impact of Alternative 3 would likely be negligible for native minnows as compared to the No Action Alternative.

O.6.16.4 Stanislaus River

Hardhead

The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are a frequent catch in the lower Stanislaus River (Bradbury and Hickey 2019). The Stanislaus River compared to other systems in the San Joaquin watershed has higher discharge and albeit slightly cooler water for most of the year. Due to the more stream-like conditions the Stanislaus River is occupied by many native fish, including hardhead. The increased discharge has also limited many non-native fishes, concentrating them in the lower reaches. Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986).

Potential Changes to Hardhead from Seasonal Operations

<u>CalSim 3 Flows</u>

During the December through May period for adult migration and spawning for flows in the Stanislaus River at the confluence with the San Joaquin the CalSim 3 modeling results show that throughout the full simulation period average flows generally increase, with a slight decrease during the months of December and January. Under Alternative 3 average flows in the Stanislaus River at the confluence ranged from 434 cfs (December) to 1,515 cfs (May) (Table O-262). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 15% reduction (December) to a 30% increase (March/April) for the full simulation period and months of December through May (Table O-262). Reduction in flows during the beginning of hardhead spawning migration period (December/January) are relatively small, but could limit migrating minnows to a degree. Increased flows during the remainder of the spawning and migration period (February-May) would likely have a positive effect on hardhead spawning and migration. Overall, hardhead spawning and migration would likely have a positive effect under Alternative 3 as compared to the No Action Alternative.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the Stanislaus River at the confluence of the San Joaquin under Alternative 3 range from 330 cfs (August) to 1,267 cfs (February) (Table O-262). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 15% reduction (December) to a 38% increase (June) for the full simulation period and all months (Table O-262). Hardhead are present in the Stanislaus River all months of the year. With increased flows in the winter/spring spawning success and rearing would likely have a positive effect. However, decreased flows in the fall and early winter may have a negative effect on rearing and migration, but the difference in flows is minor and the effect would likely be minor as well. Overall, the effect of flow on hardhead in the Stanislaus River would likely be negligible or slightly positive for Alternative 3 as compared to the No Action Alternative.

During the December through May period for adult migration and spawning for average flows in the Stanislaus River below Goodwin Dam the CalSim 3 modeling results show that throughout the full simulation period flows will have a substantial increase in late winter/spring but will

have a slight decrease in the fall and early winter under Alternative 3 compared to the No Action Alternative. Under Alternative 3 average flows in the Stanislaus River below Goodwin Dam ranged from 398 cfs (December) to 1,309 cfs (May) (Table O-261). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 19% reduction (December) to a 23% increase (March) (Table O-261). Increased flows for the majority of the hardhead spawning and migration period would likely have a positive effect, but reduced flows in the early part of the migration period may limit migration slightly. Overall, Alternative 3 would likely have a positive effect on hardhead spawning and migration as compared to the No Action Alternative.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the Stanislaus River below Goodwin Dam under Alternative 3 had a range from 271 cfs (July) to 1,309 cfs (May) (Table O-261). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 19% reduction (August) to a 37% increase (June) for the full simulation period, and all months (Table O-261). Hardhead are present in the Stanislaus River for all months of the year. The reduced flows during the beginning of the migration period may limit migration in some water year types, while increased flows in the late winter/spring would likely have a positive effect. Reduced flows in the fall would mostly be for wet water year types, given this, the overall effect would likely be positive for hardhead in the Stanislaus River under Alternative 3 as compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the outside the 59°F to 64°F water temperature optimal range for hardhead spawning during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 868 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the outside the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 69 for Orange Blossom Bridge.

Results for these two analyses are summarized in Table O-105. Table O-105, as described in Section O.4.16.4, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 59°F to 64°F water temperature optimal range for hardhead spawning under Alternative 3, there was one month-water year type combination (6.7%) with favorable and unfavorable results at Orange Blossom Bridge (Table O-105). For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were three month-water year type combinations (5.0%) with favorable results and one month-water year type combinations (1.7%) with unfavorable results at Orange Blossom Bridge.

These results suggest that Alternative 3 would have negligible water temperature-related effects on native minnows in the Stanislaus River at Orange Blossom Bridge.

Summary

Utilizing the CalSim 3 flow analysis, Alternative 3 would have generally higher flows during important periods of the year for hardhead as compared to the No Action Alternative. Higher flows during the native minnow period of spawning, rearing, and outmigration would likely have a strong beneficial impact on native minnow populations in the Stanislaus River. However, based off the temperature analysis for the Stanislaus River the impact of temperature under Alternative 3 would be negligible. Given that the impact of water temperature under Alternative 3 are negligible but flow related impacts are beneficial, overall hardhead would likely have a beneficial impact as compared to the No Action Alternative.

O.6.16.5 San Joaquin River

Sacramento Splittail, Hardhead, and Sacramento Hitch

- **Sacramento Splittail:** Historically, Sacramento splittail were widespread in the San Joaquin River and found upstream to Tulare and Buena Vista lakes, where they were harvested by native peoples (Moyle et al. 2004). Today, Sacramento splittail likely ascend the San Joaquin River to Salt Slough during wet years (Baxter 1999). During dry years, Sacramento splittail are uncommon in the San Joaquin River downstream of the Tuolumne River (Moyle et al. 2004). The population of Sacramento splittail is largely influenced by extent and period of inundation of floodplain spawning habitats, with abundance spiking following wet years and declining after dry years (Moyle et al. 2004).

- **Hardhead:** In the San Joaquin drainage, hardhead are present throughout tributary streams but are largely absent from the valley reaches of the San Joaquin River (Moyle et al. 2015, Moyle and Nichols 1973, Saiki 1984). Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986).

- **Sacramento Hitch:** Sacramento hitch historically occurred in low-elevation streams throughout the Sacramento and San Joaquin Valleys and in the Delta, but are now absent from the San Joaquin River and tributaries between Friant Dam and the Merced River (Moyle et al. 2015). Sacramento hitch are occasionally captured in low numbers in the lower San Joaquin River in the Mossdale trawl monitoring program (Interagency Ecological Program et al. 2022).

  Potential changes to Sacramento splittail, Sacramento hitch, and hardhead from seasonal operations During the December through May period for adult migration and spawning for average flows in the San Joaquin at Vernalis the CalSim 3 modeling results show that throughout the full simulation period flows are lower under Alternative 3 for most months compared to the No Action Alternative. Under Alternative 3 average flows in the San Joaquin at Vernalis ranged from 2,700 cfs (December) to 6,507 cfs (February) (Table O-263). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 16% reduction (April) to a 1% increase (February) for the full simulation period and for months December through May (Table O-263). With flows being lower during the native minnow spawning and migration period, and substantial reductions in the crucial month of April and for all water year types, Alternative 3 would likely have a negative effect as compared to the No Action Alternative.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the San Joaquin at Vernalis under Alternative 3 range from 1,171 cfs (August) to 6,507 cfs (February) (Table O-263). The difference in average flows under Alternative 3 compared to the No Action Alternative had a range from a 20% reduction (July) to a 1% increase (February) for the full simulation period, and all months (Table O-263). Presence of native minnows in the San Joaquin are not well known, but it is likely that many species are present year-round. With reduction in flows occurring most months, and substantial reduction in flow during the fall, the effect of Alternative 3 would likely be negative for native minnows in the San Joaquin as compared to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on native minnows in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Based off the CalSim 3 flow analysis flows under Alternative 3 would be generally lower in the San Joaquin compared to the No Action Alternative. Many native minnows likely use the San Joaquin and its tributaries for spawning and rearing, adequate flow is also necessary for spawning adults to access spawning areas. With a substantial reduction in flow, impacts to native minnow under Alternative 3 compared to the No Action Alternative would be likely be negative for native minnows in the San Joaquin. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.6.16.6 Bay-Delta

Hardhead, Sacramento Hitch, and Sacramento Splittail

- **Hardhead:** The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are present in low abundance in the San Francisco Estuary and Delta. Brown and Michniuk (2007) electrofished parts of the Bay-Delta in the 1980's and 2000's and captured small numbers of hardhead. Retrieval of hardhead at the SWP/CVP south Delta fish salvage facilities remain relatively low (California Department of Water Resources 2020).
- **Sacramento Hitch:** The species is distributed in the Sacramento River Basin, in low numbers in the San Joaquin River Basin, and occasionally captured during monitoring programs in the Delta (Moyle et al. 2015; Interagency Ecological Program et al. 2022). Monitoring data suggests year round presence in the Delta (Interagency Ecological Program et al. 2022).
- **Sacramento Splittail:** Adult Sacramento splittail typically migrate upstream from brackish areas in January and February and spawn in freshwater, particularly on inundated floodplains when they are available, in March and April (Sommer et al. 1997; Moyle et al. 2004; Sommer et al. 2008). A substantial amount of splittail spawning occurs in the Yolo and Sutter Bypasses and the Cosumnes River area of the Delta (Moyle et al. 2004).

Although juvenile Sacramento splittail are known to rear in upstream areas for a year or more (Baxter 1999), most move to the Delta after only a few weeks or months of rearing in floodplain habitats along the rivers (Feyrer et al. 2006). Juveniles move downstream into the Delta from April to August (Meng and Moyle 1995; Feyrer et al. 2005). Sacramento splittail recruitment is largely limited by extent and period of inundation of floodplain spawning habitats, with abundance observed to spike following wet years and dip after dry years (Moyle et al. 2004).

Potential Changes to Sacramento Splittail, Sacramento Hitch, and Hardhead from Seasonal Operations

CalSim 3 Flows

For many species of native minnow, it has been shown that changes in export flows can lead to higher levels of entrainment which can potentially influence population dynamics. Certain species such as Sacramento splittail are known to utilize the Delta for many portions of their life history so flows into the Delta will have a strong effect on these fish by limiting habitat, prey availability and access to spawning areas. Since many native minnows occupy the Delta year-round, flows and exports were examined for all months of the year.

During all months and for the full simulation period, CalSim 3 estimates of average Delta outflow would be higher under Alternative 3 for most months compared to the No Action Alternative. CalSim 3 estimates of average Delta outflow for all months have a range from 6,701 cfs (August) to 62,037 cfs (February) for Alternative 3 and for the full simulation period (Table O-254). Differences in average outflow under Alternative 3 as compared to the No Action Alternative would be from a 4% reduction (June) to a 42% increase (August) for the full simulation period and all months (Table O-254). With overall higher flows for most months, and dry water year types, the effect of Alternative 3 would be positive for native minnows as compared to the No Action Alternative.

CalSim 3 estimates of mean monthly average flow for the total exports of SWP and CVP under Alternative 3 for the full simulation period, and all months, range from 1,285 cfs (May) to 5,826 cfs (February) (Table O-253). The range of average export flow difference under Alternative 3 compared to the No Action Alternative for the full simulation period, and all months, were from a 15% reduction in exports (October) to a 69% decrease in exports (May) (Table O-253). With a few exceptions, exports would be substantially lower under Alternative 3, with less exports, entrainment would be expected to be less, and the effect would be positive for native minnows as compared to the No Action Alternative.

Summary

With overall higher flows for most months, and dry water year types, the impact of Alternative 3 would be beneficial for native minnows as compared to the No Action Alternative. With a few exceptions, exports would be substantially lower under Alternative 3, with less exports, entrainment would be expected to be less, and the impact would be beneficial for native minnows as compared to the No Action Alternative. Overall, changes to seasonal operations under Alternative 3 would likely see a strong beneficial impact for native minnows in the Bay-Delta region ass compared to the No Action Alternative.

Potential Changes to Entrainment of Sacramento Splittail, Sacramento Hitch, and Hardhead

Differences in exports under Alternative 3 compared with the No Action Alternative may have effects on native minnows entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density model.

Sacramento Splittail: Salvage Density

Predictions from the salvage density model for Sacramento splittail include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of Sacramento splittail at SWP Banks Pumping Plant for all months of the year and all water year types Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for all but critically dry water year types, with up to 53% lower for wet water year types and 2% higher for critically dry water year types (Table O-106). Predicted average monthly loss of Sacramento splittail at CVP Jones Pumping Plant for all months of the year and all water year types Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for all water year types. For all water year types Alternative 3 as compared to the No Action Alternative at Jones had a range from up to 87% lower for dry water year types to 56% lower for critically dry water year types, it should also be noted that in critically dry water year types predicted loss only occurred for six months of the year (Table O-107). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Sacramento Hitch: Salvage Density

Predictions from the salvage density model for Sacramento hitch include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of Sacramento hitch at SWP Banks Pumping Plant for all months of the year and all water years Alternative 3 was lower than predicted average monthly loss under the No Action Alternative for wet and below normal water year types, predicted loss was higher for above normal, and dry water year types, and there was no predicted loss for critically dry water year types. Predicted average monthly loss at Banks under Alternative 3 had a range from 65% lower for wet water year types to 39% higher for above normal water years (Table O-110). Predicted average monthly loss of Sacramento hitch at CVP Jones Pumping Plant for the months of March through April and all water year types Alternative 3 was lower than predicted average monthly loss under the No Action Alternative. The range of predicted loss for Sacramento hitch at Jones under Alternative 3 compared to the No Action Alternative was from 85% lower in above normal water year types to 32% lower for below normal water year types, no fish were predicted to be lost in dry and critically dry water year types. It should be noted that loss of Sacramento hitch at both facilities is rare and infrequent, with such low values of predicted loss, the percent differences may not be representative. (Table O-111). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Hardhead: Salvage Density

Predictions from the salvage density model for hardhead include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Whereas at the CVP Jones Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of hardhead of Alternative 3 compared to the No Action Alternative at the SWP Banks Pumping Plant was similar or lower all water year types, except in wet water years when it would be up to 65% lower and below normal and dry water year types when no fish are expected (Tables O108 and O-109). At the SWP Banks Pumping Plant predicted average monthly loss was between 39% and 372% greater in April of above normal water years and September of critically dry water years, respectively (Table O-108). Historical loss of hardhead at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Summary

In general, lower exports are predicted for Alternative 3, with less pumping in both the state and federal facilities entrainment and predicted salvage are lower for most months and water year types. Predicted loss at both facilities under Alternative 3 for native minnows would be generally lower, with some water year types having substantial reductions in salvage for native minnows as compared to the No Action Alternative.

O.6.17 Pacific Lamprey

O.6.17.1 Trinity River

Spawning and Egg Incubation

Pacific lamprey typically spawn from March through June, when daily mean water temperatures range from 50–64°F, with peak spawning occurring typically occurring in April and May and when water temperatures are approximately 57–59°F (Stone 2006, Brumo et al. 2009). Redds are typically constructed in gravel and cobble substrates within pool and run tailouts and low gradient riffles (Stone 2006, Brumo et al. 2009). Eggs are deposited in the redd and hatch after approximately 15 days, depending on water temperatures (Meeuwig et al. 2005, Brumo 2006). Egg-sac larvae spend another 15 days in redds before emergence. Temperatures in excess of 65°F during incubation have been shown to reduce embryo survival (Meeuwig et al. 2005). The effects analysis period for spawning and egg incubation in the Trinity River is March through July.

Potential Changes to Pacific Lamprey from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 to flows under the No Action Alternative during spawning and egg incubation periods for Pacific lamprey. Differences in monthly average flows between Alternative 3 and the No Action Alternative greater than 5% in reduction of flows would occur in March in below normal years and April in wet years (Table O-246). Under Alternative 3 compared to the No Action Alternative, flow decreases would occur during the Pacific lamprey spawning and egg

incubation period. The reduction in flows in wet and below normal years would likely be minor for spawning habitat and egg incubation as flows would remain above 400 cfs.

The flow decreases in March in below normal water years and April in wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17). Modeled monthly average water temperatures under Alternative 3 would remain well below the upper water temperature threshold for Pacific lamprey spawning and egg incubation of 65°F in the reach from Lewiston Dam to the North Fork Trinity River (Assarian et al. 2023). Similarly, the flow increases in December in below normal water years and February in above normal water years would cause only negligible changes in water temperature and there would be no change in the water temperature suitability for Pacific lamprey spawning and egg incubation relative to the No Action Alternative.

Ammocoete Rearing and Emigration

After emergence from redds, eyeless Pacific lamprey larvae, known as ammocoetes, settle out of the water column and burrow into fine silt and sand substrates, often containing organic matter. Ammocoetes rear in these habitats for four to 10 years. Water temperature requirements for the life stage are not well described. Ammocoetes have been observed burrowed in substrates in streams with water temperatures up to 80°F (Claire 2004), and upper temperature tolerances are estimated to be around 83°F (Whitesel and Uh 2022). After Pacific lamprey metamorphose to the macropthalmia stage, individuals migrate to the ocean typically in conjunction with high flow events between fall and spring, but can occur year-round. The effects analysis period for ammocoete rearing is year-round and emigration is primarily fall through spring in the Trinity River.

Potential Changes to Pacific Lamprey from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 to flows under the No Action Alternative during ammocoete rearing and emigration periods for Pacific lamprey. Differences in monthly average flows between Alternative 3 and the No Action Alternative greater than 5% in reduction of flows would occur in April of wet years (Table O-246). Under Alternative 3, monthly average flows would be almost identical to the No Action Alternative from April through November and will correspond to the No Action Alternative flows currently are managed to improve habitat conditions for anadromous fish. Increases in flow greater than 5% are modeled to occur in winter months in wet years, February in above normal years, and December in below normal years. Increases in flow would range from 65 to 135 cfs and would likely provide minor benefits to peak emigration periods of Pacific lamprey. Alternative 3 monthly average flows will have negligible to minor beneficial impacts on ammocoete rearing and emigration of Pacific lamprey when compared to the No Action Alternative even under reduced flows in wet years.

The flow increases in December, January, and February of wet water years, flow decreases in March in below normal water years and April in wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17). Modeled monthly average water temperatures under Alternative 3 would remain well below the upper water temperature threshold for Pacific lamprey ammocoete and emigration of 83°F in the

reach from Lewiston Dam to the North Fork Trinity River (Assarian et al. 2023). Similarly, the flow increases in December in below normal water years and February in above normal water years would cause only negligible changes in water temperature and there would be no change in the temperature suitability for Pacific lamprey ammocoete rearing and emigration relative to the No Action Alternative.

Adult Upstream Migration and Holding

Adult Pacific lamprey typically enter freshwater from winter to early summer, but in the Klamath River adults have been reported to enter year-round (Petersen-Lewis 2009, Parker 2018). In general, adult Pacific lampreys have two life history types: ocean maturing where individuals likely spawn several weeks after entering freshwater, and stream maturing where individuals spend one year in freshwater prior to spawning (Clemens et al. 2013, Parker et al. 2019). In general, adult Pacific lamprey hold in interstitial spaces within large cobble and boulders and also in glides, runs, and riffles (Lampman 2011). Water temperature requirements for holding adult Pacific lampreys have not been fully evaluated, but adults have been observed in temperatures ranging from 60 to 84°F (Starecvich et al. 2014). The effects analysis period for adult upstream migration and holding in the Trinity River is year-round.

Potential Changes to Pacific Lamprey from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam would generally be similar to higher under Alternative 3 to flows under the No Action Alternative during adult upstream migration and holding periods for Pacific lamprey. Differences in monthly average flows between Alternative 3 and the No Action Alternative greater than 5% in reduction of flows would occur in April of wet years (Table O-246). Under Alternative 3, monthly average flows would be almost identical to the No Action Alternative from April through November and will correspond to the No Action Alternatives flows currently are managed to improve habitat conditions for anadromous fish. Increases in flow greater than 5% are modeled to occur in winter months in wet years, February in above normal years, and December in below normal years. Increases in flow would range from 65 to 135 cfs and would likely provide minor benefits to winter and negligible impacts to spring/summer emigration periods of Pacific lamprey.

The flow increases in December, January, and February of wet water years, flow decreases in March in below normal water years and April in wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17). Modeled monthly average water temperatures under Alternative 3 would remain well below the upper water temperature suggested for Pacific lamprey adult upstream migration and holding of 84°F in the reach from Lewiston Dam to the North Fork Trinity River (Assarian et al. 2023). Similarly, the flow increases in December in below normal water years and February in above normal water years would cause only negligible changes in water temperature and there would be no change in the temperature suitability for Pacific lamprey adult upstream migration and holding relative to the No Action Alternative.

O.6.17.2 Sacramento River

Spawning and Egg Incubation

Pacific lamprey construct redds in shallow water (about 0.5 to 3.5 feet or 0.15 to 1 meter) gravel habitats in the upper river and spawning occurs from March through July with peak spawning typically occurring in early April (Gunckel et al. 2009; Schultz et al. 2014; Moyle et al. 2015). The eggs and pro-larvae incubate for about one to 1.5 months. Water flows and water temperature impacts on eggs occur between March–August but are primarily between April–May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam for Alternative 3 are a mix of increases and decreases compared to the No Action Alternative (Table O-248 and Table O-249). Impacts on Pacific lamprey spawning and egg incubation are likely to be mixed as well. Both locations are expected to see large increases in flow during wet and above normal years in May, but also large decreases for many water-year types April through July. While the increases in wet years could have beneficial impacts, much of the spawning period would likely see some adverse impacts from flow decreases. Both locations would see flow increases in below normal and dry years in August, which could have beneficial impacts on egg incubation, but spawning would likely not be impacted, as this is at the very end of the spawning period and impacts would more likely be on eggs previously laid. Flows during the spawning period are expected to remain high enough that redds should not be dewatered, which should prevent serious adverse impacts on spawning. However, large flow decreases for most water-year types during spawning months would likely have minor adverse impacts on spawning and egg incubation.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities for Pacific lamprey during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 295 for Keswick Dam and Table 296 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-112. Table O-112, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were zero and two month-water year type combinations (0% and 8.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-112). There were zero and one combinations (0% and 4.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be negligible water temperature-related

impacts of Alternative 3 on Pacific lamprey spawning and egg incubation in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey spawning and egg incubation in the Sacramento River due to differences in water temperature.

Ammocoete Rearing and Emigration

After Pacific lamprey larvae (ammocoetes) emerge, they drift downstream and burrow into fine sediments to rear. Ammocoetes select habitats that are often off-channel, with low flow velocity and shallow depths; therefore, they are vulnerable to stranding by reductions in water level. After three or more years, the ammocoetes metamorphose to the macropthalmia (juvenile) stage and migrate downstream to the Delta and ocean. Data from rotary screw trapping at sites on the mainstem Sacramento River indicate that emigration of Pacific lamprey peaks from early winter through early summer, but some emigration is observed year-round at both the RBDD and the GCID diversion dam (Hanni et al. 2006).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam are a mix of increases and decreases compared to the No Action Alternative (Table O-248 and Table O-249). Impacts on Pacific lamprey ammocoete rearing and emigration are likely to be mixed as well. Ammocoete rearing will likely see both positive and negative effects, as flows increase and decrease depending on month and water-year type. The largest impacts would likely be during dry and critically dry years, when flows are at their lowest. Smaller increases in some fall and winter months would likely benefit ammocoetes in these years, but some spring and summer decreases could prove adverse. Flows are expected to remain high enough that ammocoete survival should not be threatened in these years, so overall impacts are likely to be minor but a mixture of beneficial and adverse. Juvenile emigration is likely to see similarly minor but mixed impacts. Flows are expected to remain high enough that survival should not be threatened, but fairly large changes in flow compared to the No Action Alternative are likely to have both beneficial and adverse impacts.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific Lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 298 for Keswick Dam and Table 299 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-113. Table O-113, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results at both Keswick Dam and RBDD (Table O-113). These results suggest that there would be negligible water temperature-related impacts of Alternative 3 on Pacific lamprey ammocoete rearing and emigration in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor adverse to minor beneficial impacts on Pacific lamprey ammocoete rearing and emigration due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration in the Sacramento River due to differences in water temperature.

O.6.17.3 Clear Creek

Spawning and Egg Incubation

Pacific lamprey usually spawn in Clear Creek from March through July, depending on water temperatures and local conditions such as seasonal flow regimes. The adults construct redds similar to steelhead redds, and eggs incubate for 11 to 30 days, depending on the water temperature, prior to hatching. Although the extent of spawning is unknown, the species spawns in Clear Creek as evidenced by ammocoetes routinely collected in the screw trap at RM 1.7. Effects from water flows and temperature on eggs are likely felt March-August, and they likely peak in accordance with peak spawning April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in Clear Creek below Whiskeytown Dam under Alternative 3 would see a mix of increases and decreases compared to the No Action Alternative depending on month and water year type (Table O-257). Impacts of these flow changes on Pacific lamprey spawning would likely be mixed, with positive impacts from flow increases during the peak spawning period in March, April and May, but flow decreases during some or all water year types for February and June through August, which could have adverse impacts on the beginning and end, respectively, of the spawning period. Overall the impacts of flow changes from Alternative 3 compared to the No Action Alternative would be mixed.

Water Temperature Analysis

Potential water temperature-related impacts to Pacific lamprey spawning and egg incubation in Clear Creek were evaluated by assessing the percent of months with water temperature outside the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities for Pacific lamprey (Meeuwig et al. 2003, 2005) below Whiskeytown Dam (Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 2).

Full results of the analysis assessing the percent of months with water temperature outside the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities for Pacific lamprey during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 288 for Clear Creek below Whiskeytown Dam.

Results for the analysis are summarized in Table O-114. Table O-114, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were eight month-water year type combinations (33.3% of total combinations during the period) with favorable results and no combinations (0%) with unfavorable results below Whiskeytown Dam (Table O-114). These results suggest that there would be positive water temperature-related impacts of Alternative 3 on Pacific lamprey spawning and egg incubation in Clear Creek.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have beneficial impacts on Pacific lamprey spawning and egg incubation due to differences in water temperature.

Ammocoete Rearing and Emigration

Pacific lamprey rearing takes place over a matter of years. Hatched embryos remain in the gravel for up to one more month as gill slits develop. The ammocoetes then spend three to seven years in soft sediments as filter feeders (USFWS 2019). Once ammocoetes have become juveniles, they begin to migrate towards the ocean in spring and possibly early summer. Impacts from water temperature and flow on larval and juveniles are year-round due to their prolonged rearing in their home waters, with spring and summer flows during migratory periods being important as well.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in Clear Creek below Whiskeytown Dam under Alternative 3 would see a mix of increases and decreases compared to the No Action Alternative (Table O-257). Impacts on Pacific lamprey ammocoete rearing would likely be mixed, as rearing takes place over several years, and positive impacts during months and water years with increased

flows would likely be balanced by negative impacts from those months and water year types with decreased flows. Juvenile emigration for Pacific lamprey would likely see some positive impacts under Alternative 3, as flows generally increase during the peak outmigration period in winter and spring months, with the exception of February, which sees flow decreases in wet, above normal, and below normal years.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific Lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 291 for Clear Creek below Whiskeytown Dam.

Results for the analysis are summarized in Table O-115. Table O-115, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-115). These results suggest that there would be negligible water temperature-related impacts of Alternative 3 on Pacific lamprey ammocoete rearing and emigration in Clear Creek.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey ammocoete rearing, and minor beneficial impacts on Pacific lamprey juvenile emigration due to differences in flow. Alternative 3 relative to the No Action Alternative are expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration due to differences in water temperature.

O.6.17.4 Lower American River

Spawning and Egg Incubation

Hannon and Deason (2008) documented Pacific lamprey spawning in the lower American River from early January to late May, with peak spawning typically occurring in early April. Redds are built in shallow water environments and eggs incubate for several weeks before larvae emerge. Water temperature and flow impacts on eggs are likely January-June, with peak impacts April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the lower American River at H Street and below Nimbus Dam under Alternative 3 would see a mix of increases and decreases compared to the No Action Alternative (Table O-259 and Table O-260). Impacts on spawning for Pacific lamprey would likely be mixed, with most water year types seeing flow increases for January through April,

during the beginning and middle of the spawning period, but with flow decreases for all water year types in June and some types for May. As May is within the peak spawning period, flow decreases in below normal and dry water years could have adverse impacts on Pacific lamprey spawning, and large flow decreases during June could have negative consequences on the end of the spawning period and eggs laid during the latter half of the peak spawning period.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities during March through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 79 for Hazel Avenue and Table 80 for Watt Avenue.

Results for the analysis are summarized in Table O-116. Table O-116, as described in Section O.4.17.4.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities for Pacific lamprey spawning and egg incubation under Alternative 3, there were two and zero month-water combinations (8.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-116). There were one and two month-water combinations (4.0% and 8.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that Alternative 3 would have negligible water temperature-related impacts to Pacific lamprey spawning and egg incubation in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey spawning and egg incubation due to differences in water temperature.

Ammocoete Rearing and Emigration

Pacific lamprey ammocoetes rear in the lower American River for all or part of their 3- to 7-year freshwater residence. Larvae spend a month maturing to ammocoetes before leaving spawning areas to find suitable rearing habitat, usually shallow, off-channel areas with low flow velocity where they will spend the next several years filter-feeding and maturing to juvenile stage. Once juveniles, they will begin migrating towards the ocean. Data from rotary screw trapping in the nearby Feather River suggest that out-migration of Pacific lamprey generally occurs from early winter through early summer (Hanni et al. 2006), although some out-migration likely occurs year-round, as observed at sites on the mainstem Sacramento River (Hanni et al. 2006) and in other river systems (Moyle 2002).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the lower American River at H Street and below Nimbus Dam under Alternative 3 would see a mix of increases and decreases compared to the No Action Alternative (Table O-259 and Table O-260). Impacts on Pacific lamprey ammocoete rearing would be mixed. As rearing takes place over several years, ammocoetes would feel the range of flow increases and decreases and the accompanying beneficial and adverse impacts. Lower flows in months such as June would likely have adverse impacts, while generally increased flows December through April would likely be beneficial. Impacts of flow changes on juvenile emigration would likely be similarly mixed, though more beneficial than adverse. As emigration occurs largely between winter and early summer, the aforementioned generally increased flows December through April would likely have a positive impact on outmigration. Conversely, decreased flows in some water year types for May and June are likely to have negative impacts on juvenile emigration.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 48 for Hazel Avenue and Table 50 for Watt Avenue.

Results for the analysis are summarized in Table O-117. Table O-117, as described in Section O.4.17.4.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific lamprey ammocoete rearing and emigration under Alternative 3, there were zero month-water combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-117). There were zero and four month-water combinations (0.0% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 3, there would be negligible water temperature-related impacts to Pacific lamprey ammocoete rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey ammocoete rearing, and minor adverse to minor beneficial impacts on Pacific lamprey juvenile emigration due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration due to differences in water temperature.

O.6.17.5 Stanislaus River

Spawning and Egg Incubation

Hannon and Deason (2008) have documented Pacific lampreys spawning in the lower American River from early January to late May, with peak spawning typically in early April. Spawning time is presumably similar in the Stanislaus River. Eggs are laid in redds constructed in shallow water, and incubation takes several weeks. Impacts from water flows and temperature on eggs are present February-June, likely with a peak April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Stanislaus River at the mouth and below Goodwin Dam under Alternative 3 will see a mix of increases and decreases depending on month and water year type (Table O-261 and Table O-262). Alternative 3 would possibly have a beneficial impact on spawning for Pacific lamprey in the Stanislaus River, as flows at both the mouth of the river and below Goodwin Dam would be increased relative to the No Action Alternative during the peak spawning period of April and May for most water year types. Flows are also increased for most of the non-peak months of the larger spawning period, February through June, with the exception of critically dry years, which would see some flow decreases. Overall, Pacific lamprey spawning should mostly benefit from flow changes due to Alternative 3.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities during April through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 62 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-118. Table O-118, as described in Section O.4.17.5, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 with TUCP without VA for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities of Pacific lamprey, there were no month-water year type combinations (0.0%) with favorable or unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River (Table O-118).

These results suggest that Alternative 3 would have negligible water temperature related impacts on Pacific lamprey spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

Alternative 3 relative to the No Action Alternative is expected to have moderate beneficial to minor adverse impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey spawning and egg incubation due to differences in water temperature.

Ammocoete Rearing and Emigration

Pacific lamprey ammocoetes are expected to rear in the Stanislaus River for all or part of their three and seven year freshwater residence. Larvae usually spend a month in their spawning areas before becoming ammocoetes and moving to rearing habitat in shallow, off-channel areas. After several years, they become juveniles and migrate out to the ocean. Data from rotary screw trapping in the nearby Mokelumne and Tuolumne rivers suggest that out-migration of Pacific lamprey generally occurs from early winter through early summer (Hanni et al. 2006). Catches of juvenile Pacific lampreys in trawl surveys of the mainstem San Joaquin River, near the mouth of the Stanislaus River at Mossdale, occurred during winter and spring. Some out-migration likely occurs year-round, as observed at sites on the mainstem Sacramento River (Hanni et al. 2006).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Stanislaus River at the mouth and below Goodwin Dam under Alternative 3 will see a mix of increases and decreases relative to the No Action Alternative depending on month and water year type (Table O-261 and Table O-262). Impacts on Pacific lamprey ammocoete rearing would likely be mixed. As rearing takes place over several years, ammocoetes would experience the flow increases and decreases from Alternative 3 (depending on month and water year type) and their accompanying impacts. Impacts on juvenile emigration would also likely be mixed, as flow decreases in most water year types between November and January would likely have an adverse impact on the beginning of the outmigration period, while flows mostly increase February through June, which would likely benefit emigrating Pacific lamprey juveniles.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 63 for Orange Blossom Bridge and Table 64 for the Stanislaus River above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-119. Table O-119, as described in Section O.4.17.5, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific lamprey, there were no month-water year type combinations (0.0%) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-119). There were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 3 would have negligible water temperature related impacts on Pacific lamprey ammocoete rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Pacific lamprey ammocoete rearing and emigration due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration due to differences in water temperature.

O.6.17.6 San Joaquin River

Ammocoete Rearing and Emigration

Once Pacific lamprey larvae emerge, they spend roughly a month in spawning areas before becoming ammocoetes and moving to rearing habitat in shallow, off-channel waters with low flow velocity, where they will spend the following several years (roughly 3-7) maturing to the juvenile stage. Once juveniles, they begin a migration towards the ocean. Midwater trawl surveys in the San Joaquin River suggest that peak ammocoete out-migration occurs in January and February (Hanni et al. 2006). Ammocoetes are vulnerable to habitat loss due to the nature of their rearing habitat.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 models predict that flows in the San Joaquin River at Vernalis under Alternative 3 would largely be decreased across months and water year types compared to the No Action Alternative (Table O-263). Pacific lamprey ammocoete rearing would likely be adversely impacted by these decreased flows. As ammocoete rearing takes place over several years, ammocoetes would experience flow decreases and the accompanying adverse impacts across months and likely water year types. Juvenile outmigration would similarly see some likely adverse impacts, as flows during winter and spring months, when emigration is highest, are decreased for almost every water year type compared to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on Pacific lamprey in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor adverse impacts on Pacific lamprey ammocoete rearing and emigration due to differences in flow. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.6.17.7 Bay-Delta

Some Pacific lamprey ammocoetes likely spend part of their extended (3 to 7 years) freshwater residence rearing in the Delta, particularly in the upstream, freshwater portions (California Department of Water Resources et al. 2013). Ammocoetes are present year-round in all of the regions (California Department of Water Resources et al. 2013). Data from the Fall Midwater Trawl Survey in the lower Sacramento and San Joaquin rivers and Suisun Bay suggest that peak out-migration of Pacific lamprey through the Delta coincides with high-flow events from fall through spring (Hanni et al. 2006). Water temperature and flows affect resident ammocoetes year

round and migrating juveniles fall-spring. Duration of estuarine adult migration and holding in the San Francisco Estuary is poorly understood, but some evidence suggests they may migrate as early as the fall and throughout the spawning season until late June (Moyle et al. 2015).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that Sacramento River flow in Rio Vista under Alternative 3 would see a mix of increases and decreases compared to the No Action Alternative (Table O-256). For impacts in the southern Delta, see the San Joaquin Rive section above, which discusses flow at Vernalis. Flows at Rio Vista under Alternative 3 are expected to increase compared to the No Action Alternative from December through May, while generally decreasing from June through September. Flows are likely adequate ammocoete rearing since they burrow and rear in sandy substrates and do not require high flows. Impacts on juvenile emigration and adult migration would likely be mixed, as flows increase in winter through early summer near Rio Vista in critically dry water year types but decrease in all other water year types June through August.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor adverse impacts and minor beneficial impacts on Pacific lamprey juvenile emigration due to differences in flow, depending on the month and water year type. Alternative 3 relative to the No Action Alternative is expected to have minor adverse impacts and minor beneficial impacts on adult migration due to differences in flow, depending on month and water year type. Impacts on ammocoete rearing are expected to be negligible.

Potential Changes to Entrainment of Pacific Lamprey

Differences in exports under Alternative 3 compared with the No Action Alternative may have impacts on Pacific lamprey entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for Pacific lamprey include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of Pacific lamprey of Alternative 3 compared to the No Action Alternative at the CVP Jones Pumping Plant were lower all water year types (Tables O-120 and O-121). At the CVP Jones Pumping Plant predicted average monthly loss was up to 75 % lower for December through September of critically dry water year types (Table O-121). It should be noted that loss of Pacific lamprey is infrequent with such low values of predicted loss, the percentage differences may not imply significance at a population level.

Summary

Differences in exports between Alternative 3 and the No Action Alternative are expected to have substantially beneficial impacts on the entrainment of Pacific lamprey at CVP Jones Pumping Plant, but the species is infrequent at the facility. No impacts at the SWP Banks Pumping Plant are expected.

O.6.18 Western River Lamprey

O.6.18.1 Sacramento River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April-May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam for Alternative 3 are a mix of increases and decreases compared to the No Action Alternative (Table O-248 and Table O-249). Impacts on Western river lamprey spawning and egg incubation are likely to be mixed as well. Both locations are expected to see large increases in flow during wet and above normal years in May, but also large decreases for many water-year types April through July. While the increases in wet years could have beneficial impacts, much of the spawning period would likely see some adverse impacts from flow decreases. Both locations would see flow increases in below normal and dry years in August, which could have beneficial impacts on egg incubation, but spawning would likely not be affected, as this is at the very end of the spawning period and impacts would more likely be on eggs previously laid. Flows during the spawning period are expected to remain high enough that redds should not be dewatered, which should prevent serious adverse impacts on spawning. However, large flow decreases for most water-year types during spawning months would possibly have minor adverse impacts on Western river lamprey spawning and egg incubation.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Western river lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 304 for Keswick Dam and Table 305 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-122. Table O-122, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were five and zero month-water year type combinations (16.7% and 3.3% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-122). There were zero and one combination (0% and 3.3%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be positive water temperature-related impacts of Alternative 3 on Western river lamprey spawning and egg incubation in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts for Western river lamprey spawning and egg incubation due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have beneficial impacts on Western river lamprey spawning and egg incubation due to differences in water temperature.

Ammocoete Rearing and Emigration

Western river lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam are a mix of increases and decreases compared to the No Action Alternative (Table O-248 and Table O-249). Impacts on Western river lamprey ammocoete rearing and emigration are likely to be mixed as well. Ammocoete rearing will likely see both positive and negative impacts, as flows increase and decrease depending on month and water-year type. The largest impacts would likely be during dry and critically dry years, when flows are at their lowest. Smaller increases in some fall and winter months would likely benefit ammocoetes in these years, but some spring and summer decreases could prove adverse. Flows are expected to remain high enough that ammocoete survival should not be threatened in these years, so overall impacts are likely to be minor but a mixture of beneficial and adverse. Juvenile emigration is likely to see similarly minor but mixed impacts. Flows are expected to remain high enough that survival should not be threatened, but fairly large changes in flow compared to the No Action Alternative are likely to have both beneficial and adverse impacts.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Western river lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 304 for Keswick Dam and Table 305 for Red Bluff Diversion Dam.

Results for the three analyses are summarized in Table O-123. Table O-123, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results at both Keswick Dam and RBDD (Table O-123). These results suggest that there would be negligible water temperature-related impacts of Alternative 3 on Western river lamprey ammocoete rearing and emigration in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor adverse to minor beneficial impacts on Western river lamprey ammocoete rearing and emigration due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Western river lamprey ammocoete rearing and emigration due to differences in water temperature.

O.6.18.2 Lower American River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April-May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the lower American River at H Street and below Nimbus Dam for Alternative 3 see some increases in winter and spring months but also see some decreases in summer months compared to the No Action Alternative (Table O-259 and Table O-260). Impacts on Western river lamprey spawning are likely to be mixed, with flow increases in March and April likely being beneficial to the start of the spawning period, while large flow decreases in June and July having adverse impacts. Decreases in June could also affect some eggs laid in May during the peak spawning period. Overall impacts are likely to be mixed, with beneficial and adverse impacts in the spawning period largely dependent on month and water year type.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in Western river lamprey during February through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 83 for Hazel Avenue and Table 84 for Watt Avenue.

Results for the analysis are summarized in Table O-124. Table O-124, as described in Section O.4.18.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in Western river lamprey spawning and egg incubation under Alternative 3, there were two and one month-water combinations (6.7% and 3.3%, respectively) with favorable results at both Hazel Avenue and Watt Avenue (Table O-124). There were one and three month-water combinations (3.3% and 10.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that Alternative 3 would have negative and positive water temperature-related impacts to Western river lamprey spawning and egg incubation in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to minor adverse impacts on Western river lamprey spawning and egg incubation due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have adverse and beneficial impacts on Western River lamprey spawning and egg incubation due to differences in water temperature.

Ammocoete Rearing and Emigration

Western River lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the lower American River at H Street and below Nimbus Dam for Alternative 3 see some increases in winter and spring months but also see some decreases in summer months compared to the No Action Alternative (Table O-259 and Table O-260). Impacts on Western river lamprey ammocoete rearing are likely to be mixed. Flow increases in spring months would likely be beneficial to ammocoetes, but flow decreases in

summer and some fall water year types would likely have an adverse impact. The greatest impact might be in November of critically dry years, when flows are expected to decrease compared to the No Action Alternative and reach some of the lowest levels of the year (826 cfs at the lower American River at H Street). This could have an adverse impact on ammocoetes. Impacts on juvenile emigration would likely be mixed as well. The same decrease in critically dry years in November could adversely affect emigration, while flow increases in March and April could prove beneficial. Overall impacts on emigration then are likely to be mixed.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities in Western river lamprey year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 85 for Hazel Avenue and Table 86 for Watt Avenue.

Results for the analysis are summarized in Table O-125. Table O-125, as described in Section O.4.18.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 72°F upper limit for high survival and low occurrence of developmental abnormalities in Western river lamprey ammocoete rearing and emigration under Alternative 3, there were zero month-water combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-125). There were zero month-water combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

These results suggest that under Alternative 3, there would be negligible water temperature-related impacts to Western river lamprey ammocoete rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial to moderate adverse impacts on Western river lamprey ammocoete rearing and emigration due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Western river lamprey ammocoete rearing and emigration due to differences in water temperature.

O.6.18.3 Stanislaus River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April-May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates of monthly flows in the Stanislaus River at the mouth and below Goodwin Dam for Alternative 3 compared to the No Action Alternative are generally increased from February through June but see decreases in some water year types August through January (Table O-261 and Table O-262). Impacts on Western river lamprey spawning are likely beneficial. Increased flows for most water year types during the first half, and the peak of the spawning period would likely have beneficial impacts. The exception to this would be in critically dry years, which see little to no change during February through June. The end months of the spawning period, July and August, have some small changes, but the greatest overall impacts would be from the increases in flow in most water year types during the spawning period.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in Western river lamprey during February through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 65 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-126. Table O-126, as described in Section O.4.18.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities of Western river lamprey, there were zero month-water year type combinations (0.0%) with favorable results and three combinations (10.0%) with unfavorable results at Orange Blossom Bridge (Table O-126).

These results suggest that Alternative 3 would have negative water temperature related impacts on Western river lamprey spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

Alternative 3 relative to the No Action Alternative is expected to have beneficial impacts on Western river lamprey spawning and egg incubation due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have adverse impacts on Western River lamprey spawning and egg incubation due to differences in water temperature.

Ammocoete Rearing and Emigration

Western River lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates of monthly flows in the Stanislaus River at the mouth and below Goodwin Dam for Alternative 3 compared to the No Action Alternative are generally increased from February through June, but see decreases in some water year types August through January (Table O-261 and Table O-262). Impacts on Western river lamprey ammocoete rearing are likely to be mixed. Flow increases during spring and early summer months could be beneficial to ammocoetes, who are present for several years, but decreases in flows during fall and winter could provide adverse impacts. The greatest concern might be July through September in critically dry years, which see small decreases in flows; however, flows under the No Action Alternative are already expected to be very low, so decreases could threaten serious adverse impacts, and increase the risk of ammocoete mortality. Impacts of flow changes on juvenile emigration are likely to be mixed. Decreases in the early winter months could have adverse impacts, especially in drier years when flows are expected to be among the lowest year-round. Conversely, flows increase from February through June, which would be beneficial to emigration.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities in Western river lamprey year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 66 for Orange Blossom Bridge and Table 67 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-127. Table O-127, as described in Section O.4.18.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Western river lamprey, there were no month-water year type combinations (0.0%) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-127). There were zero to one month-water year type combinations (0.0% and 1.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 3 would have negligible water temperature related impact on Western river lamprey ammocoete rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have beneficial and adverse impacts on Western River lamprey ammocoete rearing and emigration due to differences in flow. Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on Western River lamprey ammocoete rearing and emigration due to differences in water temperature.

O.6.18.4 San Joaquin River

Ammocoete Rearing and Emigration

Western River lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 estimates for monthly flows in the San Joaquin River at Vernalis for Alternative 3 are largely decreased compared to the No Action Alternative (Table O-263). The impact on Western river lamprey ammocoete rearing would likely be adverse. Decreases in flows during summer months in critically dry years could have an adverse impact on ammocoete rearing, even possibly leading to their exposure and the drying of the sediments that ammocoetes remain buried in during maturation. Other impacts would depend on water year type, but would likely be mostly adverse, though only dry and critically dry summer months would have the risk of mortality events for ammocoetes. Impacts of changes in flows from Alternative 3 on juvenile emigration would likely be minimal. Flow decreases during the winter and spring months are expected to be small, and outmigration would likely not be affected. April could see some adverse impacts on emigration as flows decrease in all water year types, but juveniles should still be able to emigrate.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on Western river lamprey in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

<u>Summary</u>

Alternative 3 relative to the No Action Alternative is expected to have adverse impacts on Western River lamprey ammocoete rearing and emigration due to differences in flow. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.6.18.5 Bay-Delta

The Sacramento and San Joaquin River Basins are at the southern edge of the range for Western river lamprey (Moyle et al. 2009). While their population abundance is poorly understood, they are frequently caught in the Delta Juvenile Fish Monitoring Program in the winter months through trawls at Sherwood Harbor, Mossdale, and Chipps Island (Interagency Ecological Program et al. 2022). Ammocoetes spend an unknown amount of time as ammocoetes (likely 3-5 years) in silt-sand backwater eddies and have been documented during dredging studies in the Delta (Lamprey Technical Workgroup 2021; Moyle et al. 2015). Adults typically start their migration back into their natal habitats in the fall.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Bay-Delta under Alternative 3 would see a mix of increases and decreases compared to the No Action Alternative (Table O-256). For impacts in the southern Delta, see the San Joaquin River section above, which discusses flow at Vernalis. Flows at Rio Vista under Alternative 3 are expected to increase compared to the No Action Alternative from December through May, while generally decreasing from June through September. Impacts on Western river lamprey ammocoete rearing are expected to be negligible, as flows are adequate for rearing in the sandy substrate. Juveniles emigrating through the Delta would experience decreased flows in summer months closer to Rio Vista in most water year types and increased flows in critically dry water year types under Alternative 3. Adults migrating through the Sacramento River at Rio Vista would experience decreased flows in September of critically dry water year types under Alternative 3.

Summary

Alternative 3 relative to the No Action Alternative is expected to have minor beneficial and adverse impacts on Western River lamprey juvenile emigration due to differences in flow, depending on the water year type. Alternative 3 relative to the No Action Alternative is expected to have adverse impacts on adult migration in September of critically dry water year types due to differences in flow.

Potential Changes to Entrainment of Western River Lamprey

Salvage Density

Predictions from the salvage density model for Western river lamprey include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of Western river lamprey of Alternative 3 compared to the No Action Alternative at the CVP Jones Pumping Plant were similar or lower for all water year types, except dry water year types when no fish are expected (Tables O-128 and O-129). At the CVP Jones Pumping Plant predicted average monthly loss was up to 61 % lower for February through March of critically dry water year types (Table O-129). Historical loss of Western River is infrequent; this is a driver of low values of predicted loss.

Summary

Differences in exports between Alternative 3 and the No Action Alternative are expected to have generally beneficial impacts on the entrainment of Western river lamprey at CVP Jones Pumping Plant, but the species is infrequent at the facility. No impacts at the SWP Banks Pumping Plant are expected.

O.6.19 Striped Bass

O.6.19.1 Sacramento River

Spawning and Egg Incubation

It is believed that striped bass do not spawn or rear in the Sacramento River upstream of RBDD (Tehama-Colusa Canal Authority 2008). Most spawning in the Sacramento River occurs in the lower river between Colusa and the confluence of the Sacramento and Feather Rivers (Moyle 2002). About one-half to two-thirds of adults spawn in the Sacramento River and the remainder spawn in the Delta (Leet et al. 2001). After spawning, most adult striped bass move downstream into brackish and salt water for summer and fall (Moyle 2002).

Eggs are free-floating and negatively buoyant and hatch as they drift downstream, with larvae occurring in shallow and open waters of the lower reaches of the Sacramento and San Joaquin rivers, the Delta, Suisun Bay, Montezuma Slough, and Carquinez Strait. According to Hassler (1988), the distribution of larvae in the estuary depends on river flow. In low-flow years, all eggs and larvae are found in the Delta, while in high-flow years, the majority of eggs and larvae are transported downstream into Suisun Bay.

Potential Changes to Striped Bass from Seasonal Operations

<u>CalSim 3 Flows</u>

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows at Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤ 5%) increase or decrease is estimated most months except May (higher [≥6%]), June (lower [≥6%]). This suggests minor adverse impacts on striped bass, although habitat will generally remain similar under Alternative 3 compared to the No Action Alternative (Table O-249 through Table O-251).

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 68°F optimal water temperature range for spawning, embryo incubation and initial rearing for striped bass during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 317 for Butte City.

Results for the analysis are summarized in Table O-130. Table O-130, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 59°F to 68°F optimal water temperature range, there was one month-water year type combination (6.7% of total combinations during the period) with favorable results at Butte City (Table O-130). There were three combinations (20.0%) with unfavorable results at Butte City. These results suggest that there would be negative and negligible positive water temperature-related effects of Alternative 3 on striped bass spawning and egg incubation in the Sacramento River.

Summary

Overall, under Alternative 3 compared to the No Action Alternative for CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will generally remain largely similar to the No Action Alternative, with some slight adverse impacts on striped bass habitat. The optimal water temperature range modeling estimates indicate 6.7% month-water year type combinations with favorable and 20% combinations with adverse results at Butte City. Overall, these results suggest that there would be minor adverse flow impacts for spawning habitat and water temperature-related impacts on striped bass spawning and egg incubation in the Sacramento River under Alternative 3.

Laval and Juvenile Rearing and Emigration

During this early period the embryos and larvae in the Sacramento River are carried into the Delta and Suisun Bay (Moyle 2002). YOY striped bass distribute themselves in accordance with the estuarine salinity gradient (Kimmerer 2002a; Feyrer et al. 2007), indicating that salinity is a major factor affecting their habitat use and geographic distributions. Kimmerer (2002a) found that distributions of fish species, including striped bass, substantially overlapped with the low-salinity zone. Older individuals are increasingly flexible about their distribution relative to salinity (Moyle 2002). Statistically significant correlations between indices of age-0 abundance or survival in the San Francisco Estuary and Delta have been found with Delta outflow (which can be approximated by X2, the distance in km from the Golden Gate Bridge at which bottom salinity is 2 psu) (e.g., Kimmerer et al. 2009; Mac Nally et al. 2010), with evidence for greater extent of habitat as the mechanism (Kimmerer et al. 2009). However, subsequent density-dependent survival after the first summer dampens the effects of flow on subsequent recruitment (Kimmerer et al. 2000).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows at Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (<5%) increase and/or decrease is estimated most months except May (higher), June (lower), July (lower), August (higher, Wilkins Slough and Hamilton City), and September (lower, Wilkins Slough); this suggests negligible impacts on striped bass, as habitat will generally remain largely similar to the No Action Alternative (Table O-249 through Table O-251).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F range of optimal temperatures for larvae, fry, and juvenile rearing and emigration year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 318 for Butte City.

Results for the analysis are summarized in Table O-131. Table O-131, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 61°F to 71°F optimal water temperature range for larvae, fry, and juvenile rearing and emigration, there were four month-water year type combinations (6.7% of total combinations during the period) with favorable results at Butte City (Table O-131). There were three month-water year type combinations (5.0% of total combinations during the period) with favorable results at Butte City. These results suggest that there would be positive and negative water temperature-related impacts from Alternative 3 on striped bass larvae, fry, and juvenile rearing and emigration in the Sacramento River.

Summary

Overall, under Alternative 3 compared to the No Action Alternative for CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests impact to striped bass spawning habitat extent will be negligible. The optimal water temperature range modeling estimates indicate 6.7% month-water year type combinations with beneficial and 5% combinations with adverse results at Butte City. Overall, these results suggest there would be negligible flow impacts and minor beneficial and adverse water temperature-related impacts on striped bass juvenile rearing and emigration habitat extent in the Sacramento River under Alternative 3.

O.6.19.2 Lower American River

Adults

Striped bass are present in the lower American River throughout the year, with the greatest abundance in summer (Surface Water Resources 2001). Striped bass are distributed from the confluence with the Sacramento River to Nimbus Dam (Moyle 2002), and they provide a locally important sportfishing resource.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam and in the lower American River at H Street indicate that minor (≤ 5%) increase and/or decrease is estimated nearly half of the months (Table O-259 and Table O-260). Below Nimbus Dam, slight (12%, June) moderate (27%, June) decreases are expected an average 3 months out of year; slight (≤ 10%, March and August) and moderate (16%, April) increases are expected. At H street, slight (≤ 11%, March and August) and moderate (16%, April) increases are expected an average 3 months out of year; slight (13%, June) and moderate (29%, June) increases are expected. These results suggest potential adverse impacts on striped bass at below Nimbus Dam and beneficial impacts at H street, generally in June and July.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 77°F stress initiation value for adult striped bass year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 93 for Hazel Avenue and Table 94 for Watt Avenue.

Results for the analysis are summarized in Table O-132. Table O-132, as described in Section O.4.19.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 77°F stress initiation water temperature value for adult striped bass under Alternative 3, there were zero month-water combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-132). There were also zero month-water combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue.

These results suggest that under Alternative 3, there would be negligible water temperature-related impacts to adult striped bass in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Overall, under Alternative 3 compared to the No Action Alternative CalSim 3 flow and water temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests flow impacts on striped bass spawning habitat extent may experience slight to moderate beneficial and adverse impacts in June and July. The optimal water temperature range modeling estimates indicate there are no combinations with beneficial or adverse results at Butte City. Overall, these results suggest there would be generally beneficial and adverse flow impacts on adult habitat and negligible water temperature-related impacts to adult striped bass in the lower American River at Hazel Avenue and Watt Avenue under Alternative 3 compared to the No Action Alternative.

Juvenile Rearing

Although the occurrence of spawning in the lower American River is uncertain, the river is believed to serve as a nursery area for YOY and subadult striped bass (Surface Water Resources 2001). Striped bass are distributed from the confluence with the Sacramento River to Nimbus Dam (Moyle 2002), and they provide a locally important sportfishing resource.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam and H Street indicate that minor (≤ 5%) increase and/or decrease is estimated nearly half of the months (Table O-259 and Table O-260). Below Nimbus Dam, slight (12%, June) moderate (27%, June) decreases are expected; slight (≤ 10%, March and August) and moderate (16%, April) increases are expected. At H street, slight (≤ 11%, March and August) and moderate (16%, April) increases are expected; slight (13%, July) and moderate (29%, June) decreases are expected. These results suggest adverse impacts on striped bass may occur below Nimbus Dams and beneficial impacts at H street, generally in June and July.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 95 for Hazel Avenue and Table 96 for Watt Avenue.

Results for the analysis are summarized in Table O-133. Table O-133, as described in Section O.4.19.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 61°F to 71°F optimal range for juvenile striped bass rearing under Alternative 3, there were four and three month-water combinations (6.7% and 5.0%, respectively) with favorable results at both Hazel Avenue and Watt Avenue (Table O-133). There were zero and six month-water combinations (0% and 10.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 3, there would be positive and negative water temperature-related impacts to juvenile striped bass rearing in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Overall, under Alternative 3 compared to the No Action Alternative CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests flow impacts on striped bass spawning habitat extent may experience slight to moderate beneficial and adverse impacts in June and July. The optimal water temperature range modeling estimates indicate 6.7% and 5% beneficial month-water year type combinations at Hazel Avenue and Watt Avenue (respectively) and 10% adverse combinations at Watt Avenue in the lower American River. Overall, these results suggest there would be beneficial and adverse flow impacts on juvenile rearing habitat and beneficial (Hazel Avenue) and adverse (Watt Avenue) water temperature-related impacts to juvenile striped bass rearing in the lower American River.

O.6.19.3 Stanislaus River

Spawning and Egg Incubation

Striped bass have been observed at Lovers Leap and at Knights Ferry from May through the end of June. These adult fish were observed in all habitats (U.S. Fish and Wildlife Service 2002; Kennedy and Cannon 2005). The distribution of striped bass in the Stanislaus River is thought to be limited to downstream of the historic Knights Ferry Bridge due to a set of falls about 3 feet tall in the area (U.S. Fish and Wildlife Service 2002).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows be moderately (≤ 20%) to substantially (≤ 38%) greater in April through June at Goodwin Dam and mouth of the Stanislaus River (Table O-261 and Table O-262). At Goodwin Dam, moderate (≤ 20%) to substantial (≤37%) increases are expected generally April through June. At the mouth, substantial (27 to 38%) increases are generally expected April through June. These results suggest flows are anticipated to have beneficial impacts on striped bass spawning.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 59°F to 68°F optimal range of water temperature for spawning, embryo incubation, and initial rearing of striped bass for April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 70 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-134. Table O-134, as described in Section O.4.19.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 59°F to 68°F optimal range of water temperature for spawning, embryo incubation, and initial rearing of striped bass, there was one month-water year type combination (6.7%) with favorable results and one month-water year type combination (6.7%) with unfavorable results at Orange Blossom Bridge (Table O-134). These results suggest that Alternative 3 would have negligible water-temperature related effects on striped bass spawning, embryo incubation, and initial rearing at Orange Blossom Bridge in the Stanislaus River.

Summary

Overall, under Alternative 3 compared to the No Action Alternative CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests flows may have beneficial impacts. The optimal water temperature range modeling estimates indicate a 6.7% month-water year type combination with beneficial and adverse results at Orange Blossom Bridge. Overall, these results suggest generally beneficial flow impacts and negligible water temperature-related impacts to striped bass spawning and egg incubation in the Stanislaus River at Goodwin Dam and the mouth under Alternative 3.

Laval and Juvenile Rearing and Emigration

Striped bass have been observed at Lovers Leap and at Knights Ferry from May through the end of June. The distribution of striped bass in the Stanislaus River is thought to be limited to downstream of the historic Knights Ferry Bridge due to a set of falls about 3 feet tall in the area (U.S. Fish and Wildlife Service 2002).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows be minorly (≤ 3%) to substantially (≤ 38%) greater and minorly (≤ 5%) to moderately (≤ 19%) lower at Goodwin Dam and mouth of the Stanislaus River (Table O-261 and Table O-262). At Goodwin Dam, moderate (≤ 23%) substantial (≤37%) increases are expected generally February through June and slight (6%) to moderate (≤ 19%) decreases are generally expected in January, August, September, and November. At the mouth, slight (≤ 8%) to substantial (≤38%) increases are generally expected February through July and slight (≤ 15%) decreases are generally expected January, August, September, and November. These results suggest flows may be anticipated to have beneficial and adverse impacts on striped bass.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 71 for Orange Blossom Bridge and Table 72 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-135. Table O-135, as described in Section O.4.19.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing there was one month-water year type combinations (1.7%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-135). There were one and six month-water year type combinations (1.7% and 10.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 3 would have negative water temperature-related impacts on juvenile striped bass rearing in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Overall, under Alternative 3 compared to the No Action Alternative CalSim 3 flow and temperature modeling had some differences. The differences determined by CalSim 3 modeling suggests flows may have beneficial impacts and adverse impacts on striped bass. The optimal water temperature range modeling estimated 1.7% (both locations) month-water year type combinations with beneficial results and 1.7% (Orange Blossom Bridge) and 10% (above the confluence with the San Joaquin River) combinations with adverse results. Overall, these results suggest there would be beneficial and adverse flow impacts on striped bass. Water temperature-related impacts on juvenile striped bass rearing would be adverse in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

O.6.19.4 San Joaquin River

Striped bass are regularly found in San Joaquin River tributaries, including in lower mainstem deep pools of the Stanislaus and Tuolumne Rivers (e.g., Anderson et al. 2007). Ainsley et al. (2013) reported that striped bass were collected at two locations between the Head of the Old River and the mouth of the Stanislaus River on the mainstem San Joaquin River in May. In the San Joaquin River outflow is balanced by tidal currents, so that embryos and larvae stay suspended in the same general area in which spawning took place. Essentially, larval bass from both rivers are most abundant where salt and fresh water meet. Thus, when they begin to feed they are concentrated in the most productive portions of the entire estuary. Larval growth and survival rates are also highest in areas of brackish water, presumably because of reduced energy costs for osmoregulation (Moyle 2002).

Potential Changes to Striped Bass from Seasonal Operations

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows be minorly (≤ 1%) greater and minorly (≤ 5%) to moderately (≤ 20%) decreases at Vernalis (Table O-263). Minor to moderate decreases are generally expected in June through December. The largest decreases occur in April, July, and August (16%, 20%, and 16%, respectively). These results suggest flows may be anticipated to have adverse effects on striped bass.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on striped bass in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 3 compared to the No Action Alternative CalSim 3 modeling suggest flows may generally have moderate adverse impacts on striped bass in April, July, and August. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.6.19.5 Bay-Delta

Striped bass use the Delta as a migratory route and for rearing and seasonal foraging. Striped bass spend the majority of their lives in salt water, returning to freshwater to spawn. Adult striped bass spend about six to nine months of the year in San Francisco and San Pablo Bays (Hassler 1988). Striped bass also use deeper areas of many of the larger channels in the Delta, in addition to large embayments such as Suisun Bay.

Spawning occurs in spring, primarily in the Sacramento River between Sacramento and Colusa and in the San Joaquin River between Antioch and Venice Island (Farley 1966). Eggs are free-floating and negatively buoyant and hatch as they drift downstream, with larvae occurring in shallow and open waters of the lower reaches of the Sacramento and San Joaquin rivers, the Delta, Suisun Bay, Montezuma Slough, and Carquinez Strait. According to Hassler (1988), the distribution of larvae in the estuary depends on river flow. In low-flow years, all striped bass eggs and larvae are found in the Delta, while in high-flow years, the majority of eggs and larvae are transported downstream into Suisun Bay.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows be minorly (≤ 4%) to substantially (≤ 42%) greater and minorly (4%) to substantially (≤ 151%) lower in the Bay-Delta (Table O-253 through Table O-255). At SWP and CVP exports, slight (15%) to substantial (69%) flow decreases throughout the year with the greatest decreases generally occurring in April and May. At the confluence of Old and Middle River in the Delta, substantial (≤151%) flow decreases year round with the greatest decreases generally occurring in April and May. At Delta Outflow, slight (≤ 8%) to substantial (≤42%) increases are expected for an average of 8 months of the year. These differences suggest flows will have adverse effects and beneficial effects on striped bass.

Potential Changes to Striped Bass from Seasonal Operations

Differences in Delta outflow between April and June due to seasonal operations under Alternative 3 compared with the No Action Alternative may have effects on striped bass annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the striped bass.

Delta Outflow vs. Bay-Delta Species Abundance

Predictions from the Delta Outflow model for striped bass indicated that the overall average abundance index for Alternative 3 would be the highest when compared to the No Action Alternative across all water year types (+9% to +19%, +11% overall).

Summary

Overall, under Alternative 3 compared to the No Action Alternative CalSim 3 flow and Delta outflow modeling had some differences. The differences determined by CalSim 3 modeling suggests flows may have beneficial impacts at two Delta locations and adverse impacts at one location. Predictions from the Delta Outflow model for striped bass indicated that the overall average abundance index for Alternative 3 would be generally greater than the No Action Alternative all water year types. Overall, these results suggest adverse flow impacts on striped bass at export facilities and OMR but beneficial flow impacts at Delta Outflow.

Potential Changes to Entrainment of Striped Bass

Differences in exports under Alternative 3 compared with the No Action Alternative may have effects on striped bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for striped bass include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of striped bass under Alternative 3 compared to the No Action Alternative at the SWP Banks Pumping Plant and CVP Jones Pumping Plant were lower all water year types, except at SWP Banks Pumping Plant on critically dry water years when loss was up to 13% greater (Tables O-136 and O-137). At the SWP Banks Pumping Plant predicted average monthly loss was up to 58% lower on above normal water years (Table O-136). At CVP Jones Pumping Plant predicted average monthly loss of striped bass was up to 85% lower on dry water years (Table O-137).

Summary

Overall, under Alternative 3 compared to the No Action Alternative salvage density modeling had some differences. The salvage density modeling predicted monthly loss under Alternative 3 are similar or greater at SWP Bank Pumping Plant and similar or lower at CVP Jones Pumping Plant all water year types. Overall, loss decreases from entrainment are anticipated most water year types under Alternative 3.

O.6.20 American Shad

O.6.20.1 Sacramento River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento River. Migrating adults generally take 2 to 3 months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962).

Potential Changes to American Shad from Seasonal Operations

During the February to April adult American shad migration into Delta, CalSim 3 estimates of mean monthly flows below Keswick Dam under Alternative 3 range from about 3,500 cfs for March in critically dry years to 24,000 cfs for February of wet water years (Table O-248). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. Alternative 3 relative to the No Action Alternative has differences in flow that are small in these months, but flows are moderately lower (16%) for Alternative 3 in April of dry water years (Table O-248). Therefore, Alternative 3 would likely have negligible flow impacts on American shad eggs and embryos relative to the No Action Alternative.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 319 for Butte City.

Results for the analysis are summarized in Table O-138. Table O-138, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 62°F to 75°F optimal range, there were two month-water year type combinations (13.3% of total combinations during the period) with favorable results at Butte City (Table O-138). There was one combination (6.7%) with unfavorable results at Butte City. These results suggest that there would be positive water temperature-related effects of Alternative 3 on American shad spawning and larval rearing in the Sacramento River.

Alternative 3 relative to the No Action Alternative is expected to have negligible impact on American shad spawning and larval rearing due to differences in flow below Keswick Dam in the Sacramento River. Flow for spawning is not a limiting factor for American shad. Water temperatures for spawning initiation under Alternative 3 compared to the No Action Alternative will have a beneficial impact on American shad spawning and larval rearing in the Sacramento River. Therefore, the differences in flow and temperature under Alternative 3 compared to the No Action Alternative in the Sacramento River are expected to have some beneficial effects on American shad spawning and larval rearing.

Juvenile Rearing and Emigration

In the Sacramento River, summer rearing habitat occurs in the main river from Colusa to the north Delta (Stevens et al. 1987). As the season progresses, juvenile shad move downstream and enter salt water primarily during September through November (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

During the September to November juvenile American shad emigration back into Delta, CalSim 3 estimates of mean monthly flows below Keswick Dam under Alternative 3 range from about 4,700 cfs for October in critically dry years to 8,500 cfs for September of wet water years (Table O-248). Because American shad are anadromous fish that migrate great lengths to reach their spawning grounds, these flow levels are likely to be adequate for juvenile rearing and emigration, so no adverse impacts are expected to result. Alternative 3 relative to the No Action Alternative has differences in flow that are moderately lower (14%) for Alternative 3 in September and November of above normal water years (Table O-248). Therefore, Alternative 3 would likely have negligible flow impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F range optimal range for juvenile rearing and emigration during July through November are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 320 for Butte City.

Results for the analysis are summarized in Table O-139. Table O-139, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 63°F to 77°F optimal range, there were four month-water year type combinations (16.0% of total combinations during the period) with favorable results at Butte City (Table O-139). There was one month-water year type combination (4.0%) with unfavorable results at Butte City. These results suggest that there would be positive water temperature-related effects of Alternative 3 on American shad juvenile rearing and emigration in the Sacramento River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have negligible impact on American shad juvenile rearing and emigration due to differences in flow. Flow for rearing and emigration does not appear to be a limiting factor for American shad. Water temperatures for larval rearing and emigration under Alternative 3 compared to the No Action Alternative are suggested to have beneficial impact on American shad juvenile rearing and emigration in the lower American River. Therefore, the differences in flow and temperature for Alternative 3 compared to the No Action Alternative are expected to have some beneficial impacts on American shad juvenile rearing and emigration.

O.6.20.2 Lower American River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento River. Migrating adults generally take 2 to3 months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962). Adult American shad migrate into the lower American River to spawn during the late spring, typically during April through early July (California Department of Fish and Wildlife 1986).

Potential Changes to American Shad from Seasonal Operations

During the February to April adult American shad migration into Delta, CalSim 3 estimates of mean monthly flows below Nimbus Dam and H street under Alternative 3 range from about 870 cfs for April in critically dry years to 12,300 cfs for February of wet water years (Table O-259 and Table O-260). Alternative 3 relative to the No Action Alternative has differences in flow that are generally minimal in these months below Nimbus Dam with a reduction of flow (15%) in March of critically dry years, but flows are higher at H Street (37%) for Alternative 3 in April of critically dry water years (Table O-259 and Table O-260). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. This increase in flows could result in more eggs and larval fish to be washed further downstream earlier than expected but Alternative 3 cannot be determined to have adverse effects. Therefore, Alternative 3 would likely have negligible impact on American shad eggs and embryos relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range for American shad spawning and larval rearing during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 97 for Hazel Avenue and Table 98 for Watt Avenue.

Results for the analysis are summarized in Table O-140. Table O-140, as described in Section O.4.20.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 62°F to 75°F optimal range for American shad spawning and larval rearing under Alternative 3, there were three and zero month-water combinations (20.0% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-140). There were zero month-water combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 3, there would be positive water temperature-related effects to American shad spawning and larval rearing in the lower American River at Hazel Avenue and Watt Avenue.

Alternative 3 relative to the No Action Alternative is expected to have minimal impact on American shad spawning and larval rearing due to differences in flow below Nimbus Dam and at H Street. Flow for spawning is not a limiting factor for American shad. Water temperatures for spawning initiation from Hazel Avenue and Watt Avenue under Alternative 3 compared to the No Action Alternative will have a beneficial impact on American shad spawning and larval rearing in the lower American River. Therefore, the differences in flow and temperature under Alternative 3 compared to the No Action Alternative in the lower American River are expected to have some beneficial impacts on American shad spawning and larval rearing.

Juvenile Rearing and Emigration

American shad rearing and emigration in the lower American River is dependent on water temperatures. August through September, but before November, are optimal months for juvenile American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

During the September to November juvenile American shad emigration back into Delta, CalSim 3 estimates of mean monthly flows below Nimbus Dam and H street under Alternative 3 range from about 600 cfs for October in critically dry years to 4,100 cfs for November of wet water years (Table O-259 and Table O-260). Alternative 3 relative to the No Action Alternative has differences in flow that are slightly lower (14%) for Alternative 3 below Nimbus Dam in November during critically dry years (Table O-259) and increasingly lower (31%) at H St. in November during critically dry years (Table O-260). Because American shad are anadromous fish that migrate great lengths to reach their spawning grounds, these flow levels are likely to be adequate for juvenile rearing and emigration, so no adverse effects are expected to result. Therefore, Alternative 3 would likely have negligible impacts from flow on American shad juvenile rearing and emigration relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for American shad juvenile rearing and emigration during July through November are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 99 for Hazel Avenue and Table 100 for Watt Avenue.

Results for the analysis are summarized in Table O-141. Table O-141, as described in Section O.4.20.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 63°F to 77°F optimal range for American shad juvenile rearing and emigration under Alternative 3, there were three month-water combinations (12.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-141). There were one and zero month-water combinations (4.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 3, there would be positive water temperature-related effects to American shad juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 3 relative to the No Action Alternative is expected to have a negligible impact on American shad juvenile rearing and emigration due to differences in flow. Flow for rearing and emigration is not a limiting factor for American shad. Water temperatures for larval rearing and emigration at Hazel Avenue and Watt Avenue under Alternative 3 compared to the No Action Alternative are suggested to have beneficial impacts on American shad juvenile rearing and emigration in the lower American River. Therefore, the differences in flow and water temperature under Alternative 3 relative to the No Action Alternative are expected to have some beneficial impacts on American shad juvenile rearing and emigration.

O.6.20.3 Stanislaus River

Spawning and Larval Rearing

American shad migrate up the Stanislaus River to spawn in the late spring and support a sport fishery during that period. American shad have been observed on occasion from June through July at Lovers Leap (U.S. Fish and Wildlife Service 2002; Kennedy and Cannon 2005). American shad were found primarily in the faster habitats and were observed in schools of 20 or more (U.S. Fish and Wildlife Service 2002).

Potential Changes to American Shad from Seasonal Operations

During the February to April adult American shad migration into Delta, CalSim 3 estimates of mean monthly flows below Goodwin Dam and Stanislaus River mouth under Alternative 3 range from about 180 cfs for March in critically dry years to 2600 cfs for February below Goodwin Dam and at Stanislaus River Mouth of wet water years (Table O-261 & Table O-262). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these

flow levels are likely to be adequate for spawning and incubation. Alternative 3 relative to the No Action Alternative has differences in flow that are 68% higher for Alternative 3 in February below Goodwin Dam and 51% higher in March at the Stanislaus River Mouth for dry water years (Table O-261 & Table O-262) This increase in flows could result in more eggs and larval fish to be washed further downstream earlier than expected but Alternative 3 cannot be determined to have adverse effects. Therefore, Alternative 3 would likely have negligible impact on American shad eggs and embryos relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range for American shad spawning and larval rearing during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 73 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-142. Table O-142, as described in Section O.4.20.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 59°F to 68°F 62°F to 75°F optimal range for American shad spawning and larval rearing, there were zero month-water year type combinations (0.0%) with favorable and zero month-water year type combinations with unfavorable results at Orange Blossom Bridge (Table O-142).

These results suggest that Alternative 3 would have negligible water-temperature related effects on American shad spawning and larval rearing at Orange Blossom Bridge in the Stanislaus River.

Summary

Alternative 3 relative to the No Action Alternative is expected to have negligible impact on American shad spawning and larval rearing due to differences in flow. Flow for spawning is not a limiting factor for American shad. Water temperatures for spawning initiation at Orange Bridge Dam and above the confluence under Alternative 3 compared to the No Action Alternative will have negligible water-temperature related impacts on American shad spawning and larval rearing at Orange Blossom Bridge in the Stanislaus River. Therefore, the differences in flow and temperature for Alternative 3 compared to the No Action Alternative in the lower American River are expected to have some negligible impacts on American shad spawning and larval rearing.

Juvenile Rearing and Emigration

American shad rearing and emigration in the Stanislaus River is dependent on water temperatures. From Orange Blossom Bridge to just above the confluence, juvenile rearing and emigration generally occur in July for American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

During the September to November juvenile American shad emigration back into Delta, CalSim 3 estimates of mean monthly flows below Goodwin Dam and Stanislaus River Mouth under Alternative 3 range from about 160 cfs for September at Stanislaus River Mouth in critically dry years to 800 cfs below Goodwin Dam in October during wet water years (Table O-261 & Table O-262). Alternative 3 relative to the No Action Alternative has differences in flow that are unchanged below Goodwin Dam and 10% higher at Stanislaus River Mouth in September during critically dry years (Table O-261 & Table O-262). With no change below Goodwin Dam and a slight increase in flows at Stanislaus River Mouth, American Shad should see no adverse affects from Alternative 3. Therefore, Alternative 3 would likely have negligible flow impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for American shad juvenile rearing and emigration during July through November are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 74 for Orange Blossom Bridge and Table 75 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-143. Table O-143, as described in Section O.4.20.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 63°F to 77°F optimal range for American shad juvenile rearing and emigration there were zero and two month-water year type combinations (0.0% and 8.0%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-143). There were zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River.

These results suggest that Alternative 3 would have negligible water temperature-related effects on American shad juvenile rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Alternative 3 relative to the No Action Alternative is expected to have negligible impacts on American shad juvenile rearing and emigration due to differences in flow. Flow for rearing and emigration is not a limiting factor for American shad. Water temperatures for juvenile rearing and emigration at Orange Blossom Bridge and above the confluence under Alternative 3 compared to the No Action Alternative are suggested to have negligible water temperature-related impacts on American shad juvenile rearing and emigration in the Stanislaus River. Therefore, the differences in flow and temperature for Alternative 3 compared to the No Action Alternative are expected to have negligible impacts on American shad juvenile rearing and emigration.

O.6.20.4 San Joaquin River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas. Migrating adults generally take 2 to3 months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962).

Little is known about American shad populations inhabiting the San Joaquin River. American shad may spawn in the San Joaquin River system, but their abundance is unknown.

Potential Changes to American Shad from Seasonal Operations

During the February to April adult American shad migration into the Delta, CalSim 3 estimates of mean monthly flows in the San Joaquin River at Vernalis under Alternative 3 range from about 1,800 cfs for March critically dry years to 13,000 cfs for February (Table O-263). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. Alternative 3 relative to the No Action Alternative has differences in flow that are slightly lower (~10%) for Alternative 3 in March and April of critically dry water years (Table O-263) This decrease in flows could result in a reduction of spawning habitat for American shad but Alternative 3 cannot be determined to have adverse effects. Therefore, Alternative 3 would likely have negligible flow impacts on American shad eggs and embryos relative to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on American shad spawning and larval rearing in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the American shad spawning and larval rearing period (Figure O-15).

<u>Summary</u>

There may be negligible impacts from seasonal operations on American shad spawning and larval rearing based on analyses of simulated flows under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are also like to have negligible impacts on American shad juvenile rearing and non-spawning adult. Under Alternative 3, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the American shad spawning and larval rearing period.

Juvenile Rearing and Emigration

American shad juvenile rearing and emigration is dependent on water temperatures. Generally, juvenile rearing and emigration generally occur in July for American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

During the September to November juvenile American shad emigration back into the Delta, CalSim 3 estimates of mean monthly flows in the San Joaquin River at Vernalis under

Alternative 3 range from about 600 cfs for September in critically dry years to 2,800 cfs for November in the San Joaquin River at Vernalis of wet water years (Table O-263) Alternative 3 relative to the No Action Alternative has differences in flow that are slightly lower (12%) for Alternative 3 in September in the San Joaquin River at Vernalis during critically dry years (Table O-263). With these flows, American shad may lose some rearing habitat but may not be affected by Alternative 3. Therefore, Alternative 3 would likely have negligible impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on American shad in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile rearing and emigration period (Figure O-15).

Summary

There may be negligible impacts from seasonal operations on American shad juvenile rearing and non-spawning adults based on analyses of simulated flows under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are unlikely to have an impact on American shad juvenile rearing and non-spawning adult. Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are also likely to have a negligible impact on American shad in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile rearing and emigration period.

O.6.20.5 Bay-Delta

American shad spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento, Feather, American, and Yuba Rivers. Some spawning also takes place in the lower San Joaquin, Mokelumne, and Stanislaus Rivers (U.S. Fish and Wildlife Service 1995). The spawning migration may begin as early as February, but most adults migrate into the Delta in March and early April (Skinner 1962). Migrating adults generally take 2 to 3 months to pass through the Sacramento–San Joaquin estuary (Painter et al. 1979).

American shad rearing and emigration in the Bay-Delta is dependent on water temperatures. August through September, but before November, are optimal months for juvenile American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

Differences in Delta outflow between February and June due to seasonal operations under Alternative 3 compared with the No Action Alternative may have impacts on American shad annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the American shad.

Delta Outflow vs. Bay-Delta Species Abundance

Predictions from the Delta Outflow model for American shad indicate that Alternative 3 would lead to higher mean American shad abundance compared to the No Action Alternative across all water year types (+7% in wet years to +13% in critically dry years, and +9% overall).

Summary

There may be beneficial impacts from seasonal operations on American shad abundance based on analyses of simulated flows under Alternative 3 in comparison to the No Action Alternative. American shad abundance index would increase across all water year types in the Bay-Delta based on the Delta Outflow model.

Potential Changes to Entrainment of American Shad

Salvage Density

Predictions from the salvage density model for American shad include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative. Predicted average monthly loss of American shad under Alternative 3 compared to the No Action Alternative at the SWP Banks Pumping Plant decreased all water year types, except for critically dry water years when loss was similar and CVP Jones Pumping Plant decreased all water year types (Tables O-144 and O-145). At the SWP Banks Pumping Plant predicted average monthly loss was up to 58% lower on above normal water year types (Table O-144). At CVP Jones Pumping Plant predicted average monthly loss was up to 78% lower on above normal water year types (Table O-145).

Summary

There may be beneficial impacts on American shad entrainment based on analyses of simulated exports under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, entrainment decreased at both Jones Pumping Plant and Banks Pumping Plant during all water year types.

O.6.21 Threadfin Shad

O.6.21.1 Sacramento River

Spawning for threadfin shad takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Threadfin shad are occasionally caught at the Red Bluff Diversion Dam rotary screw trap in the Sacramento River, and occur year-round (Voss 2024).

Potential Changes to Threadfin Shad from Seasonal Operations

Flow Impacts

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 3 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal spawning range during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 321 for Butte City.

Results for the analysis are summarized in Table O-146. Table O-146, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 63°F to 77°F optimal range, there were four month-water year type combinations (16.0% of total combinations during the period) with favorable results at Butte City (Table O-146). There were three month-water year type combinations (12.0%) with unfavorable results at Butte City. These results suggest that there would be both positive and negative water temperature-related impacts from Alternative 3 on threadfin shad spawning in the Sacramento River.

Summary

There may be beneficial and adverse impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are likely to have negligible impacts on threadfin shad. Temperature analysis suggests both beneficial and adverse impacts of Alternative 3 on threadfin shad spawning in the Sacramento River.

O.6.21.2 Lower American River

Spawning for threadfin shad takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. Threadfin shad are occasionally captured as part of the non-salmonid bi-catch in the rotary screw traps in the lower American River (Pacific States Marine Fisheries Commission 2014).
