There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 3 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for threadfin shad adult spawning during April through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 101 for Hazel Avenue and Table 102 for Watt Avenue.

Results for the analysis are summarized in Table O-147. Table O-147, as described in Section O.4.21.2 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 63°F to 77°F optimal range for threadfin shad adult spawning under Alternative 3, there were two and one month-water combinations (8.0% and 4.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-147). There were one and zero month-water combinations (4.0% and 0.0%, respectively) with unfavorable results at both Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 3, there would be negligible water temperature-related effects to threadfin shad adult spawning in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There may be negligible impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are likely to have negligible impacts on threadfin shad. Temperature analysis suggests negligible impacts of Alternative 3 on threadfin shad spawning in the lower American River.

O.6.21.3 Stanislaus River

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and

abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Threadfin shad are occasionally captured in the Caswell RST in the lower Stanislaus River (Bradbury and Hickey 2019).

Potential Changes to Threadfin Shad from Seasonal Operations

Flow Impacts

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 3 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for threadfin shad adult spawning during April through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 76 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-148. Table O-148, as described in Section O.4.21.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 63°F to 77°F optimal range for threadfin shad adult spawning, there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge (Table O-148).

These results suggest that Alternative 3 would have negligible water-temperature related impacts on threadfin shad spawning in the Stanislaus River at Orange Blossom Bridge.

Summary

There may be negligible impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are likely to have a negligible impact on threadfin shad. Temperature analysis also suggests negligible impacts from Alternative 3 on threadfin shad spawning in the Stanislaus River.

O.6.21.4 San Joaquin River

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Juveniles can form dense schools and while they are typically abundant in freshwater, they may also be found in varying salinities throughout the estuary. Threadfin shad are fast-growing but short-lived, with an average lifespan of two years.

Potential Changes to Threadfin Shad from Seasonal Operations

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 3 are likely adequate for threadfin shad.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on threadfin shad in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

There may be negligible impacts from seasonal operations on threadfin shad based on analyses of simulated flows under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, changes in flows are likely to have a negligible impact on threadfin shad. Under Alternative 3, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the year in the San Joaquin River at Vernalis.

O.6.21.5 Bay-Delta

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004).

Potential Changes to Threadfin Shad from Seasonal Operations

There is no strong evidence that flow influences threadfin shad abundance. While Dege and Brown (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 3 are likely adequate for threadfin shad.

Summary

There may be negligible impacts from seasonal operations on threadfin shad under Alternative 3 in comparison to the No Action Alternative.

Potential Changes to Entrainment of Threadfin Shad

Differences in exports under Alternative 3 compared with the No Action Alternative may have effects on threadfin shad entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for threadfin shad include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of threadfin shad under Alternative 3 compared to the No Action Alternative at the SWP Banks Pumping Plant decreased all water year types, except for critically dry water years when loss was similar and CVP Jones Pumping Plant decreased all water year types (Tables O-149 and O-150). At the SWP Banks Pumping Plant predicted average monthly loss was up to 58% lower on above normal water year types (Table O-149). At CVP Jones Pumping Plant predicted average monthly loss was up to 78% lower on above normal water year types (Table O-150).

Summary

There may be beneficial changes to entrainment on threadfin shad juvenile rearing and non-spawning adults based on analyses of simulated exports under Alternative 3 in comparison to the No Action Alternative. Under Alternative 3, entrainment decreased at Banks across all water year types except for the critically dry water year type, while entrainment at Jones decreased across all water year types.

O.6.22 Black Basses

O.6.22.1 Three Micropterus spp.

Three *Micropterus* spp. constitute the group of black basses in California, and include largemouth bass (two species), smallmouth bass, and spotted bass (three sub-species). All three species are introduced but have recreational value in California.

Largemouth Bass

Largemouth bass first spawn during their second or third spring at about 7 inches in length. Spawning is limited to freshwater (Moyle 2002). The males begin building nests when the water temperature reaches about 60°F (15.6°C). Spawning takes place from April through June, at temperatures up to 75°F (23.9°C).

Smallmouth Bass

Smallmouth bass reach maturity in their third or fourth spring, at which point they move into shallower water. Spawning begins in May and can continue into June or July (Moyle 2002). Spawning has been observed at temperatures ranging from 13°C to 26°C (55.4°F to 78.8°F), with optimal water temperatures ranging from 16°C to 18°C (60.8°F to 64.4°F) (Wang et al. 2010).

Spotted Bass

Maturity is reached in the second or third year and spawning occurs in freshwater when temperatures reach 15°C to 18°C (59°F to 64.4°F), continuing until temperatures reach 22°C to 23°C (71.6°F to 73.4°F) in early June. Males move to shallow water in March and early April, where they construct nests 40 to 80 cm (31.5 inches) in diameter, generally in shallow areas less than or equal to 6 m deep (University of California, Agriculture and Natural Resources 2019b; Wang et al. 2010).

O.6.22.2 Sacramento River

Spawning

Spawning occurs in freshwater for all three taxa. This means all spawning occurs upstream of the brackish estuary. See details in Section O.4.22.1 above for spawning timing for each species.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

<u>CalSim 3 Flow Analysis</u>

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows at Keswick Dam, Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤5%) increase or decrease is estimated March through April and slight increase or decrease May through July. In May flows would be generally higher (≥ 6%), lower in June (≥ 10%), and lower July (≥ 6%). These results suggest slightly adverse effects on largemouth, smallmouth, and spotted bass habitat under Alternative 3 comparted to the No Action Alternative (Table O-248 through Table O-251).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 323 for Butte City. Full results of the analysis assessing the percent of months with water temperature outside the 55°F to 70°F optimal range for smallmouth bass spawning during May through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 325 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 331 for Butte City.

Results for the three analyses are summarized in Table O-151. Table O-151, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results at Butte City (Table O-151). For the 55°F to 70°F optimal range for smallmouth bass spawning, there were no month-water year type combinations (0%) with favorable results at Hamilton City. There was one combination (6.7%) with unfavorable results. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Butte City. These results suggest that there would be negligible water temperature-related effects of Alternative 3 on black bass spawning in the Sacramento River.

Summary

Overall, Alternative 3 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests slight adverse impacts on largemouth, smallmouth, and spotted bass spawning habitat extent may be expected. The optimal water temperature range modeling estimates indicate neither beneficial nor adverse impacts on largemouth and spotted bass under Alternative 3 compared to the No Action Alternative in the Sacramento River. The optimal water temperature range modeling estimates indicate 6.7% adverse combinations at Hamilton City for smallmouth bass in the Sacramento River. Overall, these results suggest that there would be slight adverse impact from flow for largemouth, smallmouth, and spotted bass spawning habitat; negligible water temperature-related impacts are anticipated on largemouth and spotted bass, and slight adverse smallmouth bass spawning and egg incubation in the Sacramento River under Alternative 3.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters and may be found from the tributaries of the Sacramento to the brackish estuary. As all three taxa require large quantities of food, they are likely to be more concentrated in areas with plentiful food and instream cover.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows at Keswick Dam, Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (<5%) increase and/or decrease is estimated most months except May (higher), June (lower), July (lower), August (higher, Wilkins Slough and Hamilton City), September (lower, Wilkins Slough), and December (higher, Keswick Dam); this suggest effects on largemouth, smallmouth, and spotted bass habitat will generally remain similar to the No Action Alternative (Table O-248 through Table O-251).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for non-spawning adult largemouth bass growth year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 324 at Butte City. Full results of the analysis assessing the percent of months with water temperature above the 66°F lower end of observed summer-time range for non-spawning adult smallmouth bass during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 327 for the Sacramento River at Hamilton. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F optimal range for non-spawning adult smallmouth bass growth year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 320 for the Sacramento River at Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 75°F to 87°F preferred summer-time range for non-spawning adult spotted bass during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 332 for the Sacramento River at Butte City.

Results for the four analyses are summarized in Table O-152. Table O-152, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 77°F to 86°F optimal range for non-spawning adult largemouth bass growth, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results at Butte City (Table O-152). For the 66°F lower end of observed summer-time range for non-spawning adult smallmouth bass, there were two month-water year type combinations (13.3%) with both favorable and unfavorable results at Hamilton City. For the 77°F to 80°F optimal range for non-spawning adult smallmouth bass growth, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Hamilton City. For the 75°F to 87°F preferred summer-time range for non-spawning adult spotted bass, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Butte City. These results suggest that there would be positive and negative effects of Alternative 3 on black bass non-spawning adults in the Sacramento River.

Summary

Overall, Alternative 3 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will generally remain similar with some slight adverse impacts. The optimal summer water temperature range modeling estimates indicate neither beneficial nor adverse conditions for largemouth and spotted bass compared to the No Action Alternative at Butte and Hamilton cities in the Sacramento River. The optimal summer water temperature range modeling estimates indicate 13.3% adverse and beneficial month-water year type combinations for smallmouth bass in the lower end of optimal range at Hamilton City. Overall, these results suggest there would be minor to slight adverse impact from flow for largemouth, smallmouth, and spotted bass; negligible water temperature-related impacts on largemouth, smallmouth, and spotted bass adults are expected in the Sacramento River under Alternative 3.

O.6.22.3 Lower American River

Spawning

Spawning for all three taxa occurs in cooler, shallow waters with flow. See details in Section O.4.22.1 above for spawning timing for each species.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam and in the lower American River at H Street indicate that minor (≤ 6%) to substantial (≤ 29%) increases or decreases are estimated March through June (Tables O-258 through O-260). Below Nimbus Dam, slight (12%, July) moderate (27%, June) decreases and minor (March) and moderate (16%, April) increases are expected. At H street, minor (March) and moderate (16%, April) increases and slight (13%, July) and moderate (29%, June) increases are expected. These results suggest adverse effects on largemouth, smallmouth, and spotted bass may be below Nimbus Dam and H street generally in June and July and beneficial effects in March and April.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 105 for Hazel Avenue and Table 106 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 55°F to 70°F optimal range for smallmouth bass spawning during May through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 109 for Hazel Avenue and Table 110 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 115 for Hazel Avenue and Table 116 for Watt Avenue.

Results for the three analyses are summarized in Table O-153. Table O-153, as described in Section O.4.22.2,reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were two and zero month-water year type combinations (13.3% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-153). There were one and zero month-water year type combinations (6.7% and 0%, respectively) with unfavorable results at both Hazel Avenue and Watt Avenue, respectively. For the 55°F to 70°F optimal range for smallmouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at Hazel Avenue and Watt Avenue. There were 0 and 4 month-water year type combinations (0.0% and 26.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were four and zero month-water year type combinations (26.7% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero and five month-water year type combinations (0.0% and 33.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results suggest that there would be similar positive and negative effects of Alternative 3 on black bass spawning in the lower American River.

Summary

Overall, Alternative 3 compared to the No Action Alternative CalSim 3 flow modeling and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests a mix of beneficial (March and April) and adverse (June and July) flow impacts largemouth, smallmouth, and spotted spawning habitat. The optimal water temperature range modeling estimates indicate two (13.3%, Hazel Avenue) beneficial and 1 (6.7%, Watt Avenue) adverse month-water year type beneficial combination for largemouth bass. The optimal water temperature range modeling estimates indicate four (26.7%, Watt Avenue) adverse combinations for smallmouth bass. The optimal water temperature range modeling estimates indicate one (6.7%, Hazel Avenue) beneficial and five (33.3%, Watt Avenue) adverse combinations for spotted bass. Overall, these results suggest that there would be generally beneficial (March and April) and adverse (June and July) flow impacts on largemouth, smallmouth, and spotted spawning habitat; water temperature-related impacts would be slightly beneficial on largemouth bass spawning, moderately adverse on smallmouth, and slightly adverse on spotted bass in the lower American River under Alternative 3.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters. However, they require large quantities of food; they are likely to remain in slower moving waters of the stream or move vertically within the lake to accommodate preferences.

Potential Changes to Black Basses from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam, and H Street indicate that minor (≤ 5%) increase and/or decrease is estimated nearly half of the months (Table O-259 and Table O-260). Below Nimbus Dam, slight (12%, June) moderate (27%, June) decreases are expected an average three months out of year; slight (≤ 10%, March and August) and moderate (16%, April) increases are expected. At H street, slight (≤ 11%, March and August) and moderate (16%, April) increases are expected an average three months out of year; slight (13%, June) and moderate (29%, June) increases are expected. These results suggest largemouth, smallmouth, and spotted bass habitat will be adversely affected below Nimbus Dam and have a beneficial effect at H street generally in June and July.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for growth for largemouth bass during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 107 for Hazel Avenue and Table 108 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 111 for Hazel Avenue and Table 112 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F optimal range for growth in smallmouth bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 113 for Hazel Avenue and 114 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 75°F to 87°F preferred summer-time range for spotted bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 117 for Hazel Avenue and Table 118 for Watt Avenue.

Results for the four analyses are summarized in Table O-154. Table O-154, as described in Section O.4.22.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0% with favorable results at both Hazel Avenue and Watt Avenue (Table O-154). There were also zero month-water year type combinations (0%,) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass, there were zero and one month-water year type combinations (0.0% and 20.0%) with favorable results at both Hazel Avenue and Watt Avenue. There was one month-water year type combinations (6.7%) with unfavorable results at both Hazel Avenue and Watt Avenue, respectively. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were zero month-water year type combinations (0.0% with favorable results at both Hazel Avenue and Watt Avenue. There were also zero month-water year type combinations (0%,) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 75°F to 87°F preferred

summer-time range for spotted bass, there were zero month-water year type combinations (0.0% with favorable results at both Hazel Avenue and Watt Avenue. There were also zero month-water year type combinations (0%,) with unfavorable results at both Hazel Avenue and Watt Avenue.

These results suggest that there would be positive effects of Alternative 3 on black bass non-spawning adults in the lower American River.

Summary

Overall, Alternative 3 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will remain similar with some beneficial and adverse impacts. The optimal water temperature range modeling estimates indicate largemouth bass are neither beneficial nor adverse at the lower American River. The optimal water temperature range modeling estimates indicate one (6.7%, Hazel Avenue and Watt Avenue) adverse month-water year type combinations and three (20.0%, Hazel Avenue) beneficial combinations at the 66°F water temperature lower end summer-time range of smallmouth bass. The optimal water temperature range modeling estimates indicate one (6.7%, Watt Avenue) beneficial combination for spotted bass. Overall, these results suggest there would be generally slight beneficial flow impacts on largemouth, smallmouth, and spotted bass; water temperature-related impacts on non-spawning adult largemouth bass would be negligible, and on non-spawning adult smallmouth and spotted bass would be slightly beneficial in the lower American River.

O.6.22.4 Stanislaus River

Spawning

Spawning for all three taxa occurs in cooler, shallow waters with flow. See details in Section O.4.22.1 above for spawning timing for each species. The Stanislaus River supports spawning for largemouth bass and spotted bass.

Potential Changes to Largemouth and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows be slightly (≤ 8%) to substantially (≤ 38%) greater and minorly (≤ 5%) lower at Goodwin Dam and mouth of the Stanislaus River (Table O-261 and Table O-262). At Goodwin Dam, moderate (≤ 20%) to substantial (≤37%) increases are expected generally March through June and minor decrease is generally expected July. At the mouth, slight (≤ 8%) to substantial (≤38%) increases are generally expected March through July and slight (≤ 15%). These results suggest flows may be anticipated to have beneficial effects on largemouth, smallmouth, and spotted bass spawning.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 78 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April

through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 82 for Orange Blossom Bridge.

Results for the two analyses are summarized in Table O-155. Table O-155, as described in Section O.4.22.4,reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results and one month-water year type combinations (6.7%) with unfavorable results at Orange Blossom Bridge (Table O-155). For the 58.1°F to 73.4°F observed range for spotted bass spawning, there was one month-water type combination (6.7%) with favorable and unfavorable results at Orange Blossom Bridge.

These results suggest that there would be negligible negative effects of Alternative 3 on spawning black basses spawning in the Stanislaus River.

Summary

Overall, Alternative 3 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The fluctuations determined by CalSim 3 modeling suggests projected averaged flows may have generally beneficial impacts. The optimal water temperature range modeling estimates indicate one (6.7%) month-water year type combinations with adverse conditions for largemouth bass. The optimal water temperature range modeling estimates indicate one (6.7%) month-water year type combinations with adverse and beneficial conditions for spotted bass. Overall, these results suggest generally beneficial flow impacts on largemouth, smallmouth, and spotted bass; water temperature-related impacts on largemouth bass spawning are slightly negative and negligible on spotted bass under Alternative 3.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters. However, they require large quantities of food; they are likely to remain in slower moving waters of the stream or move vertically within the reservoirs to accommodate preferences.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows be minorly (≤ 3%) to substantially (≤ 38%) greater and minorly (≤ 5%) to moderately (≤ 19%) lower at Goodwin Dam and mouth of the Stanislaus River (Table O-261 and Table O-262). At Goodwin Dam, moderate (≤ 23%) substantial (≤37%) increases are expected generally February through June and slight (6%) to moderate (≤ 19%) decreases are generally expected in January, August, September, and November. At the mouth, slight (≤ 8%) to substantial (≤38%) increases are generally expected February through July and slight (≤ 15%) decreases are generally expected January, August, September, and November. These results suggest flows may be anticipated to have beneficial effects and adverse effects on largemouth, smallmouth, and spotted bass.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for growth for largemouth bass during year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 79 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass during June through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 80 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F optimal range for growth in smallmouth bass during year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 81 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 75°F to 87°F preferred summer-time range for spotted bass during June through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 83 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-156. Table O-156, as described in Section O.4.22.4, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 3 for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0% with favorable and unfavorable results at Orange Blossom Road (Table O-156). For the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass, there were zero month-water year type combinations (0.0% with favorable and unfavorable results at Orange Blossom Road. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were zero month-water year type combinations (0.0% with favorable and unfavorable results at Orange Blossom Road For the 75°F to 87°F preferred summer-time range for spotted bass, there were zero month-water year type combinations (0.0% with favorable and unfavorable results at Orange Blossom Road.

These results suggest that there would be negligible effects of Alternative 3 on black bass non-spawning adults in the Stanislaus River at Orange Blossom Bridge.

Summary

Overall, Alternative 3 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests flows may have generally beneficial impacts on largemouth, smallmouth, and spotted bass. The optimal water temperature range modeling estimates were neither beneficial nor adverse for largemouth, smallmouth, and spotted bass. Overall, these results suggest generally beneficial flow and similar water temperature-related impacts on non-spawning largemouth, smallmouth, and spotted bass in the Stanislaus River under Alternative 3 compared to the No Action Alternative.

O.6.22.5 San Joaquin River

Spawning occurs in freshwater for all three taxa. This means all spawning occurs upstream of the brackish estuary. Non-spawning adults are generally more tolerant of various water quality parameters and may be found from the tributaries of the San Joaquin to the brackish estuary. As all three taxa require large quantities of food, they are more likely to be concentrated in areas with plentiful food and instream cover.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows be minorly (≤ 1%) greater and minorly (≤ 5%) to moderately (≤ 20%) decreases at Vernalis (Table O-263). Minor to moderate decreases are generally expected in June through December. The largest decreases occur in April, July, and August (16%, 20%, and 16%, respectively). These results suggest flows may be anticipated to have adverse effects on largemouth, smallmouth, and spotted bass.

Changes in water temperature from seasonal operations under Alternative 3 compared to the No Action Alternative are likely to have a negligible impact on black basses in the San Joaquin River. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 3 compared to the No Action Alternative CalSim 3 results differ. There are generally adverse impacts on largemouth, smallmouth, and spotted bass anticipated under Alternative 3 compared to the No Action Alternative. Under Alternative 3, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.6.22.6 Bay-Delta

Non-spawning adults are present year-round predominantly in the brackish water interface where food and is abundant. Larvae and Juveniles are likely to remain upstream of the brackish water interface, where plant beds and slower waters occur.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 3 compared to the No Action Alternative CalSim 3 mean monthly flows be minorly (≤ 4%) to substantially (≤ 42%) greater and minorly (4%) to substantially (≤ 151%) lower in the Bay-Delta (Table O-253 through Table O-255). At SWP and CVP exports, slight (15%) to substantial (69%) flow decreases throughout the year with the greatest decreases generally occurring in April and May. At the confluence of Old and Middle River in the Delta, substantial (≤151%) flow decreases year-round with the greatest decreases generally occurring in April and May. At Delta Outflow, slight (≤ 8%) to substantial (≤42%) increases are expected for an average of 8 months of the year. These differences suggest flows will have adverse effects and beneficial effects on largemouth, smallmouth, and spotted bass.

Summary

Overall, Alternative 3 compared to the No Action Alternative CalSim 3 flow modeling results had some differences. The differences determined by CalSim 3 modeling suggests flows may have beneficial impacts at two Delta locations and generally adverse impacts one location for largemouth, smallmouth, and spotted bass.

Potential Changes to Entrainment of Largemouth Bass

Differences in exports under Alternative 3 compared with the No Action Alternative may have effects on largemouth bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for largemouth bass include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of largemouth bass under Alternative 3 compared to the No Action Alternative at the SWP Banks Pumping Plant and CVP Jones Pumping Plant were lower all water year types, except at SWP Banks Pumping Plant on critically dry water years when loss was up to 214% greater (Tables O-157 and O-158). At the SWP Banks Pumping Plant predicted average monthly loss was up to 59% lower on above normal water years (Table O-157). At CVP Jones Pumping Plant predicted average monthly loss of largemouth bass was up to 85% lower on dry water years (Table O-158).

Potential Changes to Entrainment of Smallmouth Bass

Salvage Density

Predictions from the salvage density model for smallmouth bass include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of smallmouth bass of Alternative 3 compared to the No Action Alternative at SWP Banks Pumping Plant would decrease or increase all other water year types, except critically dry water year types when no fish are expected; at CVP Jones Pumping Plant loss would decrease on below normal and critically dry water year types, all other water year types have no anticipated loss (Tables O-159 and O-160). At the SWP Banks Pumping Plant predicted average monthly loss decreased up to 49% and 21% in December through February of below normal and dry water year types, respectively; loss would increase up to 12% in October and March of dry water years and 7% October of below normal water years (Table O-159). At the CVP Jones Pumping Plant predicted average monthly loss increased up to 64% and 55% January through March and May of below normal water years and February of critically dry water years, respectively (Table O-160). Historical loss of smallmouth bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Potential Changes to Entrainment of Spotted Bass

Differences in exports under Alternative 3 compared with the No Action Alternative may have effects on spotted bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for spotted bass include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of spotted bass of Alternative 3 compared to the No Action Alternative at SWP Banks Pumping Plant decreased below normal water years and no fish are expected all other water year types; at CVP Jones Pumping Plant loss decreased all water year types, except wet water years when it would be similar (Table O-161 and Table O-162). At the SWP Banks Pumping Plant predicted average monthly loss decreased up to 11% in March of below normal water years (Table O-161). At the CVP Jones Pumping Plant predicted average monthly loss decreased between 6% to 68% in November, December, and February of wet water years and in January and August of critically dry water years (Table O-162). Historical loss of spotted bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Summary

Overall, Alternative 3 compared to the No Action Alternative salvage density modeling results had some differences. The salvage density modeling predicted monthly loss under Alternative 3 are generally slightly to largely lower for largemouth bass for nearly all water year types; a few exceptions at SWP Banks Pumping Plant where slight loss increases are expected compared to the No Action Alternative. The salvage density modeling predicted monthly loss under Alternative 3 are generally slightly to largely lower for smallmouth bass for nearly all water year types; a few exceptions at SWP Banks Pumping Plant where slight loss increases are expected compared to the No Action Alternative. The salvage density modeling predicted monthly loss under Alternative 3 are generally slightly to largely lower for spotted bass for nearly all water year types. Overall, loss decreases at CVP Jones Pumping Plant and slight loss increases at SWP Banks Pumping Plant from entrainment of largemouth and smallmouth bass under Alternative 3 are expected; spotted bass loss decreases at SWP and CVP delta facilities from entrainment under Alternative 3.

O.6.23 Starry Flounder

O.6.23.1 Bay-Delta

Adult starry flounder primarily inhabit coastal marine waters (Orcutt 1950; Haertel and Osterberg 1967; Bottom et al. 1984; Hieb and Baxter 1993). Distribution of age-0 juveniles within the San Francisco Estuary and Delta is primarily in Suisun Bay and San Pablo Bay, with lower abundance in the west Delta (Baxter et al. 1999). Starry flounder older than age 1 (age-1+ fish) occur principally in San Pablo Bay, Suisun Bay, and Central Bay (Baxter et al. 1999).

Starry flounder can tolerate a wide range of salinities. In the Sacramento and San Joaquin Rivers, starry flounder have been observed in salinities as low as 0.02–0.06 ppt (i.e., essentially fresh water) (Orcutt 1950). Age-0 and age-1+ starry flounder are a common species in estuarine habitats along the West Coast (see Orcutt 1950; Pearson 1989; Emmett et al. 1991; Baxter et al. 1999; Kimmerer 2002b).

Spawning occurs primarily during the winter months of December and January (Orcutt 1950). By age-2 many starry flounder are nearing reproductive maturity and have migrated to ocean habitats adjacent to their natal estuaries. Adults may move seasonally into shallow coastal waters to spawn, perhaps in proximity to estuaries to take advantage of estuarine circulation which would advect fertilized eggs near the bottom into nursery areas.

Potential Changes to Starry Flounder from Seasonal Operations

Differences in Delta outflow between March and June due to seasonal operations under Alternative 3 compared with the No Action Alternative may have effects on starry flounder annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the starry flounder.

Delta Outflow vs. Bay-Delta Species Abundance

Predictions from the Delta Outflow model for starry flounder indicated that the overall average abundance index for Alternative 3 would be the highest (15% higher than the No Action Alternative). Mean starry flounder abundance across all water year types are higher under Alternative 3 (from +12% in wet years to +28% in critically dry years).

Summary

Alternative 3 relative to the No Action Alternative is expected to have possible beneficial impacts on species abundance for the starry flounder across all water year types.

Potential Changes to Entrainment of Starry Flounder

Differences in exports under Alternative 3 compared with the No Action Alternative may have effects on starry flounder entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for starry flounder include mean monthly total exports. Table O-253 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 3 and the No Action Alternative.

Predicted average monthly loss of starry flounder under Alternative 3 compared to the No Action Alternative at the SWP Banks Pumping Plant decreased in most water year types, except for dry water years when loss was similar and critically dry water years was increased. CVP Jones Pumping Plant has a decreased salvage loss during all water year types (Table O-163 and Table O-164). At the SWP Banks Pumping Plant predicted average monthly loss was up to 46% lower in December through July of wet normal water year and 38% greater in October of critically dry

water years (Table O-163). At CVP Jones Pumping Plant predicted average monthly loss decrease ranged from 53% in June and September of critically dry water years and May and November of below normal water years to 77% in June through October of above normal water years (Table O-164). Historical loss of starry flounder at both facilities is infrequent, and this is a driver of low values of predicted loss.

Summary

Differences in exports between Alternative 3 and the No Action Alternative are expected to have possibly substantial beneficial impacts on starry flounder entrainment at Delta Fish Collection Facilities. The predicted average monthly loss of starry flounder at the SWP Banks pumping plant decreased in wetter years, was similar in drier years, and slightly increased in critically dry years. At the CVP Jones pumping plant, average monthly loss was greatly decreased across all seasons and water year types.

O.6.24 Coastal Pelagic Species

O.6.24.1 Potential Changes to Northern Anchovy and Pacific Herring from Seasonal Operations

Northern anchovy and Pacific herring could be subject to operational effects of the Proposed Action as it pertains to Delta outflow and its effect on the salinity field. However, the effects on salinity would be small relative to the salinity tolerance of Coastal Pelagic Species EFH such as Northern Anchovy (Baxter et al. 1999). Kimmerer et al. (2009) showed for Northern Anchovy that neither indices of habitat extent nor indices of abundance were related to X2, an index of Delta outflow and its effects.

Kimmerer (2009) found Pacific herring abundance indices were not associated with flow. However, Pacific herring do utilize the San Francisco Bay Estuary as spawning and rearing habitat (Pak et al. 2023, Grimaldo et al. 2020, Watters et al. 2004). Grimaldo et al. (2020) found Pacific herring larvae presence and abundance was lower in landward regions (e.g. Suisun Bay) during a high outflow year, likely due to either increased advection from high flows or reduced net landward movement via gravitational circulation. Juvenile herring abundance in Suisun Bay in the spring is associated with saltier conditions that allow their range to expand landward (Pak et al. 2023).

O.6.24.2 Potential Changes to Entrainment of Northern Anchovy and Pacific Herring

There are no expected impacts to entrainment of Northern anchovy due to operations since the distribution in the San Francisco Estuary has shifted towards higher salinities (> 20) since the introduction of the invasive clam, *Potamocorbula amurensis* (Kimmerer 2006). Impacts to entrainment of Pacific herring are potentially adverse in drier water year types depending on severity but are likely to be extremely rare. Historical salvage of Pacific herring has only occurred a few times since 2000, primarily in 2014, a critically dry year (during the months of March and April), fish were also salvaged in 2019 and 2020 in much lower numbers (CDFW 2024c).

O.6.25 Southern Oregon/Northern California Coast Coho Salmon ESU

O.6.25.1 Trinity River

Spawning and Egg/Alevin Incubation

Most coho salmon spawning in the mainstem Trinity River occurs in November and December between Lewiston Dam and the North Fork Trinity River (Section O.1.2.5.1, *Coho salmon, Southern Oregon/Northern California Coast ESU*). Coho salmon eggs and alevins in the Trinity and Klamath River Basins may be present in the gravel from November to mid-May (Leidy and Leidy 1984), so effects of flow and water temperature on coho salmon eggs and alevins may occur during this period.

Potential Changes to Coho Salmon from Seasonal Operations

Under Alternative 3, modeled monthly average flows in the Trinity River below Lewiston Dam in December of wet and below normal water years, in January of wet water years, and in February of wet and above normal water years would be at least 5% greater than the No Action Alternative (Table O_Trin_Alt3). Monthly average flows in March of below normal water years and April of wet water years would be at least 5% less than the No Action Alternative. These changes would have variable effects on the availability and suitability of spawning and egg/alevin incubation habitat for coho salmon. From May through November, modeled monthly average flows under Alternative 3 would be the same as the No Action Alternative or would not differ substantially (by more than 5%) in any month or water year type.

In December when coho salmon are spawning and eggs/alevins may be incubating in the Trinity River, modeled monthly average flow would increase in wet water years from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 and in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 (Table O-246). In January when coho salmon eggs/alevins may be incubating, monthly average flow would increase in wet water years from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3. In February when coho salmon eggs/alevins may be incubating, monthly average flow would increase in wet water years from 1,843 cfs under the No Action Alternative to 1,962 cfs under Alternative 3 and in above normal water years from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3.

The modeled December flow increases may increase WUA for coho salmon spawning in the reach from Dutch Creek to North Fork Trinity River but would reduce WUA for coho salmon spawners in downstream reaches (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The effect on spawning suitability in the reach from Lewiston Dam to Dutch Creek has not been quantified for flows above 800 cfs (U.S. Fish and Wildlife Service and Hoopa Valley Tribe 1999) and, as in other reaches, is likely to vary spatially with channel confinement and incision (Goodman et al. 2018). In locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships. Although WUA for egg/alevin incubation is not available for the Trinity River, the changes in modeled monthly average flows in January and February under Alternative 3 would be unlikely to change redd hydraulics or redd substrate conditions relative to the No Action Alternative, especially in areas with a confined channel where relatively minor

changes in flow have little influence on water depth or velocity, and no effects on egg/alevin incubation suitability are expected. The monthly average flows in the Trinity River below Lewiston Dam during the coho salmon egg/alevin incubation period would be too low to cause redd scour, and flow increases under Alternative 3 would therefore have no effect on the risk of redd scour relative to the No Action Alternative. The probability of redd scour in the primary coho salmon spawning reaches of the Trinity River is predicted to be less than 1% at flows up to 5,000 cfs (Gaeuman et al. 2023).

The modeled flow increases in December, January, and February of wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17) and average water temperatures under Alternative 3 would remain well below the upper water temperature objective of 56°F to protect spawning coho salmon in the reach from Lewiston Dam to the North Fork Trinity River (Table O-11; Assarian et al. 2023). Similarly, the modeled flow increases in December of above normal water years and in February of above normal water years would cause only negligible changes in modeled monthly average water temperature and there would be no change in the temperature suitability for spawning coho salmon or incubating eggs/alevins relative to the No Action Alternative. Compared with the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of coho salmon spawning and egg/alevin incubation habitat, with considerable variability related to channel geometry and its effect on flow-habitat relationships.

During the latter portion of the coho salmon incubation period, modeled monthly average flows under Alternative 3 would decrease by at least 5% in below normal water years in March (from 427 to 400 cfs) and in wet water years in April (from 1,035 to 957 cfs) compared with the No Action Alternative (Table O-246). Although WUA for egg/alevin incubation is not available for the Trinity River, the changes in modeled monthly average flows in March and April under Alternative 3 would be unlikely to change redd hydraulics or redd substrate conditions relative to the No Action Alternative, especially in areas with a confined channel where relatively minor changes in flow have little influence on water depth or velocity, and no impacts on egg/alevin incubation suitability are expected. The March and April decreases would have little impact on modeled monthly average water temperature in the Trinity River below Lewiston Dam and only negligible changes relative to the No Action Alternative (Figure O-19 and Figure O-17, respectively). From Lewiston Dam to North Fork Trinity River, water temperatures in March under Alternative 3 would remain below the 50°F upper suitability limit recommended by Washington State Department of Ecology (WDOE) (2002, as cited in Carter 2005) to support coho salmon incubation and emergence but could exceed the objective in April of dryer water years (Assarian et al. 2023). Compared with the No Action Alternative, the flow decreases in March and April under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of coho salmon spawning and egg/alevin incubation habitat, with considerable variability related to channel geometry and its impact on flow-habitat relationships.

Juvenile Rearing and Emigration

Naturally spawned juvenile coho salmon in the Trinity River emerge from the gravel and begin rearing in winter and early spring, with the first captures of young-of-year (age-0) coho salmon typically occurring in early March (U.S. Fish and Wildlife Service 2023, unpublished; Yurok

Tribe 2023, unpublished). Fry, juvenile, and subyearling coho salmon rearing in the Trinity River strongly prefer areas of slow water velocity and habitat with cover from woody material, overhanging vegetation, and clusters of aquatic vegetation (Hampton 1988, 1997; Chase et al. 2009; Pinnix et al. 2019). During high flows, young coho salmon use floodplains and other off-channel habitats (Chase et al. 2009). Rearing occurs year-round, typically over a period of 12–15 months, and the effects of flow and water temperature on rearing coho salmon therefore occur throughout the year. Most Trinity River coho salmon outmigrate to the ocean as yearling smolts between January and July (Harris et al. 2016; Petros et al. 2015; Petros et al. 2017).

Potential Changes to Coho Salmon from Seasonal Operations

Seasonal operations under Alternative 3 would have spatially and temporally variable effects on the availability and suitability of juvenile rearing and emigration habitat for coho salmon. Compared to the No Action Alternative, substantial differences (greater than 5%) in modeled monthly average flows would occur in some water year types in December–April (Table O-246). In all other months and water year types, there would be little or no difference in monthly average flow between Alternative 3 and the No Action Alternative, and no effects on coho salmon are expected.

In December, the increase in modeled monthly average flow in wet water years from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 (Table O-246) would result in a slight increase in WUA for coho salmon fry and a decrease in WUA for coho salmon juveniles in the reach from Lewiston Dam to Dutch Creek, a slight decrease in fry and juvenile WUA in the reach from Dutch Creek to North Fork Trinity River, no change in fry WUA and a decrease in juvenile WUA in the reach from North Fork Trinity River to South Fork Trinity River, and a slight increase in fry WUA and no change in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The modeled December flow increase in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 would have similar effects on WUA for coho salmon fry and juveniles as the December flow increase in wet water years. In January and February in wet water years, modeled flow increases from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3 (January) and from 1,843 cfs under the No Action Alternative to 1,962 cfs under Alternative 3 (February) would result in an increase in fry and juvenile WUA in the reach from Lewiston Dam to Dutch Creek, no change in fry and juvenile WUA in the reach from Dutch Creek to North Fork Trinity River, a slight increase in fry WUA and a slight decrease in juvenile WUA in the reach from North Fork Trinity River to South Fork Trinity River, and no change in fry and juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In February of above normal water years, the increase in modeled monthly average flow from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3 would have the same effect on fry and juvenile coho salmon WUA as the monthly flow changes in December of wet water years. In locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships (Cooper-Hertel et al. 2022). Consequently, coho salmon WUA in all reaches is likely to vary spatially with channel confinement and incision.

The modeled flow increases in December, January, and February of wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam, but there would be no substantial differences relative to the No Action Alternative (Figure O-17), and monthly average water temperatures throughout the Trinity River under Alternative 3 would remain well below the 59°F water temperature objective for emigrating juvenile coho salmon (smolts) recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the 59°F objective is intended to be measured at Weitchpec and applicable prior to June 4, historical data and model results suggest that water temperatures in December, January, and February would remain below the 59°F objective throughout the Trinity River under a wide range of flow scenarios (Asarian et al. 2023), and there would be no change in the temperature suitability for rearing or emigrating coho salmon under Alternative 3 relative to the No Action Alternative. The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 3 through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives in portions of the coho salmon juvenile rearing and emigration period at downstream locations in some water year types under Alternative 3, water temperatures and the potential impacts on coho salmon would not differ from the No Action Alternative. Compared with the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of coho salmon rearing and emigration habitat, with considerable variability related to channel geometry and its impact on flow-habitat relationships. Substantial impacts on coho salmon would be unlikely.

Modeled monthly average flows under Alternative 3 would decrease in below normal water years in March (from 427 to 400 cfs) and in wet water years in April (from 1,035 to 957 cfs) compared to the No Action Alternative (Table O-246). The March flow reduction would increase WUA for fry and juvenile coho salmon in all reaches of the Trinity River relative to the No Action Alternative, while the April flow reduction would have variable effects on fry and juvenile WUA (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In the reach from Lewiston Dam to Dutch Creek, the April flow reduction would slightly reduce fry WUA and increase juvenile WUA. In downstream reaches, the April flow reduction would increase fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and from North Fork Trinity River to South Fork Trinity River. In the reach from South Fork Trinity River to Weitchpec, the April flow reduction would slightly reduce fry WUA and would not change juvenile WUA relative to the No Action Alternative. The March and April flow reductions would have little effect on modeled monthly average water temperature in the Trinity River below Lewiston Dam and only negligible changes relative to the No Action Alternative (Figure O-19 and Figure O-17, respectively). Throughout the Trinity River, monthly average water temperatures in March and April under Alternative 3 would remain well below the 59°F upper water temperature objective recommended for emigrating juvenile coho salmon (smolts) in normal and wetter water years and the 62.6°F objective in dry and critically dry water years (U.S. Fish and Wildlife Service and Hoopa Valley Tribe 1999; Assarian et al. 2023) and there would be no change relative to the No Action Alternative.

Compared with the No Action Alternative, the change in seasonal operations in March and April under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of coho salmon rearing and emigration habitat, with considerable variability related to channel geometry and its impact on flow-habitat relationships. Substantial impacts on coho salmon would be unlikely.

Adult Upstream Migration and Holding

From August to January, coho salmon return from the ocean through the Klamath River Estuary to the Trinity River, moving upstream toward spawning habitat. Based on recent weir counts, the date of peak abundance of upstream-migrating coho salmon in the Trinity River ranges from late September to mid-November (Kier et al. 2018, 2019, 2020, 2021, 2022). After completing their upstream migration, mature coho salmon may hold for days, weeks, or sometimes months before spawning. Because most spawning occurs in November and December, the effects of flow and water temperature on migrating and holding coho salmon would primarily occur from August through December.

Potential Changes to Coho Salmon from Seasonal Operations

During the coho salmon upstream migration and holding period there would be no differences in modeled monthly average flow between Alternative 3 and the No Action Alternative in August, September, or October; a negligible difference in November; and slightly greater but variable differences in December and January. Differences would vary by month and water year type and are described in detail in the preceding sections and shown in Table O-246. These differences may result in minor, short-term changes in physical habitat conditions but modeled monthly average flows from August through January when adult coho salmon are migrating and holding would be equal to or greater than 300 cfs in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and holding habitat to support pre-spawning coho salmon.

Modeled monthly average flows in August and September, when adult coho salmon begin migrating upstream from the ocean and water temperatures are typically at or near seasonal highs (Asarian et al. 2023), would be the same under Alternative 3 as under the No Action Alternative (Table O-246). Under both alternatives, modeled average August and September flows of 760 cfs in wet water years and 863 cfs in all other water year types would maintain suitable water temperatures for adult upstream migration (60°F in August and early September and 56°F in late September; Table O-11) in the Trinity River at Lewiston Dam (Figure O-17). Although downstream warming during August and September could result in unsuitable water temperatures for migrating coho salmon at some locations, the likelihood of this occurring would be the same under Alternative 3 as under the No Action Alternative due to the identical flows.

During the late September to mid-November peak adult migration period, the modeled monthly average flows under Alternative 3 would be the same as the No Action Alternative except for a negligible increase of 6 cfs in November of above normal water years (Table O-246). In December and January, substantial flow differences (greater than 5%) between the two alternatives would occur in December of wet water years (from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3), in December of below normal water years (from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3), and in January of wet water years (from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3).

None of the modeled December and January flow differences would have substantial impacts on modeled monthly average water temperature at Lewiston Dam in the respective water year types (Figure O-17 and Figure O-21) and there would be no impacts on water temperature suitability for coho salmon migration and holding relative to the No Action Alternative. Compared with the No Action Alternative, the differences in modeled monthly average flows and associated water temperature differences under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of coho salmon upstream migration and holding habitat and substantial impacts on coho salmon would be unlikely.

O.6.26 Upper Klamath-Trinity River Spring-run Chinook Salmon ESU

O.6.26.1 Trinity River

Spawning and Egg/Alevin Incubation

Most spring-run Chinook salmon in the Trinity River spawn from late September to mid-November, with a peak in October (Gough et al. 2021a,b). At optimal intragravel temperatures (41–55°F) the incubation period lasts 40–60 days and alevins may remain in the gravel for another 4–6 weeks (Healey 1991, Moyle 2002). In the Trinity River, spring-run Chinook salmon incubation and emergence typically occurs through February (Leidy and Leidy 1984). The effects of flow and water temperature on spring-run Chinook salmon spawning and egg/alevin incubation may therefore occur from approximately mid-September through February.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Under Alternative 3, modeled monthly average flows in the Trinity River below Lewiston Dam from September through February when spring-run Chinook salmon egg/alevin incubation occurs would be equal to or greater than 300 cfs in all water year types, and substantially greater in the wettest water years in some months, to provide suitable conditions for incubation and emergence (Table O_Trin_Alt3). From May through November, monthly average flows under Alternative 3 would be the same as the No Action Alternative or would not differ substantially (by more than 5%) in any month or water year type. Modeled monthly average flows in December of wet and below normal water years, January of wet water years, and February of wet and above normal water years would be at least 5% greater than the No Action Alternative. Monthly average flows in March of below normal water years and April of wet water years would be at least 5% less than the No Action Alternative. Only the December, January, and February differences would occur during the spring-run Chinook salmon spawning and egg/alevin incubation period. These changes would have variable effects on the availability and suitability of spawning and incubation habitat for spring-run Chinook salmon.

In December when spring-run Chinook salmon eggs/alevins may be incubating in the Trinity River, modeled monthly average flow would increase in wet water years from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 and in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 (Table O-246). In January when spring-run Chinook salmon eggs/alevins may be incubating, monthly average flow would increase in wet water years from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3. In February when spring-run Chinook salmon eggs/alevins may be incubating, monthly average flow would increase in wet water years from 1,843 cfs under the No Action

Alternative to 1,962 cfs under Alternative 3 and in above normal water years from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3.

The increased December–February average flows are not expected to reduce suitability for incubating Chinook salmon eggs/alevins, and the December flow increase may reduce risk of redd superimposition by later-spawning fall-run Chinook salmon and coho salmon. In all reaches of the Trinity River, the effects of flow changes on spawning and incubation suitability are likely to vary spatially with channel confinement and incision (Goodman et al. 2018). Where the channel is naturally unconfined and not overly incised and where channel restoration has removed remnant riparian berms and reduced legacy channel confinement and incision, a stronger positive relationship between flow and salmonid habitat suitability, particularly for flows of approximately 300–1,200 cfs, can be expected than in areas of greater channel confinement (see Section O.4.24.1.1 for a detailed discussion). This is mainly a result of increasing habitat area, which also provides more space for redds and reduces the risk of redd superimposition by later-spawning salmonids. The monthly average flows in the Trinity River below Lewiston Dam during the spring-run Chinook salmon egg/alevin incubation period would be too low to cause redd scour, and modeled monthly average flow increases under Alternative 3 would therefore have no impact on the risk of redd scour relative to the No Action Alternative. The probability of redd scour in the primary salmon spawning reaches of the Trinity River is predicted to be less than 1% at flows up to 5,000 cfs (Gaeuman et al. 2023).

The flow increases in December, January, and February of wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17). Modeled monthly average water temperatures under Alternative 3 would remain well below the upper water temperature objective of 56°F (Table O-11) to protect spring-run Chinook salmon eggs/alevins in the reach from Lewiston Dam to the North Fork Trinity River (Assarian et al. 2023). Similarly, the flow increases in December in below normal water years and February in above normal water years would cause only negligible changes in water temperature and there would be no change in the temperature suitability for incubating spring-run Chinook salmon eggs/alevins relative to the No Action Alternative.

Compared with the No Action Alternative, the increased monthly average flows in December, January, and February under Alternative 3 would likely have minor impacts on the availability and suitability of spring-run Chinook salmon spawning and incubation habitat in the Trinity River. Overall, the impacts in the reaches most heavily used by spawning spring-run Chinook salmon adults and incubating eggs/alevins would likely be negligible or slightly beneficial, with spatial variability related to channel geometry and its impact on flow-habitat relationships.

Juvenile Rearing and Emigration

In the Trinity River, spring-run Chinook salmon fry emerge from the gravel beginning in December and most emergence is complete by the end of February (Leidy and Leidy 1984). Fry and juvenile Chinook salmon rearing in the Trinity River preferentially use areas of relatively slow water velocity and habitat with woody material, undercut banks, and other complex cover (Hampton 1988, Pinnix et al. 2019). Naturally spawned juvenile spring-run Chinook salmon typically outmigrate as sub-yearlings from the Trinity River and occasionally as yearlings. Hatchery releases of spring-run Chinook salmon also include mostly sub-yearlings and some

yearling releases in spring and fall, respectively. Peak outmigration of natural and hatchery origin juveniles occurs in May, June, and July based on monitoring in the lower Trinity River near the town of Willow Creek (Harris et al. 2016; Petros et al. 2017). The effects of flow and water temperature on rearing and emigrating spring-run Chinook salmon may therefore occur from December through July.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Substantial (greater than 5%) differences in modeled monthly average Trinity River flows between Alternative 3 and the No Action Alternative would occur in December–April of below normal and wetter water years. In June of wet water years there would be a minor (less than 5%) decrease in modeled monthly average flow under Alternative 3 compared with the No Action Alternative. These changes would have variable effects on the suitability for rearing and emigrating spring-run Chinook salmon in the Trinity River. In all other months and water year types there would be little or no difference in monthly average flow between Alternative 3 and the No Action Alternative and no effects on spring-run Chinook salmon would be expected.

Modeled monthly average flow in December of wet water years would increase from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 (Table O_Trin_Alt3) and may result in changes in observed and predicted WUA for fry and juvenile spring-run Chinook salmon that would vary by reach (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). From Lewiston Dam to Dutch Creek, fry WUA would increase and juvenile WUA would decrease. In the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, WUA for both fry and juveniles would decrease. From South Fork Trinity River to Weitchpec, fry WUA would increase and juvenile WUA would decrease slightly (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In January and February of wet water years, modeled monthly average flow increases from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3 (January) and from 1,843 cfs under the No Action Alternative to 1,962 cfs under Alternative 3 (February) would result in increases in fry and juvenile WUA from Lewiston Dam to Dutch Creek, decreases in fry and juvenile WUA from Dutch Creek to North Fork Trinity River, an increase in fry and decrease in juvenile WUA from North Fork Trinity River to South Fork Trinity River, and a slight increase in fry and slight decrease in juvenile WUA from South fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The modeled December flow increase in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 would increase fry WUA and decrease juvenile WUA in the reach from Lewiston Dam to Dutch Creek, decrease fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and would increase fry WUA and decrease juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In February of above normal water years, the increase in modeled monthly average flow from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3 would have the same effect on fry and juvenile spring-run Chinook salmon WUA as the monthly flow changes in December of wet water years.

Modeled monthly average flows under Alternative 3 would decrease in below normal water years in March (from 427 to 400 cfs) and in wet water years in April (from 1,035 to 957 cfs) compared with the No Action Alternative (Table O-246). The modeled March flow reduction would increase WUA for fry and juvenile spring-run Chinook salmon in all reaches of the Trinity

River relative to the No Action Alternative, while the April flow reduction would have variable effects on fry and juvenile WUA (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In the reach from Lewiston Dam to Dutch Creek, the modeled April flow reduction would slightly reduce fry WUA and increase juvenile WUA. In downstream reaches, the April flow reduction would increase fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and from North Fork Trinity River to South Fork Trinity River. In the reach from South Fork Trinity River to Weitchpec, the modeled April flow reduction would reduce fry WUA and increase juvenile WUA relative to the No Action Alternative.

Where the channel is naturally unconfined and not overly incised and in locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships and rearing WUA in some restored areas may exhibit a stronger positive relationship to flow up to approximately 3,500 cfs (Cooper-Hertel et al. 2022). Consequently, spring-run Chinook salmon WUA in all reaches is likely to vary spatially with channel confinement and incision and in WUA in restored areas may be greater than described in U.S. Fish and Wildlife Service and Hoopa Valley Tribe (1999). See Section O.4.24.1.1 for additional details. The changes in WUA for spring-run Chinook salmon fry and juveniles may have short-term, spatially variable effects on the ability of these life stages to access cover and preferred habitat that would occur in certain water year types during five months of the eight-month rearing and emigration period and in some reaches of the Trinity River.

The modeled flow increases in December, January, and February of wet water years may result in negligible changes in monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17). Similarly, the modeled flow increases in December of below normal water years and February of above normal water years would have little or no effect on modeled monthly average water temperatures in the Trinity River below Lewiston Dam relative to the No Action Alternative (Figure O-19 and Figure O-18, respectively). From December through February, modeled monthly average water temperatures under Alternative 3 would remain well below the 62.6°F water temperature objective for emigrating juvenile spring-run Chinook salmon recommended for normal and wetter water year types and the 68°F objective recommended for dry and critically dry water year types (U.S. Fish and Wildlife Service and Hoopa Valley Tribe 1999). Although the objectives are intended to be measured at Weitchpec and applicable prior to July 9, historical data and model results suggest that Trinity River water temperatures in December–February would remain below both objectives under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating spring-run Chinook salmon under Alternative 3 relative to the No Action Alternative.

The modeled March and April flow reductions under Alternative 3 would have minor effects on modeled monthly average water temperature in the Trinity River below Lewiston Dam relative to the No Action Alternative (Figure O-19 and Figure O-17, respectively). Although the objectives are intended to be measured at Weitchpec and applicable prior to July 9, historical data and model results suggest that Trinity River water temperatures in March and April under the modeled monthly average flows under Alternative 3 would likely remain below the recommended 62.6°F and 68°F water temperature objectives at Weitchpec (Assarian et al. 2023)

and there would be no change in the temperature suitability for rearing or emigrating spring-run Chinook salmon under Alternative 3 relative to the No Action Alternative.

The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 3 through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives in portions of the spring-run Chinook salmon juvenile rearing and emigration period at downstream locations in some water year types, water temperatures under Alternative 3 and the potential impacts on spring-run Chinook salmon would not differ substantially from the No Action Alternative. Compared with the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of spring-run Chinook salmon rearing and emigration habitat, with considerable variability related to channel geometry and its impact on flow-habitat relationships.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon typically enter the Trinity River from April through September. By the end of July, most fish have arrived at the primary spawning reach, which extends from Lewiston Dam downstream to the confluence with the North Fork Trinity River. After entering freshwater, spring-run Chinook salmon remain in deep pools until the onset of the spawning season, which typically begins in late September (Leidy and Leidy 1984; Gough et al. 2019, 2021a,b). The effects of flow and water temperature on migrating and holding spring-run Chinook salmon adults may therefore occur from April through September.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

During the spring-run Chinook salmon upstream migration and holding period, there would be a substantial (greater than 5%) difference in modeled monthly average flow between Alternative 3 and the No Action Alternative only in April, with a minor difference in June and no difference between the two alternatives in May, July, August, and September (Table O-246). The April difference may result in minor, short-term changes in physical habitat conditions but modeled monthly average flows during the majority of the spring-run Chinook salmon migration and holding period would be approximately 500 cfs or greater in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and holding habitat to support pre-spawning spring-run Chinook salmon.

Modeled monthly average flows in July, August, and September, when adult spring-run Chinook salmon are migrating and holding and water temperatures are typically at or near seasonal highs (Asarian et al. 2023), would be the same under Alternative 3 as under the No Action Alternative (Table O-246). Under both alternatives, modeled average July flows would be approximately 500 cfs or greater in all water year types and substantially greater in wetter years. Modeled average flows in August and September would be 760 cfs in wet water years and 863 cfs in all other water year types. Under both alternatives, July–September flows would maintain suitable water temperatures for adult upstream migration (60°F from July 1 to September 14 and 56°F from September 15 to September 30 at Douglas City [RM 93.7]; Table O-11) (Assarian et al. 2023).

Although downstream warming during the warmest months and driest water year types could result in unsuitable water temperatures for migrating spring-run Chinook salmon at some locations (Buxton 2023), the likelihood of this occurring would be the same under Alternative 3 as under the No Action Alternative because modeled monthly average flows in July–September would be the same under both alternatives. In April and June, modeled decreases in monthly average flows under Alternative 3 would occur only in the wettest water year types when flows in the Trinity River below Lewiston Dam are relatively high and the impact on water temperature, as well as differences between Alternative 3 and the No Action Alternative, would likely be minor (Assarian et al. 2023).

Compared with the No Action Alternative, the differences in monthly average flows and associated water temperature differences under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of spring-run Chinook salmon upstream migration and holding habitat.

O.6.27 Upper Klamath-Trinity River Fall-run Chinook Salmon ESU

O.6.27.1 Trinity River

Spawning and Egg/Alevin Incubation

Most fall-run Chinook salmon in the Trinity River spawn from late October to December, with a peak in spawning occurring in November (Myers et al. 1998, Leidy and Leidy 1984). Optimal spawning temperatures are reported to be less than 55.4°F (Moyle 2002). At optimal intragravel temperatures (43–54°F) the incubation period lasts 40–60 days and alevins may remain in the gravel for another four to six weeks (Moyle 2002). In the Trinity River, fall-run Chinook salmon incubation and emergence typically occurs from December through late February (Leidy and Leidy 1984). The effects of flow and water temperature on fall-run Chinook salmon spawning and egg/alevin incubation may therefore occur from approximately mid-October through February.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Under Alternative 3, modeled monthly average flows in the Trinity River below Lewiston Dam from October through February when fall-run Chinook salmon may be spawning and eggs/alevins may be incubating would be equal to or greater than 300 cfs in all water year types, and substantially greater in the wettest water years in some months, to provide suitable conditions for spawning, incubation, and emergence (Table O_Trin_Alt3). From May through November, modeled monthly average flows under Alternative 3 would be the same as the No Action Alternative or would not differ substantially (by more than 5%) in any month or water year type. Modeled monthly average flows in December in wet and below normal water years, January in wet water years, and February in wet and above normal water years would be at least 5% greater than the No Action Alternative. Monthly average flows in March in below normal water years and April in wet water years would be at least 5% less than the No Action Alternative. Only the December, January, and February differences would occur during the fall-run Chinook salmon spawning and egg/alevin incubation period. These changes would have variable effects on the availability and suitability of spawning and incubation habitat for fall-run Chinook salmon.

In December when fall-run Chinook salmon eggs/alevins may be incubating in the Trinity River, modeled monthly average flow would increase in wet water years from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 and in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 (Table O-246). In January when fall-run Chinook salmon eggs/alevins may be incubating, monthly average flow would increase in wet water years from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3. In February when fall-run Chinook salmon eggs/alevins may be incubating, monthly average flow would increase in wet water years from 1,843 cfs under the No Action Alternative to 1,962 cfs under Alternative 3 and in above normal water years from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3.

The increased December–February average flows are not expected to reduce suitability for incubating Chinook salmon eggs/alevins, and the December flow increase may reduce risk of redd superimposition by spring-run Chinook salmon and coho salmon. In all reaches of the Trinity River, the effects of flow changes on spawning suitability are likely to vary spatially with channel confinement and incision (Goodman et al. 2018). Where the channel is naturally unconfined and not overly incised and where channel restoration has removed remnant riparian berms and reduced legacy channel confinement and incision, a stronger positive relationship between flow and salmonid habitat suitability, particularly for flows of approximately 400–1,200 cfs, can be expected than in areas of greater channel confinement (see Section O.4.24.1.1 for a detailed discussion). This is mainly a result of increasing habitat area, which also provides more space for redds and reduces the risk of redd superimposition by later-spawning salmonids. The monthly average flows in the Trinity River below Lewiston Dam during the fall-run Chinook salmon egg/alevin incubation period would be too low to cause redd scour, and modeled monthly average flow increases under Alternative 3 would therefore have no impact on the risk of redd scour relative to the No Action Alternative. The probability of redd scour in the primary salmon spawning reaches of the Trinity River is predicted to be less than 1% at flows up to 5,000 cfs (Gaeuman et al. 2023).

The flow increases in December, January, and February of wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17). Modeled monthly average water temperatures under Alternative 3 would remain well below the upper water temperature objective of 56°F (Table O-11) to protect fall-run Chinook salmon eggs/alevins in the reach from Lewiston Dam to the North Fork Trinity River (Assarian et al. 2023). Similarly, the modeled average flow increases in December in below normal water years and February in above normal water years would cause only negligible changes in modeled monthly average water temperature and there would be no change in the temperature suitability for incubating fall-run Chinook salmon eggs/alevins relative to the No Action Alternative.

Compared with the No Action Alternative, the increased monthly average flows in December, January, and February under Alternative 3 would likely have minor impacts on the availability and suitability of fall-run Chinook salmon spawning and incubation habitat in the Trinity River. Overall, the impacts in the reaches most heavily used by spawning fall-run Chinook salmon adults and incubating eggs/alevins would likely be negligible or slightly beneficial, with spatial variability related to channel geometry and its impact on flow-habitat relationships.

Juvenile Rearing and Emigration

In the Trinity River, fall-run Chinook salmon fry emerge from the gravel beginning in December and most emergence is complete by mid-April. Natural juvenile fall-run Chinook salmon primarily outmigrate as sub-yearlings from the Trinity River. Hatchery releases of fall-run Chinook salmon also include mostly smolts released primarily in late spring and fall. Peak outmigration occurs in March, April, and May but can extend to July based on monitoring in the lower Trinity River near the town of Willow Creek (Moyle 2002, Chesney and Yokel 2004). The effects of flow and water temperature on rearing and emigrating fall-run Chinook salmon may therefore occur primarily from December through July.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Substantial (greater than 5%) differences in modeled monthly average Trinity River flows between Alternative 3 and the No Action Alternative would occur in December–April of below normal and wetter water years. In June of wet water years there would be a minor (less than 5%) decrease in modeled monthly average flow under Alternative 3 compared with the No Action Alternative. These changes would have variable effects on the suitability for rearing and emigrating fall-run Chinook salmon in the Trinity River. In all other months and water year types there would be little or no difference in monthly average flow between Alternative 3 and the No Action Alternative and no effects on fall-run Chinook salmon would be expected.

Modeled monthly average flow in December of wet water years would increase from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 (Table O_Trin_Alt3) and may result in changes in observed and predicted WUA for fry and juvenile fall-run Chinook salmon that would vary by reach (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). From Lewiston Dam to Dutch Creek, fry WUA would increase and juvenile WUA would decrease. In the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, WUA for both fry and juveniles would decrease. From South Fork Trinity River to Weitchpec, fry WUA would increase and juvenile WUA would decrease slightly (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In January and February in wet water years, modeled monthly average flow increases from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3 (January) and from 1,843 cfs under the No Action Alternative to 1,962 cfs under Alternative 3 (February) would result in increases in fry and juvenile WUA from Lewiston Dam to Dutch Creek, decreases in fry and juvenile WUA from Dutch Creek to North Fork Trinity River, an increase in fry and decrease in juvenile WUA from North Fork Trinity River to South Fork Trinity River, and a slight increase in fry and slight decrease in juvenile WUA from South fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The modeled December flow increase in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 would increase fry WUA and decrease juvenile WUA in the reach from Lewiston Dam to Dutch Creek, decrease fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and would increase fry WUA and decrease juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In February of above normal water years, the increase in modeled monthly average flow from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3 would have the same effect on fry and juvenile fall-run Chinook salmon WUA as the monthly flow changes in December in wet water years.

Modeled monthly average flows under Alternative 3 would decrease in below normal water years in March (from 427 to 400 cfs) and in wet water years in April (from 1,035 to 957 cfs) compared to the No Action Alternative (Table O-246). The modeled March flow reduction would increase WUA for fry and juvenile fall-run Chinook salmon in all reaches of the Trinity River relative to the No Action Alternative, while the April flow reduction would have variable effects on fry and juvenile WUA (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In the reach from Lewiston Dam to Dutch Creek, the modeled April flow reduction would slightly reduce fry WUA and increase juvenile WUA. In downstream reaches, the April flow reduction would increase fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and from North Fork Trinity River to South Fork Trinity River. In the reach from South Fork Trinity River to Weitchpec, the modeled April flow reduction would reduce fry WUA and increase juvenile WUA relative to the No Action Alternative.

Where the channel is naturally unconfined and not overly incised and in locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships and rearing WUA in some restored areas may exhibit a stronger positive relationship to flow up to approximately 3,500 cfs (Cooper-Hertel et al. 2022). Consequently, fall-run Chinook salmon WUA in all reaches is likely to vary spatially with channel confinement and incision and in WUA in restored areas may be greater than described in U.S. Fish and Wildlife Service and Hoopa Valley Tribe (1999). See Section O.4.24.1.1 for additional details. Compared with the No Action Alternative, the changes in WUA for fall-run Chinook salmon fry and juveniles may have short-term, spatially variable effects on the ability of these life stages to access cover and preferred habitat that would occur in certain water year types during the rearing and emigration period and in some reaches of the Trinity River.

The modeled flow increases in December, January, and February of wet water years may result in negligible changes in monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17). Similarly, the modeled flow increases in December of below normal water years and February of above normal water years would have little or no effect on modeled monthly average water temperatures in the Trinity River below Lewiston Dam relative to the No Action Alternative (Figure O-19 and Figure O-18, respectively). From December through February, modeled monthly average water temperatures under Alternative 3 would remain well below the 62.6°F water temperature objective for emigrating juvenile fall-run Chinook salmon recommended for normal and wetter water year types and the 68°F objective recommended for dry and critically dry water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the objectives are intended to be measured at Weitchpec and applicable prior to July 9, historical data and model results suggest that Trinity River water temperatures in December–February would remain below both objectives under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating fall-run Chinook salmon under Alternative 3 relative to the No Action Alternative.

The modeled March and April flow reductions under Alternative 3 would have minor effects on modeled monthly average water temperature in the Trinity River below Lewiston Dam relative to the No Action Alternative (Figure O-19 and Figure O-17, respectively). Although the objectives are intended to be measured at Weitchpec and applicable prior to July 9, historical data and model results suggest that Trinity River water temperatures in March and April under the modeled monthly average flows under Alternative 3 would likely remain below the recommended 62.6°F and 68°F water temperature objectives at Weitchpec (Assarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating fall-run Chinook salmon under Alternative 3 relative to the No Action Alternative.

The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 3 through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives in portions of the fall-run Chinook salmon juvenile rearing and emigration period at downstream locations in some water year types, water temperatures under Alternative 3 and the potential impacts on fall-run Chinook salmon would not differ substantially from the No Action Alternative. Compared with the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of fall-run Chinook salmon rearing and emigration habitat, with considerable variability related to channel geometry and its impact on flow-habitat relationships. Substantial impacts on fall-run Chinook salmon would be unlikely.

Adult Upstream Migration and Holding

Adult fall-run Chinook salmon typically enter the Trinity River from September through October (Moyle et al. 2015). Two to four weeks after river entry, adults have made it to the primary spawning reach which extends from Lewiston Dam downstream to the confluence of the North Fork Trinity River. After entering freshwater, fall-run Chinook salmon remain in deep pools until the onset of the spawning season, which typically ranges from the third week of September through November, peaking in October (Chensey and Knechtle 2012). The effects of flow and water temperature on migrating and pre-spawning fall-run Chinook salmon adults may therefore occur from August through November.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

During the fall-run Chinook salmon upstream migration and pre-spawning period, there would be no difference in modeled monthly average flow between Alternative 3 and the No Action Alternative, except a slight increase of 6 cfs in November in above normal water years (Table O-246). The November difference would be unlikely to change water depth or other habitat conditions that could affect migrating or pre-spawning adult fall-run Chinook salmon and there would be effects relative to the No Action Alternative.

Modeled monthly average flows in August, September, and October when adult fall-run Chinook salmon are migrating and holding would be the same under Alternative 3 as under the No Action Alternative (Table O-246). Under both alternatives, modeled average August and September flows would be approximately 760 cfs or greater in all water year types and substantially greater in wetter years. Modeled average flows in October would be 373 cfs in all water year types. Under both alternatives, September through October flows would maintain suitable water temperatures for adult upstream migration (60°F to 56°F in September, and <56°F from August through October at Douglas City [RM 93.7]; Table O-11) (Assarian et al. 2023).

Compared with the No Action Alternative, the differences in monthly average flows and associated water temperature differences under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of fall-run Chinook salmon upstream migration and pre-spawning habitat and substantial impacts on fall-run Chinook salmon would be unlikely.

O.6.28 Klamath Mountains Province Steelhead DPS

O.6.28.1 Trinity River

Monthly average flows in the Trinity River below Lewiston Dam would generally be similar under Alternative 3 to flows under the No Action Alternative. Minor differences in monthly average flows between Alternative 3 and the No Action Alternative would occur in November through April and in June of some water year types, with most differences less than 5%. Like the No Action Alternative, seasonal flow releases under Alternative 3 are expected to maintain a low risk of disease outbreaks for steelhead by maintaining minimum flows and relatively cool water temperatures.

Spawning and Egg/Alevin Incubation

Spawning across run types in the Trinity River may occur anytime from December through May so effects of flow and water temperature on spawning may occur during this period.

Steelhead eggs and alevins across run types in the Trinity River may be present in the gravel from December through June, so effects of flow and water temperature on steelhead eggs and alevins may occur during this period.

Potential Changes to Steelhead from Seasonal Operations

Under Alternative 3, modeled monthly average flows in the Trinity River below Lewiston Dam in December of wet and below normal water years, January of wet water years, and February of wet and above normal water years would be at least 5% greater than the No Action Alternative (Table O_Trin_Alt3). Monthly average flows in March of below normal water years and April of wet water years would be at least 5% less than the No Action Alternative. These changes would have variable effects on the availability and suitability of spawning and egg/alevin incubation habitat for steelhead. From May through November, modeled monthly average flows under Alternative 3 would be the same as the No Action Alternative or would not differ substantially (by more than 5%) in any month or water year type.

In December, modeled monthly average flow would increase in wet water years from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 and in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 (Table O-246). In January, modeled monthly average flow would increase in wet water years from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3. In February, modeled monthly average flow would increase in wet water years from 1,843 cfs under the No Action Alternative to 1,962 cfs under Alternative 3 and in above normal water years from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3.

The modeled December flow increases may result in a negligible increase in WUA for steelhead spawning in the reach from Dutch Creek to North Fork Trinity River in wet water years but would have little to no change in WUA for steelhead spawners in downstream reaches or in below normal water years (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The modeled January flow increase would not change WUA for steelhead spawning in the reach from Dutch Creek to South Fork Trinity River but may negligibly increase spawning WUA from South Fork Trinity to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The modeled February flow increases would have little to no change in spawning WUA.

The modeled flow increases in December, January, and February of wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17) and average water temperatures under Alternative 3 would remain well below the upper water temperature objective of 56°F to protect spawning coho salmon in the reach from Lewiston Dam to the North Fork Trinity River (Table O-11). Similarly, the modeled flow increases in December of above normal water years and February of above normal water years would cause only negligible changes in modeled monthly average water temperature and there would be no change in the temperature suitability for spawning steelhead or incubating eggs/alevins relative to the No Action Alternative. Compared to the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of steelhead spawning and egg/alevin incubation habitat, with considerable variability related to channel geometry and its effect on flow-habitat relationships.

Modeled monthly average flows under Alternative 3 would decrease by at least 5% in below normal water years in March (from 427 to 400 cfs) and in wet water years in April (from 1,035 to 957 cfs) compared to the No Action Alternative (Table O-246). The March flow decrease would result in a slight increase in WUA for spawning steelhead in the reach from North Fork Trinity to South Fork Trinity, and little to no change in WUA from Lewiston Dam to North Fork Trinity and South Fork Trinity to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The April flow decrease would result little to no change in WUA for spawning steelhead in any of the reaches The March and April decreases would have little impact on modeled monthly average water temperature and only negligible changes relative to the No Action Alternative (Figure O-19 and Figure O-17, respectively). Water temperatures in March and April under Alternative 3 would remain well below the 56°F upper water temperature objective for spawning salmon. Compared to the No Action Alternative, the flow decreases in March and April under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of steelhead spawning and egg/alevin incubation habitat.

Juvenile Rearing and Emigration

Rearing or moving (migrating or redistributing) fry and/or juveniles can occur downstream of Lewiston Dam any time of year with three peak emigration times in March, May/June, and October/November.

Potential Changes to Steelhead from Seasonal Operations

Seasonal operations under Alternative 3 would have spatially and temporally variable effects on the availability and suitability of juvenile rearing and emigration habitat for steelhead. Compared to the No Action Alternative, substantial differences (greater than 5%) in modeled monthly average flows would occur in some water year types in December–April (Table O-246). In all other months and water year types there would be little or no difference in monthly average flow between Alternative 3 and the No Action Alternative and no effects on steelhead would be expected in those months (May–November).

In December, the increase in modeled monthly average flow in wet water years from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 (Table O-246) would result in little to no change in measured or estimated WUA for steelhead fry or juveniles from Lewiston Dam to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The modeled December flow increase in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 would have similar effects on WUA for steelhead fry and juveniles as the December flow increase in wet water years.

In January and February in wet water years, modeled flow increases from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3 (January) and from 1,843 cfs under the No Action Alternative to 1,962 cfs under Alternative 3 (February) would result in an increase in measured and predicted fry WUA in the reach from Lewiston Dam to Dutch Creek and South Fork Trinity to Weitchpec and little to no change in juvenile WUA (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

In February of above normal water years, the increase in modeled monthly average flow from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3 would have little to no effect on fry and juvenile steelhead WUA.

In locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships (Cooper-Hertel et al. 2022). Consequently, steelhead WUA in all reaches is likely to vary spatially with channel confinement and incision.

The modeled flow increases in December, January, and February of wet water years may result in negligible changes in monthly average water temperature in the Trinity River below Lewiston Dam. Average water temperatures under Alternative 3 would remain well below the 59°F water temperature objective for emigrating juvenile salmonids recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the 59°F objective is intended to be measured at Weitchpec and applicable prior to June 4, historical data and model results suggest that water temperatures in November, December, February, and March would remain below the 59°F objective under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating

steelhead trout under Alternative 3 relative to the No Action Alternative. Similarly, the flow increases in December of above normal water years and February of above normal water years would cause only negligible changes in modeled monthly average water temperature and there would be no change in the temperature suitability for spawning steelhead or incubating eggs/alevins relative to the No Action Alternative. The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 3 through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives in portions of some water year types under Alternative 3, water temperatures and the potential effects on steelhead would not differ from the No Action Alternative. Compared to the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of steelhead trout rearing and emigration habitat, with considerable variability related to channel geometry and its effect on flow-habitat relationships.

Modeled monthly average flows under Alternative 3 would decrease in below normal water years in March (from 427 to 400 cfs) and in wet water years in April (from 1,035 to 957 cfs) compared to the No Action Alternative (Table O-246). The March flow reduction would increase WUA for fry and juvenile steelhead overall across all reaches of the Trinity River relative to the No Action Alternative, while the April flow reduction would have little to no change on fry and juvenile WUA (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

The March and April flow reductions would have little effect on modeled monthly average water temperature and only negligible changes relative to the No Action Alternative (Figure O-19 and Figure O-17, respectively). Modeled monthly average water temperatures in March and April under Alternative 3 would remain well below the 59°F upper water temperature objective for emigrating juvenile salmonids. Compared to the No Action Alternative, the change in seasonal operations in March and April under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of steelhead rearing and emigration habitat, with considerable variability related to channel geometry and its impact on flow-habitat relationships. Substantial adverse impacts on steelhead fry and juveniles would be unlikely and Alternative 3 may slightly benefit fry and juvenile habitat in some water years.

Adult Upstream Migration and Holding

Consistent adult monitoring data are limited by environmental conditions and challenges in overlapping populations with different run timing, kelting or “runbacks”, and half pounders but summer/fall steelhead (stream-maturing steelhead) are thought to return from the ocean about April through November and hold for varying lengths of time in the Klamath-Trinity watershed (Moyle et al. 2017, Moyle et al. 2015, Pinnix et al 2007). Winter steelhead (ocean-maturing steelhead) can return from the ocean about November through March (Moyle et al. 2017, Moyle et al. 2015, Pinnix et al 2007). Given the overlapping run timings and varying life history strategies, adults at various stages of maturation can enter the Klamath-Trinity watershed, hold in Trinity River, and/or migrate up or down Trinity River and into tributaries in any month of the year.

Potential Changes to Steelhead from Seasonal Operations

Alternative 3 relative to the No Action Alternative would have differences in flow that vary by month and water year type, and are described in detail in the preceding sections and shown in Table O-246. These differences may result in minor, short-term changes in physical habitat conditions but monthly average flows from would be equal to our greater than 300 cfs in all months and all water year types, and substantially greater in some months and water years, to provide a range of suitable depth and velocity for upstream passage as well as access to cover and holding habitat to support pre-spawning steelhead.

Seasonal operations under Alternative 3 would have spatially and temporally variable effects on the availability and suitability of adult holding habitat for steelhead. Compared to the No Action Alternative, substantial differences (greater than 5%) in modeled monthly average flows would occur in some water year types in December–April of Alternative 3 (Table O-246). In all other months and water year types there would be little or no difference in monthly average flow between Alternative 3 and the No Action Alternative and no effects on steelhead would be expected in those months (May–November).

In December, the increase in modeled monthly average flow in wet water years from 1,133 cfs under the No Action Alternative to 1,252 cfs under Alternative 3 (Table O-246) would result in a decrease in WUA for steelhead adult holding from Dutch Creek to North Fork Trinity River and little to no change in downstream reaches (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999) (WUA for adult holding over 800 cfs is not available for the reach between Lewiston Dam and Dutch Creek).

The modeled December flow increase in below normal water years from 931 cfs under the No Action Alternative to 997 cfs under Alternative 3 would result in negligible decreases from Dutch Creek to North Fork Trinity and South Fork Trintiy to Weitchpec and little to no change from North Fork Trinity to South Fork Trinity (WUA for adult holding over 800 cfs is not available for the reach between Lewiston Dam and Dutch Creek).

In January and February in wet water years, modeled flow increases from 1,872 cfs under the No Action Alternative to 2,007 cfs under Alternative 3 (January) and from 1,843 cfs under the No Action Alternative to 1,962 cfs under Alternative 3 (February) would result in negligible decreases in measured and predicted adult holding WUA in the reach from Dutch Creek to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999) (WUA is not available between Lewiston Dam and Dutch Creek).

In February of above normal water years, the increase in modeled monthly average flow from 1,194 cfs under the No Action Alternative to 1,302 cfs under Alternative 3 would result in negligible decreases in adult steelhead holding WUA from Dutch Creek to North Fork Trinity and from South Fork Trinity to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999) (WUA is not available between Lewiston Dam and Dutch Creek).

In locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships (Cooper-Hertel et al. 2022). Consequently, steelhead WUA in all reaches is likely to vary spatially with channel confinement and incision.

The modeled flow increases in December, January, and February of wet water years may result in negligible changes in monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative (Figure O-17) and modeled monthly average water temperatures under Alternative 3 would remain well below the 59°F water temperature objective for emigrating juvenile salmon recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the 59°F objective is intended to be measured at Weitchpec and applicable prior to June 4, historical data and model results suggest that water temperatures in November, December, February, and March would remain below the 59°F objective under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for migrating and holding adult steelhead under Alternative 3 relative to the No Action Alternative. Similarly, the flow increases in December of above normal water years and February of above normal water years would cause only negligible changes in modeled monthly average water temperature and there would be no change in the water temperature suitability for adult steelhead migration and holding relative to the No Action Alternative. The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 3 through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives in portions of some water year types under Alternative 3, water temperatures and the potential effects on steelhead would not differ from the No Action Alternative. Compared to the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of adult steelhead migration and holding habitat, with considerable variability related to channel geometry and its effect on flow-habitat relationships.

Modeled monthly average flows under Alternative 3 would decrease in below normal water years in March (from 427 to 400 cfs) and in wet water years in April (from 1,035 to 957 cfs) compared to the No Action Alternative (Table O-246). The March flow reduction would increase WUA for fry and juvenile steelhead overall across all reaches of the Trinity River relative to the No Action Alternative, while the April flow reduction would have little to no change on fry and juvenile WUA (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

The March and April flow reductions would have little effect on modeled monthly average water temperature and only negligible changes relative to the No Action Alternative (Figure O-19 and Figure O-17, respectively). Modeled monthly average water temperatures in March and April under Alternative 3 would remain well below the 59°F upper water temperature objective for migrating and holding adult steelhead. Compared to the No Action Alternative, the change in seasonal operations in March and April under Alternative 3 would cause only negligible changes in factors affecting the availability or suitability of adult steelhead migration and holding habitat, with considerable variability related to channel geometry and its effect on flow-habitat relationships.

Alternative 3 may result in some minor decreases overall in steelhead adult holding habitat relative to the No Action Alternative but substantial adverse impacts are unlikely because this the changes are very small relative to the total amount of holding habitat and would only occur in a few months and only in some water year types.

O.6.29 Northern DPS Green Sturgeon

O.6.29.1 Trinity River

Spawning and Egg Incubation

Northern DPS green sturgeon adults spawn primarily from March through July, though most spawning takes place from April to June (O.1.2.5.1, *Green Sturgeon, Northern DPS*). Northern DPS green sturgeon eggs hatch approximately a week after fertilization, and optimal temperatures for incubation range from 51.8–62.6°F (Eenennaam et al. 2005).The effects analysis period for incubating eggs is considered to be the same as the spawning period due to the short incubation period and includes March through July.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be similar to flows under the No Action Alternative during spawning and egg incubation periods for green sturgeon. Under Alternative 3, reductions in flow greater 5% would occur in March of below normal years and in April of wet years compared to the No Action Alternative (Table O-246). Under Alternative 3 compared with the No Action Alternative, flow decreases would occur during the green sturgeon spawning and egg incubation period. These reductions in flows would likely be negligible for spawning habitat and egg incubation because flows would remain above 400 cfs.

Larval and Juvenile Rearing and Emigration

The northern DPS green sturgeon spawning period is from March through July, and the larval period is considered to be March through September. The juvenile stage of green sturgeon begins when metamorphosis of the larva is complete, typically about 45 days after hatching and approximately up to 2 cm TL. Juveniles (up to 150 cm TL) typically slowly migrate downstream, and rear in the lower Klamath River for up to a year or until approximately their first summer, and optimal growth temperatures range from 59–66.2°F (Moyle 2002; Mayfield and Cech, Jr. 2004). During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near Burnt Ranch to the Klamath River Estuary (Section O.1.2.5.1, *Green Sturgeon, Northern DPS*). The effects analysis period for larval and juvenile life stages in the Trinity River should be considered April to September.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be similar to flows under the No Action Alternative during larval and juvenile rearing and emigration periods for green sturgeon. Under Alternative 3, monthly average flows greater than 5% in reduction would occur in April of wet years compared to the No Action Alternative (Table O-246). Under Alternative 3, monthly average flows would be almost identical to the No Action Alternative from April through September and would correspond to the No Action Alternative

flows that are currently managed to improve habitat conditions for anadromous fish. Alternative 3 monthly average flows would have no impacts to negligible impacts on larval and juvenile rearing and emigration of green sturgeon when compared with the No Action Alternative, even with reduced flows during wet years.

Green sturgeon larvae and juveniles are only known to occur within the lower 43 miles of the Trinity River, and after hatching, they begin to migrate downstream. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several tributaries that enter the Trinity River, and results of previous water temperature modeling for the Trinity River predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43, and smaller temperature differences are expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling impact of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations are not likely to have a detectable influence on the water temperature suitability for larval and juvenile rearing and emigration of green sturgeon.

Adult Upstream Migration and Holding

Green sturgeon adults enter the Trinity River from the Klamath River Estuary as early as February to make their way upstream to spawn in deep pools from the lower section of the mainstem Trinity River to the confluence with the Klamath River, approximately 43 miles to Gray's Falls near Burnt Ranch. After spawning, the adults remain in mainstem river pools for varying amounts of time, representing distinct migration patterns. Directly after spawning, 25% emigrate back to the Klamath River Estuary and ocean, but freshwater residency may last up to 199 days (Moyle 2002, Section O.1.3.2.5, *Green Sturgeon, Northern DPS*). With the extended adult holding period, effects analysis of flow and water temperature on adult upstream immigration, holding, and emigration may occur from February through December.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be similar to flows under the No Action Alternative. Under Alternative 3 increases in flow greater than 5% would occur in December of wet and above normal years, in January of wet years, and in February of wet and above normal years when compared to the No Action Alternative. Under Alternative 3, Flow reductions greater than 5% would occur in February of below normal years and in April of wet years (Table O-246).

During the green sturgeon upstream migration and holding period, generally flows would increase in February and flows would decrease in March and April under Alternative 3 compared with the No Action Alternative. The increase in flow in February of wet years would be negligible to beneficial because releases would provide adequate passage and pool holding habitats. The reduction in flows in April of wet years would be negligible to upstream migration and pool holding habitats because flows would remain above 957 cfs. Monthly average flows during the summer and fall months under Alternative 3 compared with the No Action Alternative would be identical and would provide adequate flows for downstream movements and pool habitats. Under Alternative 3, increased flows in December in wet and below normal water years would be beneficial to aid downstream migration and pool habitats.

O.6.30 Eulachon

O.6.30.1 Lower Klamath River from Confluence With Trinity River to Pacific Ocean

Spawning and Egg Incubation

Eulachon adults spawn from December and through May, with peak spawning occurring in March and April (O.1.2.6, *Eulachon*). Eulachon eggs hatch in 20 to 40 days depending on water temperature, with cooler temperatures leading to longer incubation times. Spawning is reported to occur at temperatures from 39 to 50°F; colder temperatures may stop migration (National Marine Fisheries Service 2017). The effects analysis period for eulachon spawning and egg incubation is December through June.

Potential Changes to Eulachon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative during the eulachon spawning and egg incubation periods, except in below normal water years in March and wet water years in April when the Alternative 3 flows would have a greater than 5% decrease compared to the No Action Alternative flows (Table O-246). The reduction in flows in wet and below normal years would likely be negligible for eulachon spawning habitat and egg incubation as flows would still be above 400 cfs. Alternative 3 flows would be greater than 5% higher than the No Action Alternative in wet years from December through February; during above normal years in February; and during below normal years in December (Table O-246). These higher flows are unlikely to have a detectable influence on habitat suitability for eulachon spawning and egg incubation in the lower Klamath River because of all the other water that enters the system during this time period. In addition to water released at Lewiston Dam, flows in this portion of the lower Klamath River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River (e.g., Canyon Creek, North Fork Trinity River, New River, South Fork Trinity River, and small tributaries).

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Water temperature within this section of the Klamath River below the confluence with the Trinity River is influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 3 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for spawning and egg incubation of eulachon in the Lower Klamath River.

Larval Emigration

Eulachon spawning period is from December through May and eggs hatch in 20 to 40 days, so the larval period is considered to be January through June. After hatching, larval eulachon are

quickly carried out to the ocean by river currents (Scott and Crossman 1973). Larval eulachon only remain in the Klamath River for about 5 days until they are washed out to sea. Larvae live on their yolk sac reserves after hatching —they do not feed while in fresh water (Gustafson et al. 2022). Effects of flow and water temperature on eulachon larvae may occur from January through June in the Klamath River.

Potential Changes to Eulachon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative during the eulachon larval emigration period, except in below normal water years in March and wet water years in April when the Alternative 3 flows would have a greater than 5% decrease than the No Action Alternative flows (Table O-246). The reduction in flows in wet and below normal years would likely be negligible for eulachon spawning habitat and egg incubation as flows would still be above 400 cfs. Alternative 3 flows would be greater than 5% higher than the No Action Alternative in wet years in January and February and during above normal years in February (Table O-246). Greater than 5% increases in flow under Alternative 3 compared to the No Action Alternative during wet and above normal years would provide increased water velocity and, similar to flow increases from spring freshets, could benefit eulachon larvae as they are washed out to the ocean.

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Water temperature within this section of the Klamath River below the confluence with the Trinity River is influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 3 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for eulachon larval emigration.

Adult Upstream Migration

The spawning migration period for adult eulachon in the Klamath River begins in December and continues until May, with peak migration occurring in March and April (Yurok Tribal Fisheries Program 1998; Larson and Belchik 1998, Section O.1.2.6). Eulachon distribution in the Trinity River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Eulachon are broadcast spawners most commonly over sand, though spawning substrates can range from silt, sand or gravel to cobble and detritus (California Department of Fish and Wildlife 2010; National Marine Fisheries Service 2017). Eulachon usually die after spawning. The effects analysis period for eulachon adult upstream migration is December through May.

Potential Changes to Eulachon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative during the eulachon adult upstream migration period, except in below normal water years in March and wet water years in April when the Alternative 3 flows would have a greater than 5% decrease than the No Action Alternative flows (Table O-246). The reduction in flows in wet and below normal years would likely be negligible for eulachon adult upstream migration as flows would still be above 400 cfs. Alternative 3 flows would be greater than 5% higher than the No Action Alternative in wet years from December through February; during above normal years in February; and during below normal years in December (Table O-246). These higher flows are unlikely to have a detectable influence on habitat suitability for eulachon adult upstream migration in the lower Klamath River because of all the other water that enters the system during this time period. In addition to water released at Lewiston Dam, flows in this portion of the lower Klamath River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River (e.g., Canyon Creek, North Fork Trinity River, New River, South Fork Trinity River, and small tributaries).

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Water temperature within this section of the Klamath River below the confluence with the Trinity River is influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 3 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for eulachon adult upstream migration.

O.6.31 Coastal Cutthroat Trout

O.6.31.1 Lower Klamath River from Confluence With Trinity River to Pacific Ocean

Spawning and Egg Incubation

Generally, spawning of anadromous and resident coastal cutthroat trout may occur from September to April (Moyle 2002). Coastal cutthroat trout are associated with shaded streams and instream cover with water temperatures below 64°F, while preferred temperatures range from 48–54°F, with spawning temperatures of 43–63°F. (Moyle 2002). Spawning habitat is typically found in headwater streams with 1–3 feet/sec flow velocities and unembedded small- to medium-sized gravel (0.08–4 inches) (Moyle 2002). Embryos hatch about 6–7 weeks following incubation and alevins emerge 1–2 weeks thereafter (Moyle 2002).

The effects analysis period for coastal cutthroat trout spawning and egg incubation is September through June.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative, except in below normal water years in March and wet water years in April when the Alternative 3 flows would be more than 5% lower than the No Action Alternative flows (Table O-246). The reduction in flows in wet and below normal years would be unlikely to reduce the availability or suitability of coastal cutthroat trout spawning pools and egg incubation habitat in adjacent tributaries as Trinity River flows do not impact tributaries. Alternative 3 flows would be greater than 5% higher than the No Action Alternative in wet years from December through February; during above normal years in February; and during below normal years in December (Table O-246). These increases in flows are not anticipated to have a detectable impact on coastal cutthroat trout spawning and egg incubation.

Seasonal operations under Alternative 3 are not expected to impact suitable habitat conditions for coastal cutthroat trout spawning and egg incubation in the Trinity River. Compared with the No Action Alternative, changes in the availability or suitability of coastal cutthroat trout juvenile spawning and egg incubation habitat under Alternative 3 would likely be negligible since Trinity River flows do not impact tributaries where coastal cutthroat trout spawn.

Juvenile Rearing and Emigration

Juvenile coastal cutthroat trout may spend anywhere from one to three years in freshwater to rear. Cutthroat fry are typically associated with slow water velocities (less than 1 foot/sec, while prefer <0.3 feet/sec), and trout are typically found in shaded streams with instream cover and water temperatures below 64°F, while preferred temperatures range from 48–54°F (Moyle 2002).

For the amphidromous life history, most coastal cutthroat trout leave their streams for the summer months and return to overwinter in fresh water, even as non-spawning fish (Moyle 2002). During outmigration, many of the trout migrate to estuaries or lagoons and if they do go to the ocean, they remain close to the coast (Moyle 2002). In a Klamath River tributary, yearling and older cutthroat emigration occurred mainly between April and June (Moyle 2002). For individuals that emigrated to an estuary, Wallace (2004) found that the residence time within the estuary ranged from 5 to 89 days, with a mean of 27 days. Resident coastal cutthroat trout will remain in freshwater their entire lives, rather than emigrating to a lagoon or estuary or the ocean.

The effects analysis period for coastal cutthroat trout juvenile rearing and emigration is April through June for amphidromous coastal cutthroat trout and January through December for resident coastal cutthroat trout.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative, except in below normal water years in March and wet water years in April when the Alternative 3 flows would be more than 5% lower than the No Action Alternative flows (Table O-246). These reductions in flows in wet and below normal years would likely be negligible for coastal cutthroat trout juvenile rearing and emigration as flows would still be above 400 cfs and, with the combined influence of both the upper Klamath River and several tributaries that enter the Trinity River, are unlikely to have a

detectable influence on coastal cutthroat trout juvenile rearing and emigration. Alternative 3 flows would be greater than 5% higher than the No Action Alternative in wet years from December through February; during above normal years in February; and during below normal years in December (Table O-246). These increases in flows are not anticipated to have a detectable impact on coastal cutthroat trout juvenile rearing and emigration.

Water temperature and habitat conditions within the Klamath River below the confluence with the Trinity River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 3 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for coastal cutthroat trout juvenile rearing and emigration.

Seasonal operations under Alternative 3 are expected to maintain suitable habitat conditions for coastal cutthroat trout juvenile rearing and emigration in the Trinity River. Compared to the No Action Alternative, substantial changes in the availability or suitability of coastal cutthroat trout juvenile rearing and emigration habitat would be minimal and unlikely to have adverse impacts on coastal cutthroat trout, and minor benefits to larval emigration in January and February.

Adult Holding and Migration

Migration of coastal cutthroat trout to freshwater typically occurs between August and October between the ages of one and five (Moyle 2002). While most anadromous salmonids die after completing spawning, coastal cutthroat may survive spawning, re-enter the ocean, and return the following year(s) to spawn up to five times (Moyle 2002). Overwintering coastal cutthroat trout prefer pools with cover (e.g., logs, undercut banks, boulders) (Moyle 2002).

The effects analysis period for coastal cutthroat trout adult holding and migration is August through October for amphidromous coastal cutthroat trout and January through December for resident coastal cutthroat trout.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative, except in below normal water years in March and wet water years in April when the Alternative 3 flows would be more than 5% lower than the No Action Alternative flows (Table O-246). The reduction in flows in wet and below normal years would likely be negligible for coastal cutthroat trout adult holding and migration as flows would still be above 400 cfs and, with the combined influence of both the upper Klamath River and several tributaries that enter the Trinity River, are unlikely to have a detectable influence on coastal cutthroat trout adult holding and migration. Alternative 3 flows would be greater than 5% higher than the No Action Alternative in wet years from December through February; during above normal years in February; and during below normal years in December (Table O-246). These increases in flows are not anticipated to have a detectable impact on coastal cutthroat trout adult holding and migration.

Water temperature and habitat conditions within the Klamath River below the confluence with the Trinity River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 3 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for coastal cutthroat trout adult holding and migration.

Seasonal operations under Alternative 3 are expected to maintain suitable habitat conditions for coastal cutthroat trout adult holding and migration in the Trinity River. Compared to the No Action Alternative, substantial changes in the availability or suitability of coastal cutthroat trout adult holding and migration habitat would be minimal and unlikely to have adverse impacts on coastal cutthroat trout.

O.6.32 Brown Trout

O.6.32.1 Trinity River

Spawning and Egg Incubation

Brown trout spawn in fall and winter, most commonly in November and December in California (Moyle 2002). Trout typically mature and spawn in their second or third year, but they may wait longer (7 or 8 years) (Moyle 2002). Adults begin selecting spawning locations when water temperatures are between 42.8–50ºF (Moyle 2002). Spawning habitat is comprised of pea- to walnut-sized gravel in less turbulent waters, which are typically found at pool tailouts (Moyle 2002). Embryos hatch in 7–8 weeks (ranging from 4–21 weeks), with alveins emerging three to six weeks later, depending on water temperature.

The effects analysis period for brown trout spawning and egg incubation is November through April.

Potential Changes to Brown Trout from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative during the brown trout spawning and egg incubation periods, except in below normal water years in March (6% reduction in flow) and wet water years in April (8% reduction in flow) (Table O-246). These increases in flows are not anticipated to have a detectable impact on brown trout spawning and egg incubation.

Seasonal operations under the Alternative 3 are expected to maintain suitable habitat conditions for brown trout spawning and egg incubation in the Trinity River. Compared to the No Action Alternative, substantial changes in the availability or suitability of brown trout spawning and egg incubation habitat would be minimal and unlikely to have adverse impacts on brown trout.

Juvenile Rearing and Emigration

The ideal temperature range for brown trout is between 53.6–68°F, with optimal growth between 62.6–64.4°F; they can survive for only short period at higher temperatures up to 84.2°F (Moyle 2002). Cold temperatures reduce brown trout's ability to effectively capture prey: when temperatures reduced from 58.5°F to 42.3°F the foraging effectiveness reduced from 96% to 53% (Watz and Piccolo 2010, as cited in Asarian et al. 2023).

In California, brown trout reach 2–3 inches in length their first year, 5–6 inches in their second year, 8–11 inches in their third, and 14–16 inches in their fourth year (Moyle 2002). Fry rear in edge-water habitat that is slow and shallow (<12 inches deep), with juveniles selecting riffles and pools with deeper water (20–30 inches), higher velocities (0.3–1.3 feet/second), and cover from overhead, rocks, and logs (Moyle 2002). It is uncertain the degree to which brown trout exhibit an anadromous life history in the Trinity River, with juveniles emigrating to the ocean, or are riverine (potamodromous) with juveniles emigrating further downstream while continuing to remain in freshwater. In Ireland, where they are native, brown trout juveniles emigrated to brackish or marine habitats throughout the year, with distinct seasonal peeks in spring (March through June) and fall (September through December) (Wynne et al. 2023).

The effects analysis period for brown trout juvenile rearing and emigration is January through December.

Potential Changes to Brown Trout from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative during the brown trout juvenile rearing and emigration periods, except in below normal water years in March (6% reduction in flow) and wet water years in April (8% reduction in flow) (Table O-246). These increases in flows are not anticipated to have a detectable impact on brown trout juvenile rearing and emigration.

Seasonal operations under the Alternative 3 are expected to maintain suitable habitat conditions for brown trout juvenile rearing and emigration in the Trinity River. Compared to the No Action Alternative, substantial changes in the availability or suitability of brown trout juvenile rearing and emigration habitat would be minimal and unlikely to have adverse impacts on brown trout.

Adult Holding and Migration

Upstream migration occurs in fall and winter, prior to spawning, which most commonly occurs in November and December. Sullivan and Hilemean (2018) noted a shift in migration timing on the Trinity River to later in the season following the implementation of the Record of Decision (ROD) flows (2005-2011, 2017), as compared to the between baseline Pre-ROD flows (1982–2002). In rivers, adults will hold in a wide range of habitats, but are often associated with low velocity pools ranging from 2.3–11.5 feet deep that have cover (Moyle 2002).

The effects analysis period for brown trout adult holding and migration is January through December with migration primarily in November and December.

Potential Changes to Brown Trout from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative during the brown trout adult holding and migration periods, except in below normal water years in March (6% reduction in flow) and wet water years in April (8% reduction in flow) (Table O-246). These increases in flows are not anticipated to have a detectable impact on brown trout adult holding and migration.

Seasonal operations under the Alternative 3 are expected to maintain suitable habitat conditions for brown trout adult holding and migration in the Trinity River. Compared to the No Action Alternative, substantial changes in the availability or suitability of brown trout adult holding and migration habitat would be minimal and unlikely to have adverse impacts on brown trout.

O.6.33 Trinity Reservoir Species

O.6.33.1 Trinity Reservoir

Spawning and Egg Incubation

Coldwater fish species (rainbow trout, brown trout, Kokanee, and landlocked Chinook salmon) in the lake generally migrate into tributaries to spawn either during from December through March (rainbow trout), November–December (brown trout), or August through April (kokanee). Populations of rainbow trout, brown trout, and Kokanee are sustained through a combination of natural reproduction and fish hatchery stocking practices. Landlocked Chinook salmon do not typically reproduce (Perales et al. 2015) and are supported by annual stocking practices.

Warmwater fish species (smallmouth bass, largemouth bass, white catfish, and brown bullhead) typically rely on habitat in the lake during all life stages. In general, smallmouth and largemouth bass spawn from April through July in shallow water (1.5 feet to 6.0 feet deep) along the lake margins at water temperatures ranging from 55°F to 75°F (Moyle 2002). These nests are vulnerable to fluctuations in water levels. Rapid drops in water levels may cause guarding males to abandon the nests, increase predation, and limit water circulation and dissolved oxygen levels around the eggs (USFWS 1983, Habitat Suitability Information: Smallmouth Bass, FWS/OBS-82/10.36). White catfish spawning typically occurs during June and July when water temperatures exceed 68°F, but spawning can sometimes extend into September; spawning occurs in sandy substrate adjacent to cover (e.g., rocks, wood, or aquatic vegetation) and eggs hatch in about a week (Moyle 2002). Brown bullhead spawn from May through mid-July and will build their nests in sand or gravel near cover (Moyle 2002). Warmwater fish species in Trinity Lake are currently self-sustaining through natural reproduction.

The effects analysis period for coldwater fish species spawning and egg incubation is August through April. The effects analysis period for warmwater fish species spawning and egg incubation is April through September.

Potential Changes to Trinity Reservoir Fish Species from Seasonal Operations

Trinity Reservoir storage under Alternative 3 would generally be higher than storage under the No Action Alternative, except in wet years from April through December when Trinity Reservoir storage would be slightly lower than the No Action Alternative (Table O-247). Minor differences, less than 5%, in April–December during wet years would be unlikely to reduce the availability or suitability of spawning and egg incubation habitat for Trinity Reservoir fish species.

There would be increases in reservoir storage of greater than 5% under Alternative 3 compared with the No Action Alternative in below normal years from July through December; in dry years from August through November; and critically dry years from April through January. These increases in Trinity Reservoir storage between Alternative 3 and the No Action Alternative are not likely to have a negative impact on the water temperature and habitat suitability for spawning and egg incubation of Trinity Reservoir warmwater fish species benefit spawning and egg incubation under the assumption that an increase in reservoir volume could increase the amount of shallow edge habitat available where warmwater fish species build nests. Changes in reservoir storage between Alternative 3 and the No Action Alternative are not anticipated to impact coldwater fish species spawning and egg incubation because coldwater fish species migrate into tributaries to spawn.

Larval and Juvenile Rearing and Emigration

Rainbow trout fry emerge 3–4 weeks after fertilization and will remain in the gravel for about 2–3 weeks (Moyle 2002, USFWS 1984, Habitat Suitability Information: Rainbow Trout, FWS/OBS-82/10.60). Juvenile rainbow trout may spend two summers in their natal stream and two summers in a reservoir or lake before maturing. Brown trout fry typically hatch in 2 months, though it can range from one to five months depending on water temperature, and larvae will emerge from the gravel around one month later. Juveniles will spend several years in tributaries before emigrating to the reservoir where they will become sexually mature (Moyle 2002, Belica 2007).

Smallmouth and largemouth bass fry prefer shallow water and are vulnerable to fluctuations in water levels. These fry hatch in two to seven days and then spend another week in the nest. Larval bass stay in shallow water on the edge of vegetation (Moyle 2002). Rapid drops in water levels may cause stranding. Juvenile bass tend to live in deeper water habitats with submerged shelter (e.g., logs or boulders). White catfish will move throughout the reservoir and don't have a regular seasonal migration, thought they tend to concentrate at depts of 10–30 ft but will move deeper in the summer as temperatures increase (Moyle 2002). Brown bullhead typically live in deeper water (6–30 ft deep) in areas with aquatic plants and muddy substrate (Moyle 2002).

The effects analysis period for both coldwater and warmwater fish species larval and juvenile rearing and emigration is January through December.

Potential Changes to Trinity Reservoir Fish Species from Seasonal Operations

Trinity Reservoir storage under Alternative 3 would generally be higher than storage under the No Action Alternative, except in wet years from April through December when Trinity Reservoir storage would be slightly lower than the No Action Alternative (Table O-247). Minor differences, less than 5%, in April–December during wet years would be unlikely to reduce the availability or suitability of larval and juvenile rearing and emigration Trinity Reservoir fish species. There would be increases in reservoir storage of greater than 5% under Alternative 3 compared with the No Action Alternative in below normal years from July through December; in dry years from August through November; and critically dry years from April through January. These increases in Trinity Reservoir storage between Alternative 3 and the No Action Alternative are not likely to have a detectable influence on the water temperature and habitat suitability for larval and juvenile rearing and emigration of Trinity Reservoir fish species.

Adult Holding

The life expectancy of rainbow trout can be four to eight years in northern California lake populations. After maturing, resident rainbow trout will migrate upstream to spawn in tributaries. They can spawn annually and will quickly move back downstream to the reservoir or lake (Moyle 2002), moving to cooler, deeper waters during the summer months (Belica 2007). Brown trout typically become sexually mature at age 2 or 3 and have been found as old as can live for up to 9 years in California, spawning several times during their life (Moyle 2002, Belica 2007). Brown trout will use varying habitats within the reservoir and will also move to cooler waters in the summer habitats (Belica 2007).

Warmwater species will remain in the reservoir their entire lives. Smallmouth bass prefer narrow bays and upstream ends of reservoirs or along the shore where rocky shelves are present at a depth of 1–10m (Moyle 2002). They become sexually mature at age three to four and typically live less than 7 years (USFWS 1983, Habitat Suitability Information: Smallmouth Bass, FWS/OBS-82/10.36). Age of largemouth bass in California reservoirs is four to five years and they typically spawn during their second season (Moyle 2002). Adult bass tend to prefer deeper, colder waters in lakes and reservoirs in areas with vegetation and other forms of cover (USFWS 1983, Habitat Suitability Information: Largemouth Bass, FWS/OBS-82/10.16). White catfish will move throughout the reservoir and don't have a regular seasonal migration, thought they tend to concentrate at depts of 10–30 ft but will move deeper in the summer as temperatures increase (Moyle 2002). Brown bullhead typically live in deeper water (6–30 ft deep) in areas with aquatic plants and muddy substrate (Moyle 2002). They become sexually mature at age 3 and will spawn multiple times during their lifetime of up to eight to 10 years (Moyle 2002).

The effects analysis period for both coldwater and warmwater fish species adult holding is January through December.

Potential Changes to Trinity Reservoir Fish Species from Seasonal Operations

Trinity Reservoir storage under Alternative 3 would generally be higher than storage under the No Action Alternative, except in wet years from April through December when Trinity Reservoir storage would be slightly lower than the No Action Alternative (Table O-247). Minor differences, less than 5%, in April–December during wet years would be unlikely to reduce the availability or suitability for adult holding habitat of Trinity Reservoir fish species. There would be increases in reservoir storage of greater than 5% under Alternative 3 compared with the No Action Alternative in below normal years from July through December; in dry years from August through November; and critically dry years from April through January. These increases in Trinity Reservoir storage between Alternative 3 and the No Action Alternative are unlikely to have a detectable influence on the water temperature and habitat suitability for adult holding habitat of Trinity Reservoir fish species.

O.6.34 Central Valley Reservoir Species

O.6.34.1 Potential Changes to Central Valley Reservoir Species from Seasonal Operations

Shasta Reservoir

Warmwater Species

Reductions in Shasta Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-165.

For Alternative 3, there would be the same or up to 16 fewer WSE reductions of 6 feet or more compared to the No Action Alternative. These results indicate that Alternative 3 would have a beneficial effect on warmwater species in Shasta Reservoir.

Coldwater Species

Shasta Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-166.

For Alternative 3, storage would be similar to or greater than storage under the No Action Alternative. This indicates that Alternative 3 would have beneficial effects to coldwater reservoir species in Shasta Reservoir.

Whiskeytown Reservoir

Warmwater Species

Reductions in Whiskeytown Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-167.

For Alternative 3, there would be no or negligible difference in WSE month-over-month reductions of 6 feet or more relative to the No Action Alternative. Therefore, there would be no effect or negligible effects of Alternative 3 on warmwater species in Whiskeytown Reservoir.

Coldwater Species

Whiskeytown Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-168.

End-of-month storage volume under Alternative 3 would be similar to that of the No Action Alternative. These results indicate that Alternative 3 would have negligible effects on coldwater species in Whiskeytown Reservoir.

Folsom Reservoir

Warmwater Species

Reductions in Folsom Reservoir WSE month-over-month reductions of six feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O=169.

There would be zero to 20 fewer reductions of six feet or more under Alternative 2 than the No Action Alternative depending on month. These results indicate that there would be a beneficial effect of Alternative 3 on warmwater species in Folsom Reservoir.

Coldwater Species

Folsom Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-170.

For Alternative 3, there would be negligible difference in storage volume compared to the No Action Alternative in wet water years. In the other water years, storage volume under Alternative 3 would be 11.1% lower to 10.4% higher than storage volume under the No Action Alternative. These results indicate that there would be both beneficial and negative effects of Alternative 3 on coldwater species in Folsom Reservoir.

New Melones Reservoir

Warmwater Species

Reductions in New Melones Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Melones 2.

For Alternative 3, there would be zero to six fewer WSE month-over-month reductions of six feet or more than the No Action Alternative depending on month. These results indicate that there would be a beneficial effect of Alternative 3 on warmwater species in New Melones Reservoir.

Coldwater Species

New Melones Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table O-172.

For Alternative 3, there would be negligible differences in storage volume throughout the period analyzed compared to the No Action Alternative. This indicates that Alternative 3 would have negligible effects on coldwater species in New Melones Reservoir.

O.6.35 Delta-Mendota Canal/California Aqueduct Species

O.6.35.1 Potential Changes to Delta-Mendota Canal/California Aqueduct Species from Seasonal Operations

Water from the Delta is diverted through the California Aqueduct and Delta-Mendota Canal and held for off-stream storage (e.g., in San Luis Reservoir) and there is no coldwater habitat in the Delta-Mendota Canal. Therefore, no analysis of coldwater habitat was conducted. Warmwater species such as black basses and striped bass support recreational fishing in the California Aqueduct. Water velocity in the canal is not specifically managed to support or enhance recreational fisheries. Increases in water velocity may decrease water temperatures and flowing water for species, improving conditions; while decreases in water velocity may increase water temperatures and lead to stagnant water for species, diminishing conditions.

Differences in flows and velocity under Alternative 3, relative to the No Action Alternative, are expected to be minimal thus, impacts to species present are not expected to change.

O.6.36 San Luis Reservoir Species

O.6.36.1 Potential Changes to San Luis Reservoir Species from Seasonal Operations

Warmwater Species

Reductions in San Luis Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects. Please see Section O.4.33.2, *Methods,* for details on the methods used in this analysis. Results are presented in Table O-173.

For Alternative 3, there would be 11 fewer to 22 more WSE month-over-month reductions of six feet or more than under the No Action Alternative depending on month. These results indicate that there would be predominantly negative effects of Alternative 3 on warmwater species in San Luis Reservoir with some beneficial effects.

O.6.37 Southern Resident Killer Whale

O.6.37.1 Nearshore Pacific Ocean on the California Coast

Changes in water operations under the alternatives could have the potential to affect Chinook salmon prey for Southern Resident Killer Whale (Southern Resident) relative to the No Action Alternative. Outlined below are expected changes in Southern Resident prey. Four lines of evidence were used (Salmort, XT, CVPIA SIT LCM, and DPM), and Attachment F.7, *Change in Abundance Estimate of Central Vally Chinook Salmon Available to Southern Resident Killer Whales*, provides detailed results of all models and analyses.

Based on the lines of evidence, Alternative 3 is predicted to have an annual abundance of about 233,449 Chinook salmon that survive to adulthood or about 3,505,241 pounds of Chinook salmon biomass in the ocean available as potential prey to Southern Residents. This is about 699 more Chinook salmon or 10,495 pounds more than the No Action Alternative. The modeling results suggest Alternative 3 would benefit Southern Residents relative to the No Action Alternative.

O.7 Alternative 4

Alternative 4 provides alternative criteria for Shasta Reservoir and incorporates improved real-time analytics for using real-time information to support water deliveries in the Delta while limiting effects on listed species.

O.7.1 Trinity River

O.7.1.1 Trinity River Flows below Lewiston Dam

CalSim 3 modeling suggests that average flow released at Lewiston Dam under Alternative 4 would generally be higher than or similar to flow under the No Action Alternative (Table O-264) with substantial increases (greater than 5%) in wet years in December and January and above normal years in February. Table O-264 shows that the highest flows under both alternatives are expected primarily in May and June of all water year types and during winter, spring, and early summer of wet water years and January through March and May through July of above normal water years. Throughout the full simulation period, flows on average are slightly higher under Alternative 4 December through March.

O.7.1.2 Trinity Reservoir storage

CalSim 3 modeling suggests that average monthly Trinity Reservoir storage under Alternative 4 would generally be higher than storage under the No Action Alternative (Table O-265). Table O-265 shows that there are no increases or decreases in storage greater than 5% throughout the year under Alternative 4 compared with the No Action Alternative. Throughout the full simulation period, Trinity Reservoir storage on average is slightly higher under Alternative 4 than the No Action Alternative across all months.

O.7.2 Sacramento River

Alternative 4 provides alternative criteria for Shasta Reservoir and incorporates improved real-time analytics for using real-time information to support water deliveries in the Delta while limiting effects on listed species. On the Sacramento River, Reclamation would make releases from Shasta Reservoir for flood control, minimum instream flows, senior water rights, Delta requirements, and deliveries to CVP water service contractors.

Reclamation would manage planned releases from Shasta Reservoir for water service contract deliveries to achieve an EOS storage of 2.0 MAF in Shasta Reservoir based on the 90% forecast unless a less conservative forecast requires more releases. To address early season hydrologic uncertainty, Reclamation would limit the use of water under North of Delta Agricultural water service contractor allocations to no more than 30 TAF prior to the temperature management season and completion of a TMP. If reductions to water service contracts would not achieve 2.0 MAF of storage in Shasta Reservoir by EOS, Reclamation would reduce releases for the Project Water component of the SRS Contractors' Contracts, resulting in diversions of ~60% of contract totals. Alternative 4 includes drought toolkit action such as Wilkins Slough Relief and relaxation of D-1641 water quality requirements that may improve the volume of coldwater pool and level of drought protection in Shasta Reservoir.

Reclamation would coordinate through governance to implement a water temperature management strategy that considers EOS Coldwater Pool and minimization of modeled Temperature Dependent Mortality. The water temperature management strategy would start with a 53.5°F temperature target at or downstream of CCR from May 15 through October 30 while preserving a projected EOS coldwater pool of 400 TAF. If projections show EOS coldwater pool cannot be achieved, the water temperature management strategy would relax water temperatures in the following order: target ≤56°F at CCR starting May 15 and delay the ≤53.5°F target to no later than June 15; target June 16 temperatures ≤54°F at CCR through October 30; relax end-of-October temperatures to ≤56°F daily to as early as October 1 and reduce the EOS coldwater pool target to 200 TAF; increase June 16 through September 30 temperatures to ≤56°F; reduce the EOS coldwater pool target and confer on additional drought toolkit actions that prepare a TMP consistent with requirements in WRO 90-5 and update the plan throughout the water temperature management season to improve water temperature conditions on or after June 16.

December through February default releases at Keswick Dam would be determined by the Shasta Reservoir EOS Storage level. If storage is less than 2.4 MAF, then releases would be at 3,250 cfs. If storage is greater than or at 2.4 MAF, then releases would be at 4,000 cfs. If storage is greater than or at 2.8 MAF, then releases would be at 4,500 cfs. If storage is greater than or at 3.2 MAF, then releases would be at 5,000 cfs.

O.7.2.1 Sacramento River Flows below Keswick Dam

Under Alternative 4 compared to the No Action Alternative, CalSim 3 modeling suggests that average monthly flows below Keswick Dam are similar (less than a 5% difference) throughout the full simulation period apart from December and September, which see a flow increase and decrease, respectively (Table O-266). The largest decreases under Alternative 4 compared to the No Action Alternative are expected in February and May through August of critically dry water years, with the largest decrease in May (11%). The largest increases under Alternative 4

compared to the No Action Alternative are expected in October (10%) and November (18%) of critically dry water years.

O.7.2.2 Sacramento River Flows below Red Bluff Diversion Dam

Under Alternative 4 compared to the No Action Alternative, CalSim 3 modeling suggests that average monthly flows below Red Bluff Diversion Dam are similar throughout the full simulation period, with the exception of September (Table O-267). Decreases under Alternative 4 compared to the No Action Alternative are expected in May through August of critically dry water years, with the largest decrease expected in June and July (11%). Increases under Alternative 4 compared to the No Action Alternative are expected in October (9%) and November (15%) of critically dry water years and November (7%) of below normal water years.

O.7.2.3 Sacramento River Flows at Wilkins Slough

Under Alternative 4 compared to the No Action Alternative, CalSim 3 modeling suggests that average monthly flows at Wilkins Slough are similar throughout the full simulation period except for September (Table O-268). The largest decreases in flow under Alternative 4 are expected in June and July of critically dry water years (7%). The largest increases in flow under Alternative 4 are expected in October, November, and April of critically dry water years (15%, 19%, and 9%, respectively).

O.7.2.4 Sacramento River Flows at Hamilton City

Under Alternative 4 compared to the No Action Alternative, CalSim 3 modeling suggests that average monthly flows at Hamilton City are similar throughout the full simulation period except for September (Table O-269). Decreases under Alternative 4 compared to the No Action Alternative are expected in July and August of critically dry water years, with the largest decreases in July (8%). The largest increases in flow under Alternative 4 are expected in October, November, and April of critically dry water years (11%, 14%, and 7%, respectively).

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.7.3 Bay-Delta

O.7.3.1 Delta Exports

Alternative 4 provides alternative criteria for Shasta Reservoir and incorporates improved real-time analytics for using real-time information to support water deliveries in the Delta while limiting effects on listed species. Reclamation and DWR will operate to the Hutton (2008) OMR index to allow for operational planning and real-time adjustments. Reclamation and DWR will reduce exports to achieve certain OMR thresholds when one or more of the following conditions listed in Chapter 3 Alternatives Section 3.6.4.2.1 to 3.6.4.4. Other alterations to operations are the same as Alternative 2.

O.7.3.2 Delta X2

CalSim 3 modeling suggests that the estimated X2 position under Alternative 4 when compared to the No Action Alternative, does not greatly change (Table O-270). Table O-270 suggests that most landward X2 positions are expected during late summer to fall months in the critically dry years and the most seaward positions are expected during the winter to early spring months in wet years for both alternatives. The largest changes in X2 position under Alternative 4 as compared to the No Action Alternative are expected in September and October of wet and above normal years. For the full simulation period, when comparing Alternative 4 to the No Action Alternative, X2 position did not change.

O.7.3.3 Delta Exports

CalSim 3 modeling suggests that the total exports of the SWP and CVP under Alternative 4 when compared to the No Action Alternative increased from February to May across most water year types. Exports only decreased in June and December for most of the water year types (Table O-271). Table O-271 suggests that exports were generally highest in August for both alternatives. Exports were generally the lowest in summer during the critically dry water year type for both alternatives. For the full simulation period, total exports when compared to the No Action Alternative increased from February–May and decreased in June and December.

O.7.3.4 Delta Outflow

Under Alternative 4 when compared to the No Action Alternative, Delta outflow generally decreased in May and July for the wet and above normal water years. Outflow increased in June in above normal water year types, in June for the below normal water year type and in December in wet, above normal, and critically dry water year types (Table O-272). Table O-272 suggests total Delta outflow is highest in February during wet years and lowest in the late summer–fall during the critically dry water year type for both alternatives. For the full simulation period when compared to the No Action Alternative, total Delta outflow decreases in May and August through October and increases in December.

O.7.3.5 Delta OMR

CalSim 3 modeling suggests that Old and Middle River (OMR) combined flows under Alternative 4 when compared to the No Action Alternative is generally more negative across all water year types from February–May and generally less negative across most water year types from December–January and June (Table O-273). Table O-273 suggests that OMR flows were generally the most negative in August of below normal years for both alternatives, and the least negative in April during critically dry years for both alternatives. For the full simulation period, OMR flows were more negative from February–May and less negative from December and June.

O.7.3.6 Sacramento River at Rio Vista

CalSim 3 modeling suggests that average flows in the Sacramento River at Rio Vista under Alternative 4 compared to the No Action Alternative are similar (less than 5% difference) with the exception of September (Table O-274). The greatest reductions are expected August through October of wet and above normal water year type under Alternative 4 compared to the No Action Alternative. The greatest increase is expected during April of critically dry water year types under Alternative 4 compared to the No Action Alternative.

O.7.4 Clear Creek

Alternative 4 provides alternative criteria for Shasta Reservoir and incorporates improved real-time analytics for using real-time information to support water deliveries in the Delta while limiting effects on listed species. Reclamation would release water through Whiskeytown Dam to provide intra-annual variation to emulate natural processes. As provided in Figure 3.4-1 and Table 3.4-2 (Chapter 3 Alternatives), flows would oscillate over a one-year period, with releases transitioning from 300 cfs in the winter, down to 100 cfs in the summer, and back to 300 cfs by the following winter. Reclamation, through the Clear Creek Technical Team, may modify the timing and flow rates provided in Figure 3.4-1 and Table 3.4-2 by February 1 and update through May on a case-by-case basis; the flow schedule is subject to agreement by Redding Electric Utility for use of their facilities.

Reclamation would release up to 10,000 acre-feet from Whiskeytown Dam for channel maintenance, spring attraction flows, and to meet other physical and biological objectives, except in years with significant uncontrolled flow. In critical years, Reclamation would release up to 5,000 acre-feet. Reclamation, through the Clear Creek Technical Team, would develop pulse flow schedules, which include measures (e.g., nighttime down ramping, slow down ramping rates, coordination with natural precipitation events) to mitigate for potential risks (e.g., potential juvenile fish stranding). Due to unknowns in winter precipitation, Clear Creek pulse flows are not to occur prior to the February SVI reporting. The full pulse flow volume (10,000 acre-feet) will be available if the SVI is greater than 5.4, at the SVI updates (i.e., dry or wetter years). If the SVI updates are equal to or less than 5.4 (critical years), Reclamation would limit releases of pulse(s) flows to 5,000 acre-feet. Reclamation would also target Whiskeytown Dam releases at 61°F from June 1 through August 15, 60°F from August 16 through September 15, and 56°F from September 16 through November 15 to not exceed the mean daily temperatures at Igo gauge. In dry, critical, or import curtailment years, Reclamation may not be able to meet these water temperatures and will operate Whiskeytown Dam as close to these water temperatures as practicable within the constraints of minimum instream flows.

O.7.4.1 Clear Creek below Whiskeytown Dam

CalSim 3 modeling under Alternative 4 compared to the No Action Alternative suggests average monthly flows below Whiskeytown Dam will generally increase November through January and March through May, and generally decrease in February and June through October (Table O-275). The largest decreases under Alternative 4 compared to the No Action Alternative are expected June through August. The largest increases under Alternative 4 compared to the No Action Alternative are expected in January or May, depending on the water year type.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.7.5 Lower American River

Alternative 4 provides alternative criteria for Shasta Reservoir and incorporates improved real-time analytics for using real-time information to support water deliveries in the Delta while limiting effects on listed species; Reclamation would seek to develop and operate under a new ATSP, otherwise operations on the lower American River are the same as the No Action Alternative.

If unable to develop and operate under a new ATSP, management actions for the American River would be the same as the No Action Alternative Reclamation and would implement the minimum release requirement (MRR) proposed by the Sacramento Area Water Forum, based on the month and annual hydrology, Figure 3.2-3 and Figure 3.2-4 (EIS, Chapter 3). Reclamation will use the 90% exceedance from the Sacramento River Index in January and the American River Index in February through December to develop the MRR (with certain spills subtracted). Reclamation will implement a spring pulse in years that the MRR for March is between 1,000 cfs and 1,500 cfs. The peak flow of the pulse flow would be three times the March MRR, even if implemented in April or May, but no higher than 4,000 cfs and lasting two days. Reclamation, through the American River Group, will develop a pulse flow schedule and may facilitate an additional spring pulse flow event if water is made available from non-CVP sources, or if there is flexibility to shape planned releases in a more variable schedule. Reclamation, through Governance, will schedule MRR releases consistent with the implementation of redd dewatering protective adjustments to limit potential redd dewatering January through May. Table 3.2-3 (Chapter 3, *Alternatives*), with linear interpolation, shows the minimum flow for steelhead redds through May.

If unable to develop and operate under a new ATSP, Reclamation will implement the existing ATSP. Each ATSP schedule determines a monthly series of water temperature targets at the Watt Avenue bridge. Schedule 1 has a water temperature upper limit of 63°F from May through September, and 56°F in October and November. Schedules 2 through 77 each represent a change in a single month's upper temperature limit by 1.0°F. Schedule 78 has a water temperature upper limit of 72°F from May through November. The ATSP may be modified for Schedule 28 or higher when temperatures are greater than 65°F at Watt Avenue Bridge in May through September, the TMP may consider a temperature location at Hazel Avenue; any schedule when greater than 65°F at Hazel Avenue bridge for May through September, the TMP will include an evaluation of whether modified Folsom Reservoir operations could support an improved temperature schedule (e.g., an alternate release schedule over the summer); any schedule when greater than 65°F at Hazel Avenue for May through September, the TMP will include an evaluation of whether modified Folsom Reservoir operations could support an improved temperature schedule (e.g., an alternate release schedule over the summer) and evaluate a power bypass during the summer and/or fall; any schedule when temperatures are greater than 56°F at Hazel Avenue in November, the TMP will evaluate a power bypass.

O.7.5.1 Lower American River for Folsom Reservoir Storage

CalSim 3 modeling under Alternative 4 compared to the No Action Alternative suggest that at Folsom Reservoir storage monthly average volume would be similar or greater throughout the full simulation period (Table O-276). Folsom Reservoir storage is not expected to decrease by more than 5% throughout the year. Increases are expected in all months of dry and critically dry water year types, with projected storage increases for almost all water year types September through December.

O.7.5.2 Lower American River below Nimbus Dam

CalSim 3 modeling of Alternative 4 compared to the No Action Alternative suggest that monthly average flows below Nimbus Dam are mostly similar throughout the year under the full simulation period (Table O-277). The largest flow increases are expected in February of dry water year types and July of critically dry year types when compared to the No Action Alternative. The largest flow decreases are expected in August through October, and February through May of critically dry water year types when compared to the No Action Alternative. October would see flow decreases for all water year types except wet years.

O.7.5.3 Lower American River at H Street

CalSim 3 modeling of Alternative 4 compared to the No Action Alternative suggest monthly average flows below Nimbus Dam are generally similar throughout the year under the full simulation period (Table O-278). The largest flow increases are expected in February of dry water year types and July of critically dry year types when compared to the No Action Alternative. The largest flow decreases are expected August through October, and February through May of critically dry water year types when compared to the No Action Alternative.

O.7.6 Stanislaus River

Alternative 4 provides alternative criteria for Shasta Reservoir and incorporates improved real-time analytics for using real-time information to support water deliveries in the Delta while limiting effects on listed species. Minimum instream flows (i.e., Goodwin Dam releases) would be in accordance with the 2019 New Melones SRP as modified to increase the potential outmigration response of juvenile steelhead from Winter Instability Flows, as shown in Figure 3.4-2 (EIS, Chapter 3). The SRP includes the ability to shape monthly and seasonal flow volumes. Reclamation, through the Stanislaus Watershed Team, schedules the winter instability flow volume, including combining the additional January and February releases, in consideration of timing flows to coincide with a natural storm event which may naturally cue outmigration. Modifications would use a single pulse and increase peak releases from 400 cfs to 1,500 cfs. In addition to description of the No Action Alternative, Reclamation may release additional pulse flows in November.

O.7.6.1 Stanislaus River below Goodwin Dam

CalSim 3 modeling suggests monthly average flows below Goodwin Dam under Alternative 4 compared to the No Action Alternative are expected to increase in December, February, July, and August and decrease in April (Table O-279). The largest decreases under Alternative 4 compared to the No Action Alternative are expected in April of below normal and dry water year types, May of below normal water year types, June of wet water year types, and January of above normal water year types. The largest increases under Alternative 4 compared to the No Action Alternative are expected in February of dry and critically dry water year types and June, July and August of critically dry water year types.

O.7.6.2 Stanislaus River at Mouth

CalSim 3 modeling suggests monthly average flows at the mouth of the Stanislaus River under Alternative 4 compared to the No Action Alternative are similar nearly year-round, except August and September when flows are expected to increase (Table O-280). The largest decreases under Alternative 4 compared to the No Action Alternative are expected in May of below normal and January of above normal water year types. The largest increases under Alternative 4 compared to the No Action Alternative are expected in June through September of critically dry water year types.

Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.7.7 San Joaquin River

Alternative 4 provides alternative criteria for Shasta Reservoir and incorporates improved real-time analytics for using real-time information to support water deliveries in the Delta while limiting effects on listed species. In the San Joaquin River, Reclamation will operate the Friant Division consistent with the San Joaquin River Restoration Program Record of Decision, which is a related action not included in this consultation. There are anticipated changes in San Joaquin River flow below the confluence with the Stanislaus River, because of changes in operations at New Melones reservoir.

O.7.7.1 San Joaquin River at Vernalis

CalSim 3 modeling suggests that monthly average flows in the San Joaquin River at Vernalis under Alternative 4 compared to No Action Alternative are similar (less than 5% difference) October through September (Table O-281). The largest increases under Alternative 4 compared to the No Action Alternative are expected in July and August of critically dry water year types (22%). There are no anticipated decreases greater than 5% difference under Alternative 4 compared to the No Action Alternative.

Results are based on the 100-year simulation period and displayed with calendar year–year type sorting. All scenarios are simulated at the 2022 median climate change and 15 centimeter sea level rise. Water year types are as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (Water Board D-1641, 1999). The percent of years of each water year type is given in parentheses. Bold blue font indicates a greater than 5% increase in flow; bold red font indicates a greater than 5% reduction in flow.

O.7.8 Sacramento River Winter-run Chinook Salmon ESU

O.7.8.1 Sacramento River

Spawning and Egg/Alevin Incubation

Winter-run Chinook salmon adults spawn from April through August with peak spawning between May and July (Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). Fry emergence occurs up to three months after eggs are spawned, so effects of flow and water temperature on winter-run Chinook salmon eggs and alevins may occur from May through November, but primarily occur during June through October.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 4, differences in mean spawning WUA are increases across all water year types when compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 4 and the No Action Alternative is a 1.9% increase in dry water years. Under Alternative 4, there are no reductions in mean estimated spawning WUA when compared to the No Action Alternative.

The monthly median value of spawning WUA under Alternative 4 is similar to the No Action Alternative across all four spawning months. Spawning WUA median values for all the modeled alternatives are relatively similar in May, June, and August. In July, the median values of spawning WUA are lower across all alternatives when compared to the other months of spawning. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in July than in the other three months (Table O-266). This results in lower spawning WUA results because the winter-run spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 5,000 to 10,000 cfs).

The results of suitable habitat analysis using the SIT LCM habitat models indicate that spawning habitat for winter-run in the upper Sacramento River may not be a limiting factor under both the No Action Alternative and Alternative 4 (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The results of the two spawning habitat analyses based on CalSim 3 simulated flows suggest that Alternative 4 may have a negligible (less than 2%) increase in estimated spawning habitat during above normal water year types when compared to the No Action Alternative, and that spawning habitat may not be a limiting factor for winter-run Chinook salmon in the mainstem upper Sacramento River.

SIT Winter-run Lifecycle Model: Spawner Abundance

In the CVPIA winter-run SIT life cycle model, mean winter-run Chinook salmon spawner abundance in the central valley under Alternative 4 is similar to the No Action Alternative, with up 4.7% increase in above normal water year types and 0.5% decrease in wet and dry water year types (Attachment F.2, *CVPIA SIT Winter-run LCM*). For all years, the mean annual spawner abundance was similar under Alternative 4 compared to the No Action Alternative. Over the full model run period (1980–1999), abundance under Alternative 4 was similar or slightly lower by 0.4% than abundance under the No Action Alternative. Overall, the spawner abundance predicted by the CVPIA winter-run Chinook salmon life cycle model is expected to be similar under Alternative 4 and the No Action Alternative, with a slight annual decrease in abundance, and increases expected during critically dry and above normal years and decreases expected during above normal and wet years.

IOS: Egg Survival

Under Alternative 4, in critically dry water years, mean predicted winter-run Chinook salmon egg survival is 26.34% higher than when compared to the No Action Alternative. Alternative 4 reflects a change of 0.184 mean predicted winter-run Chinook salmon egg survival when compared to the No Action Alternative (0.698 under the No Action Alternative to 0.882 under Alternative 4). The change in mean predicted winter-run Chinook salmon egg survival in all other water year types less than or equal to 0.000. Alternative 4 provides a substantial benefit to predicted survival of winter-run Chinook salmon eggs during critically dry years when compared to the No Action Alternative.

OBAN: Spawner Abundance and Probability of Quasi-Extinction

Predicted spawner abundance under Alternative 4 is expected to be less under the No Action Alternative (14% less Table O-30). This decrease under Alternative 4 would have an adverse effect on winter-run Chinook salmon.

Probability of quasi-extinction under Alternative 4 was the same as under the No Action Alternative (0.98, Table O-30).

IOS: Female Escapement

Under Alternative 4 in all water year types, mean annual predicted female escapement of winter-run Chinook salmon is 2.21-5.62% higher than when compared to the No Action Alternative. However, the change in mean annual predicted female escapement of in all water year types except below normal ranged from 75-96 individuals. In below normal water years, the change in mean annual predicted female escapement was 206. Alternative 4 provides a slightly positive impact to mean annual predicted female escapement of winter-run Chinook salmon in below normal water years when compared to the No Action Alternative.

OBAN: Egg-to-Fry Survival

Egg to fry survival under Alternative 4 was less than under the No Action Alternative (-0.015 difference, Table O-30). This decrease under Alternative 4 would have an adverse effect on winter-run Chinook salmon.

Redd Dewatering Analysis

The results for Alternative 4 show reduced mean winter-run Chinook salmon redd dewatering potential in wet water years, higher redd dewatering potential in below normal and dry water years, and intermediate values in above normal and critically dry water year types. Winter-run Chinook salmon spawning and incubation occur during late spring through early fall, when flows tend to be less variable. The low percentages of winter-run Chinook salmon redd dewatering in wet years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*) may result from increased stability in project operations related to greater reservoir storage levels. Mean redd dewatering potential is 15.7% higher under Alternative 4 than under the No Project Alternative for wet water year types and 33.3% higher for above normal water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). Mean redd dewatering is 24.2% lower under Alternative 4 than under the No Action Alternatives for critically dry water years and little different for below normal and dry water years.

Overall, the results indicate that redd dewatering potential under Alternative 4 would be similar to than that under the No Action Alternative, with substantial increases in above normal and wet water years and reductions for the other water year types.

Temperature Dependent Mortality

Under Alternative 4 for the Anderson model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.146, 0.608, and 0.007 (less than the No Action Alternative in critically dry, up to 15% less; greater than the No Acton Alternative in wet, up to 133% greater). Expected proportional TDM values for the Anderson model were less under Alternative 4 than No Action Alternative for all water year types except wet.

Under Alternative 4 for the Martin model, expected proportional TDM values calculated across all water year types, for only critically dry water year types, and for only wet water year types were 0.147, 0.585, and 0.015 (less than the No Action Alternative in all but an above normalwater year type, up to 6% less in a wet water year type). Expected proportional TDM values for the Martin model were less under Alternative 4 than No Action Alternative in all water year types except above normal.

Relative to the Anderson model, expected proportional TDM values were higher for the Martin model across all water year types combined and for all water year types except below normal and critically dry. For the Anderson and Martin models, greater than 70% of modeled water years resulted in expected proportional TDM values less than 0.125. For critically dry water year types, 0% of modeled water years resulted in expected proportional TDM values less than 0.5. For above normal and wet water year types only, expected proportional TDM never exceeded 0.125 (Attachment L.2, *Egg-to-fry Survival and Temperature Dependent Mortality*). A decrease in TDM under Alternative 4 compared with the No Action Alternative in all but a wet water year type would generally have a beneficial effect on incubating winter-run Chinook salmon eggs, but could have adverse effects in some water year types.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during January through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 16 for Keswick Dam and Table 18 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during January through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 20 for Keswick Dam and Table 22 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during May through November are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 24 for Keswick Dam and Table 26 for below Clear Creek.

Results for the three analyses are summarized in Table O-31. Table O-31, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 42.1°F to 55°F range for spawning initiation, there were three to five month-water year type combinations (8.6% to 14.3.0%) with favorable results, depending on location, no combinations (0% of total combinations during the period) with unfavorable results at Keswick Dam, and one combination with unfavorable results below Clear Creek (Table O-31). For the 59.9°F adult pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were four to six combinations (11.4% to 17.1%) with favorable results, depending on location, no combinations (below Keswick Dam) or one combination (2.9% below Clear Creek) with unfavorable results. These results suggest that there would be mostly no effect or positive biologically meaningful temperature-related effects of Alternative 4 on winter-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River, although there were some negligible negative effects on egg incubation and fry emergence below Clear Creek.

Summary

Alternative 4 relative to the No Action Alternative is expected to have potential adverse impacts on spawning habitat, potential beneficial impacts in critically dry water years, potential adverse to beneficial impacts on spawner abundance dependent on water year type and model, a beneficial impact on female escapement, and no impact on the probability of quasi-extinction due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have a possible beneficial impact using four secondary biological models due to differences in water temperature: IOS, Anderson and Martin (TDM), and OBAN. Using a coarser analysis, Alternative 4 relative to the No Action Alternative is expected to have no impact to beneficial impact on spawning and egg/alevin incubation.

Juvenile Rearing and Emigration

Winter-run Chinook salmon juveniles rear in the Sacramento River primarily from late summer to late winter and emigrate from the river to the Delta beginning in November (see Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). The proportion of juveniles

surviving to emigrate to the Delta depends largely on habitat conditions, including flow and water temperature. Inundated floodplain habitat has been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001a, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 4, mean fry rearing WUA increases in critically dry water year types and decreases in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 1.9% increase in critically dry water years. The largest decrease in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a -0.9% decrease in below normal water year types.

The monthly median value of fry rearing WUA under Alternative 4 is similar to the No Action Alternative throughout the fry rearing period (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Fry rearing WUA median values for all the modeled alternatives are relatively similar September through December but slightly lower in August. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in August in comparison to the other fry rearing months, with an average flow of 10,225 cfs under Alternative 4 (Table O-266). Segment 5, which has the highest distribution of winter-run spawning, has decreased WUA values when flows are between 5,000 and 10,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), leading to lower WUA values during higher flows in August. Winter-run fry rearing WUA starts to increase at flows above 10,000 cfs, and peak at flows around 30,000 cfs. The peak rearing flows are not expected to occur under the No Action Alternative or Alternative 4 during the fry rearing period in the Sacramento River below Keswick Dam. Winter-run Chinook salmon is the only Sacramento River salmonid race or species that shows this pattern.

The results of the winter-run Chinook salmon fry rearing habitat analysis suggest that Alternative 4 may have a minor (less than 2%) increase and/or decrease in estimated fry rearing habitat across all water year types and potentially no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Juvenile Rearing Habitat Analyses

Under Alternative 4, mean juvenile rearing WUA increases in wet and critically dry water year types and decreases in above normal, below normal and dry water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated juvenile rearing habitat between Alternative 4 and the No Action Alternative is a 0.7% increase in critically dry water years. The largest reduction in estimated juvenile rearing habitat between Alternative 4 and the No Action Alternative is a -0.5 % decrease in below normal water year types.

The monthly median value of juvenile rearing WUA under Alternative 4 is similar to the No Action Alternative October through January (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are higher in January compared to the other months of juvenile rearing (Table O-266). Segment 5 has decreased WUA values when flows are between 5,000 and 10,000 cfs but the WUA values do not change as drastically with juvenile rearing in comparison to fry rearing (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Winter-run juvenile rearing WUA values start increasing at flows above 15,000 cfs, and peak at flows around 30,000 cfs. These peak rearing flows are not expected to occur under the No Action Alternative or Alternative 4 during the juvenile rearing period in the Sacramento River below Keswick Dam. Winter-run is the only Sacramento River salmonid race or species that shows this pattern.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for winter-run Chinook salmon in the upper Sacramento River under Alternative 4 have a 0.6% to -3.0% difference between the months of October through January in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest reduction in estimated habitat may occur in November under Alternative 4 in comparison to the No Action Alternative.

The results of the two winter-run Chinook salmon juvenile rearing habitat analyses suggest that Alternative 4 may have a negligible (less than 1%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and potentially no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles who generally are stronger swimmers. Alternative 4 shows a large and consistent reduction in stranding of winter-run fry from critically dry to wet water year types (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*) and an increase from July to October (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Winter-run Chinook salmon fry rearing occurs primarily during summer through early fall, when flows tend to be less variable. The minimum rates of stranding for winter-run Chinook salmon fry during wet years may result from increased stability in project operations related to greater reservoir storage levels. Alternative 4 has lower juvenile stranding of winter-run Chinook salmon fry than the No Action Alternative in below normal, dry, and critically dry water years, and higher stranding in wet and above normal water years. The reductions in below normal and critically dry years are 9.1% and 8.7% respectively, but all other differences are less than 5% (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*).

Overall, winter-run Chinook salmon juvenile stranding for fry is lower or little different under Alternative 4 in comparison to the No Action Alternative.

Survival and Travel Time: XT and Flow Survival Threshold Models

Mean daily Sacramento River flows at Keswick Dam and mean daily Sacramento River flows below Wilkins Slough (March 15th to June 15th) are equal to or greater under Alternative 4 compared with the No Action Alternative except during May and June at Keswick Dam in critically dry water year types when flows are less under Alternative 4 compared with the No Action Alternative (Attachment J.4, *XT Model*; Attachment J.5, *Flow Threshold Salmon Survival Model*). The XT and Flow Survival Threshold models provide results that demonstrate the flows under Alternative 4 compared with the No Action Alternative could increase survival and decrease travel time for outmigrating juvenile Chinook salmon on the Sacramento River limiting juveniles' exposure to predation and poor environmental conditions.

Annual mean survival probability under Alternative 4 was greater than annual mean survival probability under the No Action Alternative in all water year types (5% to 7% greater in wet and above normal water year types to up to 20% to 25% greater in critically dry and dry water year types). This increase, particularly in dry and critically dry water year types of up to 25%, would have a large beneficial effect on outmigrating juvenile Chinook salmon. Under both scenarios, average annual mean survival probability was highest during the wet water year types and decreased as the water year type became drier. (Attachment J.5, *Flow Threshold Salmon Survival Model*).

Mean survival probability for outmigrating Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 4 was equal to or greater than mean survival probability under the No Action Alternative (survival equal in wet, above normal, and below normal water year types and to up to 1% greater in dry and critically dry water year types). This increase of up to 1% would have no effect on outmigrating juvenile Chinook salmon. (Attachment J.4, *XT Model*).

Mean travel time (days) for outmigrating winter-run Chinook salmon between Red Bluff Diversion Dam to the confluence of the American and Sacramento rivers and between Red Bluff Diversion Dam to the DCC on the Sacramento River under Alternative 4 was both greater than and less than mean travel time under the No Action Alternative (5% less in dry water year type to the terminus of both reaches and up to 2% greater in wet water year type to the terminus of both reaches). This decrease of 5% may have a minimal effect on outmigrating juvenile winter-run Chinook salmon, particularly dependent on predator presence and environmental conditions (e.g., water temperature) (Attachment J.4, *XT Model*).

Winter-run Juvenile Production Index (JPI)

Under Alternative 4, the mean predicted JPI is generally lower than No Action Alternative, ranging from 5.9% higher in 2020 to 27.68% lower in 2014. In 15 of the years analyzed (2002-2021), the JPI was lower under Alternative 4 than the No Action Alternative, six of those years being over a 10.00% lower and three over 5.00% lower. These results suggest that Alternative 4 is expected to have a negative effect on the number of juveniles produced annually when compared to the No Action Alternative.

IOS: Fry Survival and Juvenile River Migration Survival

Under Alternative 4, in critically dry water years, mean predicted winter-run Chinook salmon fry survival is 19.97% higher than when compared to the No Action Alternative (Attachment F.5, *Interactive Object-oriented Simulation Model (Winter-run Chinook Salmon*). Alternative 4 reflects a change of 0.13 mean predicted winter-run Chinook salmon fry survival when compared to the No Action Alternative (0.65 under the No Action Alternative to 0.782 under Alternative 4). The change in mean predicted winter-run Chinook salmon fry survival in all other water year types was less than or equal to ± 0.003. Alternative 4 provides a substantial benefit to predicted survival of winter-run Chinook salmon fry during critically dry water years when compared to the No Action Alternative.

Under Alternative 4, in all water years, mean predicted river migration survival of winter-run Chinook salmon juveniles is higher than when compared to the No Action Alternative. However, the change in mean predicted river migration survival in all water year types less than or equal to 0.002. There is not a substantial difference in predicted river migration survival of winter-run Chinook salmon juveniles between Alternative 4 and the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during July through December are presented in Attachment L.1, Sacramento River Water Temperature Analysis, Table 28 for Keswick Dam, Table 30 for Red Bluff Diversion Dam, and Table 32 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during July through December are presented in Attachment L.1, Sacramento River Water Temperature Analysis, Table 34 for Keswick Dam, Table 36 for Red Bluff Diversion Dam, and Table 38 for Hamilton City.

Results for the two analyses are summarized in Table O-32. Table O-32, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 55.4°F to 68°F optimum water temperature range analysis, there were zero to two month-water year type combinations (0% to 6.7% of total combinations during the period) with favorable results, depending on location, and there were zero to three combinations (0% to 10%) with unfavorable months, depending on location (Table O-32). For the 75.2°F upper incipient lethal temperature under Alternative 4, there would be no favorable or unfavorable results at any location. These results suggest that there would be positive and negative water-temperature-related effects on winter-run Chinook salmon juvenile rearing and outmigration in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have potential beneficial to adverse impacts on fry and juvenile rearing habitat, a slightly beneficial impact to no impact on fry stranding, adverse impact on the juvenile production index, and a beneficial impact on fry survival particularly in critically dry years due to differences in flow. Alternative 4 relative to the No Action Alternative could have an adverse to beneficial impact in all water year types, potential beneficial dependent on model, on individuals' survival and travel time in the upper Sacramento River due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have adverse and beneficial water temperature-related impacts on juvenile rearing and emigration.

Adult Upstream Migration and Holding

Winter-run Chinook salmon adults enter the Sacramento River from the Delta and make their way to the upper Sacramento River, beginning as early as December through late spring (May/June) (see Section O.1.3.2.1, *Winter-run Chinook Salmon, Sacramento River ESU*). They hold in the upper River within 10 to 15 miles of Keswick Dam until they are ready to spawn, which may extend through August (Windell et al. 2017). Most of the run passes Red Bluff Diversion Dam from January to May with the peak in mid-March (Hallock and Fisher 1985).

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

CalSim 3 Flows

During the December through May/June period of adult winter-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 4 at Sacramento River below Red Bluff Diversion Dam, Hamilton City, and Wilkins Slough generally be similar to or greater than flows under the No Action Alternative, except a decrease at all three locations in May and June of a critically dry water year type (up to 6% lower). At Sacramento River below Keswick Dam flows under Alternative 4 would range from less than to greater than flows under the No Action Alternative, depending on month and water year type, generally similar to or greater than flows under the No Action in December through April) and generally less than flows under the No Action Alternative May and June of critically dry years Flows at Hamilton City and Wilkins Slough under Alternative 4 would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 4 between December and May/June would be greater than 5,200 cfs at Wilkins Slough and greater than 7,500 cfs at Hamilton City (Table O-267, Table O-266, Table O-268, Table O-269).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range for winter-run Chinook salmon adult migration and holding are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 4 for Keswick Dam, Table 6 for Red Bluff Diversion Dam, and Table 8 for Hamilton City.

Results are summarized in Table O-33. Table O-33, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Table O-33 indicates that, under Alternative 4, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at all locations, except Hamilton City, at which there was one combination (3.3%) with an unfavorable result (Table O-33). These results suggest that there would be minimal effects of Alternative 4 on water temperature conditions for winter-run Chinook salmon adult migrants in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have no impact to a minimal beneficial impact, depending on location and month except June of critically dry water year type, on upstream migrating and holding adult winter-run Chinook salmon, average monthly flows at Hamilton City and Wilkins Slough are high enough to allow upstream passage. Differences in temperature between Alternative 4 and the No Action Alternative are expected to have minimal impact on upstream migrating and holding adult winter-run Chinook salmon.

O.7.8.2 Bay-Delta

Juvenile Rearing and Emigration

Rearing winter-run Chinook salmon are present in the Delta from October to May (see Section O.1.9.1.1, *Winter-run Chinook Salmon, Sacramento River ESU*). Key habitat attributes relevant to seasonal operations in the Delta include out-migration cues and entrainment risk. Juveniles enter the Delta primarily during December through April and most emigrate past Chipps Island by the end of April but can potentially exit as late as May (Brandes and McLain 2001; del Rosario et al. 2013). A critical assumption in these analyses is LAD criteria used to identify juveniles (vs genetic ID) are sufficient to represent juveniles' downstream migration patterns.

Potential Changes to Winter-run Chinook Salmon from Seasonal Operations

Zone of Influence

The proportional overlap of Alternative 4 (pumping vs no pumping) was less than proportional overlap of the No Action Alternative (pumping vs no pumping) at Turner Cut under all OMR bins except < -5,500 (Attachment I.3, *Delta Export Zone of Influence Analysis*). The proportional overlap of Alternative 4 (pumping vs no pumping) was less than proportional overlap of the No Action Alternative (pumping vs no pumping) at the San Joaquin River at Jersey Point under the two OMR bins (-2,000 and -5,000). The proportional overlap of Alternative 4 (pumping vs no pumping) was less than proportional overlap of the No Action Alternative (pumping vs no pumping) at Old River at Middle River under the most positive OMR bins (-2,000).

With incremental decreases in OMR under Alternative 4 and the No Action Alternative, proportional overlap at these three locations decreases, with more subtle changes along the San Joaquin River at Jersey Point compared to Turner Cut and Old River at Middle River. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping.

Flow into Junctions

For a full description of Flow into Junctions model background, see Section O.4.8.2, *Sacramento River Winter-run Chinook Salmon ESU, Juvenile Rearing and Emigration in the Bay-Delta*. The following section covers discussion of the Central Valley Project and Head of Old River junctions. An expanded set of junction analysis results can be found in Attachment I.10, *Flow into Junctions*.

Under Alternative 4 in all OMR bins except -3,500, predicted proportion of flow entering the Central Valley Project is less than the No Action Alternative. Changes in predicted proportion of flow entering the CVP in OMR bins -3,500, -5,000, and <-5,500 was less than ± 0.0372, indicating a negligible difference between Alternative 4 and the No Action Alternative. However, in OMR bin -2,000 the change in predicted proportion of flow into CVP was -0.0676 indicating that slightly less flow will be routed into CVP under Alternative 4 than when compared to the No Action Alternative.

Under Alternative 4 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the Head of Old River (HOR) is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.026, indicating a negligible difference between Alternative 4 and the No Action Alternative.

Summary

Alternative 4 relative to the No Action Alternative is expected to influence flow into the HOR and CVP junctions differences in water management. Under Alternative 4, no change to possibly less flow into CVP under OMR -2,000; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 4 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Winter-run Chinook Salmon

Salvage Density and Negative Binomial

Predictions from the salvage density model for genetic and LAD winter-run Chinook salmon include mean monthly total exports. Predictions from the negative binomial loss model for LAD winter-run Chinook salmon include mean monthly total exports and mean monthly San Joaquin River flows at Vernalis. Table O-271 shows modeled mean monthly total exports at SWP and CVP and Table O-281 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of genetic winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through May of all water year types for Alternative 4 had greater than predicted average monthly loss under the No Action Alternative. Predicted loss of genetic winter-run Chinook salmon at Banks under Alternative 4 was up to 17% higher than the No Action Alternative for critically dry water year types (Table O-36). Predicted average monthly loss of genetic winter-run Chinook salmon at CVP Jones Pumping Plant for all the

months December through April for Alternative 4 was greater than predicted average monthly loss under the No Action Alternative for wet, above normal, and below normal water year types, with up to a 10% increase for wet water year types. Predicted loss of genetic winter-run Chinook salmon under Alternative 4 compared to the No Action Alternative for dry and critically dry water year types was lower, with up to a 3% decrease in predicted loss for the critically dry water year types (Table O-37). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly loss of LAD winter-run Chinook salmon at SWP Banks Pumping Plant for all the months December through April, and of all water year types, Alternative 4 was greater than predicted average monthly loss under the No Action Alternative. Predicted loss of LAD winter-run at Banks under Alternative 4 compared to the No Action Alternative for all water year types had an increase of up to 135% for wet water year types. (Table O-34). Predicted average monthly loss of LAD winter-run Chinook salmon at CVP Jones Pumping Plant for all the months December through April Alternative 4 was greater than predicted average monthly loss under the No Action Alternative for wet, above normal, and below normal water year types with up to a 7% increase for the above normal water year types. Predicted loss of LAD winter-run Chinook salmon at CVP Jones Pumping Plant from Alternative 4 compared to the No Action Alternative for dry and critically dry water year types had a decrease in predicted loss of up to 1% for both water year types (Table O-35). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly salvage of LAD winter-run Chinook salmon at the Delta fish collection facilities for the months of December through April under Alternative 4 was higher than predicted average monthly salvage under the No Action Alternative for all water year types. Predicted loss for genetic and LAD winter-run Chinook salmon under Alternative 4 compared to the No Action Alternative had an increase in predicted loss of up to 28% for wet water year types (Table O-38). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.

<u>Winter-run Chinook Salmon Coded Wire Tag Salvage Model</u>

Predicted mean of annual and monthly proportion of winter-run Chinook salmon salvaged at CVP and SWP for all months October through May under Alternative 4 in all water year types, varied from positive to negative between months when compared to the No Action Alternative (Attachment I.9,, *Winter-run Chinook Salmon Coded Wire Tag Salvage Model*). Salvage is predicted to increase in wet years under Alternative 4 when compared to the No Action Alternative, however all predicted proportion salvaged are less than ± 0.01 in all months and years. Overall, there is not a substantial difference in predicted proportion salvaged between Alternative 4 and the No Action Alternative.

<u>Summary</u>

Alternative 4 relative to No Action Alternative are largely expected to have a possible substantial adverse impact on the entrainment of genetically and LAD identified juvenile winter-run Chinook salmon in the Delta at both fish facilities due to differences in flow, supported by results from two quantitative models. However, differences in flow between Alternative 4 and the No Action Alternative are expected to have a possible minimal beneficial impact on entrainment during dry and critically dry water year types. A third model suggests no impact of differences in

flow between Alternative 4 and the No Action Alternative on predicted salvage proportion of juvenile winter-run Chinook salmon.

Potential Changes to Routing of Winter-run Chinook Salmon

STARS

Average Sacramento River flows at Freeport December through May are similar under Alternative 4 compared with the No Action Alternative. The STARS model is responsive to modeled Freeport flows and daily operations of the DCC gates, both obtained from CalSim 3.

The STARS model provides predictions of routing and survival probabilities, in this section routing results are discussed. In the "survival" section survival results are discussed. Mean proportion of particles routed to the Interior Delta via either Georgiana Slough or the DCC), averaged across all water year types by month under Alternative 4 was equal to or less than the No Action Alternative for all months December through April except January where a 0.5% increase was predicted (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*). The difference in proportion of particles routed to the Interior Delta under Alternative 4 is minimal and would likely have no effect on outmigrating juveniles.

ECO-PTM

Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under Alternative 4 ranged from less than the No Action Alternative (up to 7% less under <-5,500 cfs) to greater than the No Action Alternative (up to 12% greater under -3,500 cfs) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in the attachment. The decrease in routing to the Interior Delta could have a beneficial effect on outmigrating juveniles while the increase in routing could have an adverse effect on outmigrating juveniles.

Summary

Two flow-based quantitative models suggest depending on considered variables, flows under Alternative 4 relative to the No Action Alternative may be adverse or beneficial for outmigrating juvenile Chinook salmon when results are binned by OMR grouping. Alternative 4 relative to the No Action Alternative's STARS modeling results suggest little to no impact on routing into the Interior Delta. Alternative 4 relative No Action Alternative using ECO-PTM suggest a potential adverse or beneficial impact dependent on OMR grouping.

Potential Changes to Through Delta Survival of Winter-run Chinook Salmon

Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. Juvenile Chinook salmon entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010, 2018).

Differences in monthly flows on the Sacramento River under Alternative 4 compared with the No Action Alternative may have effects on juvenile Chinook salmon's routing and survival probabilities in the Sacramento River. These possible differences were evaluated using several quantitative models: STARS, ECO-PTM, the Delta Passage Model, IOS, and OBAN.

STARS

Average Sacramento River flows at Freeport December through May are similar under Alternative 4 compared with the No Action Alternative. The STARS model is responsive to modeled Freeport flows and daily operations of the DCC gates, both obtained from CalSim 3.

The STARS model provides predictions of routing and survival probabilities, in this section survival results are discussed. In the "routing" section routing results are discussed. Mean predicted through-Delta survival of particles across all routes, averaged across all water year types by month under Alternative 4 was minimally greater than the No Action Alternative in all months December through April (up to 0.4% in April and December) (Attachment I.5, *Survival, Travel Time, and Routing Simulation Model*). This minimal increase in survival would have no effect on outmigrating juveniles.

ECO-PTM

Mean through-Delta percent survival December through March under Alternative 4 ranged from less than the No Action Alternative (up to 5% less under -3,500 cfs) to greater than the No Action Alternative (up to 6% more under <-5,500 cfs) (Attachment I.7, *ECO-PTM*). Survival through Delta-specific routes is discussed further in the attachment. The increase in survival under some OMR conditions could have a beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have an adverse effect on outmigrating juveniles.

Delta Passage Model

Under Alternative 4, in all water year types except dry water years, predicted mean survival of winter-run Chinook salmon to Chipps Island is higher than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). The change in mean predicted survival to Chipps Island in all water year types was less than or equal to 0.001..

IOS: Through-Delta Survival

Under Alternative 4 in above normal and critically dry water years only, mean predicted through Delta survival of winter-run Chinook salmon juveniles is lower than when compared to the No Action Alternative. The change in mean predicted river migration survival in all water year types less than or equal to ± .005.

OBAN: Delta Survival

Delta survival under Alternative 4 was less than under the No Action Alternative (1.1% less, Table O-30). This decrease would have a minimal adverse effect on outmigrating juvenile winter-run Chinook salmon.

Summary

Alternative 4 relative to the No Action Alternative are largely expected to have a possible adverse to beneficial impact on survival of outmigrating juvenile winter-run Chinook salmon dependent on model due to differences in flow. Alternative 4 relative to the No Action Alternative are expected to have a possible minimal beneficial impact in all months December through April (STARS), minimal adverse impact (OBAN), adverse or beneficial impact dependent on OMR grouping (ECO-PTM), or no impact (DPM, IOS).

O.7.9 Central Valley Spring-run Chinook Salmon ESU

O.7.9.1 Sacramento River

Spawning and Egg/Alevin Incubation

Spring-run Chinook salmon adults spawn from August through October (Williams 2006) with peak spawning in September (see Section O.1.3.2). Monitoring spring-run Chinook salmon spawning in the mainstem Sacramento River is complicated due to lack of spatial/geographic segregation and temporal isolation from fall-run Chinook salmon. Most spring-run Chinook salmon spawning occurs between the Keswick Dam and Ball Ferry Bridge (National Marine Fisheries Service 2017c). Fry emergence occurs up to three months after eggs are spawned (Moyle 2002), so effects of flow in the upper Sacramento River on incubating spring-run Chinook salmon eggs and alevins potentially occur from August through January, peaking in December.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 4, mean spawning WUA increases in wet and critically dry water year types and lower in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 4 and the No Action Alternative is a 3.2% increase in critically dry water year types for Alternative 4. The largest reduction in estimated spawning habitat is a -2.2% decrease for Alternative 4 in above normal water year types (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The monthly median value of spawning WUA under Alternative 4 is similar to the No Action Alternative for the three months of spring-run spawning (August–October) (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA for all of the modeled alternatives are substantially lower in August than in September or October. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently higher in August than in the other two months (Table O-266). This results in lower spawning WUA results because the fall-run Chinook salmon spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), which were used to estimate spring-run spawning WUA, peak at relatively low flows (approximately 3,000 to 6,000 cfs).

The results of suitable habitat availability analysis using the SIT LCM habitat models indicate that spawning habitat for spring-run in the upper Sacramento River may not be a limiting factor under both the No Action Alternative and Alternative 4 (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The results of the two spawning habitat analyses based on CalSim 3 simulated flows suggest that Alternative 4 has a minor (less than 3.5%) increase and/or decrease on estimated spawning habitat when compared to the No Action Alternative, and that spawning habitat may not be a limiting factor for spring-run Chinook salmon in the mainstem upper Sacramento River.

SIT Spring-run Lifecycle Model: Spawner Abundance

In the CVPIA spring-run SIT life cycle model, mean spring-run Chinook salmon spawner abundance in the Central Valley under Alternative 4 in Chinook salmon spawner abundances are similar to the No Action Alternative in the Central Valley, with up to 0.1% increase in wet water year types and 0.1% decrease in dry and above normal water year types (Attachment F.3, *CVPIA SIT Spring-run LCM*). Over the full model run period (1980–1999), abundance under Alternative 4 was equal to abundance under the No Action Alternative. Overall, the spawner abundance predicted by the CVPIA spring-run life cycle model is expected to be similar under Alternative 4 and the No Action Alternative.

Redd Dewatering Analysis

Under Alternative 4, the spring-run Chinook salmon redd dewatering results show a consistent reduction from wetter to drier water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation is expected for spring-run Chinook salmon because their spawning occurs in the fall, with incubation extending into early winter. During wet winters, periodic storms and high runoff increase flow fluctuations, which tends to result in greater redd dewatering potential. In drier winters, flow fluctuations are reduced and fewer redds are dewatered. Mean redd dewatering potential is much lower under Alternative 4 than under the No Action Alternative in wet, above normal, and critical water years but differences are minor for below normal and dry water year types. The largest reduction is 40.4% for above normal water years and the only increase is 2.3% for dry years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). For individual month periods, redd dewatering is moderately higher for September spawning than for October spawning (Attachment L.4, *Sacramento River Redd Dewatering Analysis*).

Overall, the results indicate that redd dewatering potential would be lower under Alternative 4 than under the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 48 for Keswick Dam and Table 50 for Red Bluff Diversion Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 54 for Keswick Dam and Table 56 for Red Bluff Diversion Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during September through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 60 for Keswick Dam and Table 62 for Red Bluff Diversion Dam.

Results for the three analyses are summarized in Table O-39. Table O-39, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 42.1°F to 55°F spawning initiation range analysis, there were six and zero month-water year type combinations (17.1% and 0% of total combinations during the period) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively (Table O-39). There were zero and one combinations (0% and 2.9%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. For the 59.9°F pathogen virulence threshold, there were three and seven combinations (8.6% and 20.0%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively, and there were zero and three combinations (0% and 8.6%) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were two and zero combinations (5.7% and 0%) with favorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively, and zero and two combinations (0% and 5.7%, respectively) with unfavorable results below Keswick Dam and at Red Bluff Diversion Dam, respectively. These results suggest that there would be positive and negative effects of Alternative 4 on spring-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative are expected to have negligible impacts on spring-run Chinook salmon spawning, spawner abundance and egg/alevin incubation (mortality) due to differences in flow. There is a beneficial impact on redd dewatering, with lower redd dewatering potential in wet, above normal water years, and critically dry water years and little difference in below normal and dry water years. Flow for spawning habitat is not a limiting factor for spring-run Chinook salmon. Water temperatures for spawning and egg/incubation will have beneficial and adverse impacts under Alternative 4 compared to the No Action Alternative.

Juvenile–Yearling Rearing and Emigration

Spring-run Chinook salmon juveniles rear in the Sacramento River primarily from November through June and most emigrate to the Delta during December and again in March and April (Roberts 2007) (see Section O.1.3.2, *Spring-run Chinook Salmon*). Migratory cues, such as increased flow and/or turbidity from runoff, may spur emigration of juveniles from the upper Sacramento River basin when they have reached the appropriate stage of maturation (National Marine Fisheries Service 2009a). Inundated floodplain habitats have been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001a, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 4, mean fry rearing WUA increases in wet and above normal water year types and decreases in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increases in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 0.1% increase in wet water year types. The largest reduction in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a -0.8% decrease in below normal water year types.

The monthly median value of fry rearing WUA under Alternative 4 is similar to the No Action Alternative January through April (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Fry rearing WUA median values for all the modeled alternatives are similar across December, January, and March, which are important months for rearing. The results during these three months show little variation in the third quartile of the WUA distributions. This occurs because the fry rearing WUA curves peak at the lowest flows encountered in the river (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and Keswick Dam flow releases are frequently low during these months in critically dry years when Shasta Reservoir is operated to rebuild storage volume (Table O-266). The first quartile is much wider because a greater range of flows affect the fry rearing WUA values below the median. November and April have the lowest median WUA values across all alternatives.

The results of the fry rearing habitat analysis suggest that Alternative 4 may have a negligible (less than 1%) increase and/or decrease in estimated spring-run fry rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative.

Juvenile Rearing Habitat Analyses

Under Alternative 4, juvenile rearing WUA decreases in all water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). There are no increases in estimated juvenile rearing habitat under Alternative 4 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat is a 1.4% decrease in critically dry water year types between Alternative 4 and the No Action Alternative.

The monthly median value of juvenile rearing WUA under Alternative 4 is similar to the No Action Alternative January through May (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The juvenile rearing WUA values under all the modeled alternatives are similar for January through March, but they are generally lower for April and May. For the January through March period, as described above for spring-run Chinook salmon fry rearing WUA, the third quartiles of the WUA distributions have high values and reduced variation. This reduced variation occurs because, as described for the fry rearing WUA curves, the juvenile rearing WUA curves peak at the lowest flows encountered in the river (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and low flows are frequent during January through March in dry and critically dry years when Shasta Reservoir is operated to rebuild storage (Table O-266).

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for spring-run in the upper Sacramento River show a 0.7% to -1.1% difference between the months of January and May (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest increase in estimated spring-run habitat may occur in the month of May and the greatest reduction in estimated habitat may occur in January under Alternative 4 in comparison to the No Action Alternative.

The results of the two spring-run Chinook salmon juvenile rearing habitat analyses suggest that Alternative 4 may have a minor (less than 2%) increase and/or decrease in estimated juvenile rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in comparison to the No Action Alternative in the mainstem upper Sacramento River.

Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. Alternative 4 shows an increase in mean stranding of spring-run fry from critically dry, dry, and below normal water years to above normal and wet years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The higher mean stranding levels for spring-run fry during wetter water year types likely results from increased variability of flow. Spring-run Chinook salmon fry rearing occurs primarily during late fall and winter. For individual months, Alternative 4 shows the highest median stranding in November and lowest median stranding in December and January, with February median stranding at an intermediate level (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Fry stranding means are lower under Alternative 4 than under the No Action Alternative in all water year types except for a 10.0% increase in critically dry water year types (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The reductions range from 0.6% lower in below normal water years to 6.6% lower in dry water years.

Overall, spring-run stranding of fry is slightly lower under Alternative 4 relative to the No Action Alternative, except for an increase in stranding under critically dry water years.

Survival and Travel Time: XT and Flow Survival Threshold Models

For a detailed description of how flows under Alternative 4 may impact juveniles and yearlings' travel time and survival probabilities in the Upper Sacramento River, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.1).

Results from the Flow Survival Threshold model indicate that the average annual mean survival probability of juvenile Chinook salmon is always highest during wetter years and lowest during drier years. For all water year types, the annual mean survival probability is greater under Alternative 4 than under the No Action Alternative, ranging from 5% greater in wet water years to 25% dry water years (Attachment J.5, *Flow Threshold Salmon Survival Model).*

The XT model results indicate that mean travel times from Red Bluff Diversion Dam both to the confluence of the American and Sacramento rivers and to the DCC range from negligibly higher under Alternative 4 than under the No Action Alternative for wet years (+1%) to 5% less for dry years, with potentially minimal positive effects on outmigrating juvenile Chinook salmon. The mean survival probability as indicated by the XT model for the same reaches was essentially similar under Alternative 4 and the No Action Alternative (up to 1% greater in dry and critically dry water years). (Attachment J.4, *XT Model*).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for juvenile growth, smoltification, and predation vulnerability during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 66 for Keswick Dam, Table 68 for RBDD, and Table 70 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating juveniles during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 74 for Keswick Dam, Table 76 for RBDD, and Table 78 for Hamilton City. Full results of

the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for yearling growth, smoltification, and predation vulnerability are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 82 for Keswick Dam during April through December, Table 84 for RBDD during April through December, and Table 98 for Hamilton City during October through December (migration only). Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating yearlings are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 88 for Keswick Dam during April through December, Table 90 for RBDD during April through December, and Table 106 for Hamilton City during October through December (migration only).

Results for the four analyses are summarized in Table O-40. Table O-40, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 55.4°F to 68°F juvenile optimum temperature range under Alternative 4, there were zero to two month-water year type combinations (0% to 6.7% of total combinations during the period) with favorable results depending on location (Table O-40). There were zero to two combinations (0% to 5.0%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles under Alternative 4, there would be no combinations with either favorable or unfavorable results at any location. For the 55.4°F to 68°F yearling optimum temperature range under Alternative 4, there would be zero combinations (0%) with favorable results at each location. There would be zero to five combinations (0% to 11.1%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating yearlings under Alternative 4, there would be no combinations (0%) with either favorable or unfavorable results at any location.

These results indicate that there would generally be a mix of favorable and unfavorable water temperature-related conditions under Alternative 4 related to optimum water temperatures on juveniles and yearlings, and there would be no exacerbation of lethal water temperatures at any location associated with Alternative 4.

<u>Summary</u>

Alternative 4 relative to the No Action Alternative is largely expected to be similar, with negligible impact on spring-run Chinook salmon juvenile and yearling rearing habitat due to differences in flow. There is a minor beneficial impact on stranding in comparison to the No Action Alternative, except for an adverse impact in critically dry years. Annual mean survival would have a beneficial impact, and mean survival is negligible or slightly beneficial compared to the No Action Alternative. Travel time was mixed, with both beneficial and adverse impacts. Water temperatures for optimum juvenile and yearling rearing is a mix of minor beneficial and adverse water temperature-related conditions under Alternative 4 and there would be negligible impacts of Alternative 4 on lethal temperatures at all locations.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon enter the San Francisco Estuary from the Pacific Ocean to begin their upstream spawning migration in late January and early February (California Department of Fish and Wildlife 1998). Spring-run Chinook salmon generally enter rivers as sexually immature fish and must hold in freshwater for up to several months before spawning (Moyle 2002). While maturing, adults hold in deep pools with coldwater. Documentation of holding locations in the Sacramento River was not identified.

Spring-run Chinook salmon adults enter the Sacramento River from March to September, primarily in May and June (Moyle 2002; Yoshiyama et al. 1998). In the upper Sacramento River, migration extends from mid-March through July with peak migration in late May and early June (California Department of Fish and Wildlife 1998).

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

CalSim 3 Flows

During the January through June/July period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 4 at Sacramento River below Keswick Dam, below Red Bluff Diversion Dam, Hamilton City, and Wilkins Slough would generally be similar to flows under the No Action Alternative. Flows under Alternative 4 in May, June and July during critically dry years would decrease below Keswick Dam and below Red Bluff Diversion Dam, while during critically dry years flows under Alternative 4 would decrease in July at Hamilton City and Wilkins Slough compared to the No Action Alternative Flows at all sites range from -5% to -11% at Keswick Dam in May during a critically dry year. Flows at Hamilton City under Alternative 4 would be high enough (> 3,250 cfs) to allow upstream passage. The average monthly flows across all water year types under Alternative 4 between January and June/July would be greater than 5,500 cfs at Wilkins Slough (except in June) and greater than 7,500 cfs at Hamilton City (Table O-266 through Table O-269).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during March through September are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 40 for Keswick Dam, Table 42 for RBDD, and Table 44 for Hamilton City.

Results for the analysis are summarized in Table O-41. Table O-41, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4, there were zero to two month-water year type combinations (0% to 5.7% of total combinations during the period) with favorable results and zero to two combinations (0% to 5.7%) with unfavorable results, depending on location (Table O-41). These results suggest that there would be mostly negligible water temperature-related effects of Alternative 4 on spring-run Chinook salmon migration and holding in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts, on upstream migrating and holding adult spring-run Chinook salmon, except in May during critically dry years when there could be an adverse impact due to differences in flow. Average monthly flows at Hamilton City and Wilkins Slough are high enough to allow upstream passage. Differences in water temperatures between Alternative 4 and the No Action Alternative are expected to have negligible impacts on upstream migrating and holding adult spring-run Chinook salmon.

O.7.9.2 Clear Creek

Spawning and Egg Incubation

Spawning occurs in gravel substrate in relatively fast-moving, moderately shallow riffles or along banks with relatively high water velocities to promote higher oxygen levels. Spawning in Clear Creek normally occurs between mid-August and early October, peaking in September (Moyle 2002).

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 4, mean spawning WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean spawning WUA under Alternative 4 in comparison to the No Action Alternative. The largest reduction in estimated spawning habitat is a 12.7% decrease in below normal water year types. On average across all water year types, there is an 11.9% reduction in estimated spawning habitat under Alternative 4.

The mean values of spawning WUA by month are lower under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). October is expected to have the highest spawning WUA values under the four phases of Alternative 4.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that spawning habitat for spring-run in Clear Creek may be a limiting factor under all of the modeled alternatives and that spawning habitat may decrease 9.5-11.1% in September and October for Alternative 4 in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The two spawning habitat analyses indicate that Alternative 4 may have an adverse impact, as spring-run Chinook salmon spawning habitat may decrease on average by 11.9% across all water year types in Clear Creek when compared to the No Action Alternative, and that spawning habitat may be a limiting factor for spring-run Chinook salmon in Clear Creek.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 52 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water

temperature above the 59.9°F adult pathogen virulence threshold during April through October are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 58 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during September through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 6 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-42. Table O-42, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 42.1°F to 55°F spawning initiation range analysis, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-42). For the 59.9°F pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be no water temperature-related effects of Alternative 4 on spring-run Chinook salmon spawning in Clear Creek.

Summary

Alternative 4 relative to the No Action Alternative is expected to have adverse impacts on spawning habitat area due to a decrease in flows. There are no anticipated water temperature-related effects of Alternative 4 relative to the No Action Alternative.

Juvenile–Yearling Rearing and Emigration

While the majority of juvenile spring-run Chinook salmon outmigrate as fry, a proportion rears in Clear Creek through the spring and summer and emigrates as sub-yearlings with the first rainstorms in the fall or winter following their birth (National Marine Fisheries Service 2014a). Spring-run Chinook salmon outmigration from Clear Creek occurs during late October through late April with peak emigration of juveniles occurring in November, and few fish exiting through the end of May.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 4, mean fry rearing WUA increases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is an 8.0% increase in dry water year types. There are no anticipated reductions in mean fry rearing WUA under Alternative 4 in comparison to the No Action Alternative.

The mean values of fry rearing WUA by month are generally higher under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the five fry rearing months, January and February are expected to have the highest fry rearing WUA values under the four phases of Alternative 4.

The results of the spring-run Chinook salmon fry rearing habitat analysis indicate that Alternative 4 may have up to an 8.0% increase in estimated spring-run Chinook salmon fry rearing habitat across all water year types in Clear Creek.

Juvenile Rearing Habitat Analyses

Under Alternative 4, mean juvenile rearing WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under Alternative 4 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between Alternative 4 and the No Action Alternative is a 5.7% decrease in critically dry water year types. On average across all water year types, there is a 5% reduction in estimated juvenile rearing habitat under Alternative 4.

The mean values of juvenile rearing WUA by month are lower June through August and higher in April and May under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the five juvenile rearing months, May and June are expected to have the highest juvenile rearing WUA values.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for spring-run Chinook salmon in Clear Creek may decrease 12.4-15.0% during the summer months (June through August) but may increase 4.2-12.6% in the spring months April and May under Alternative 4 compared to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest decrease in estimated juvenile rearing habitat may occur in June and the greatest increase in estimated juvenile rearing habitat may occur in May.

The results of the two spring-run Chinook salmon juvenile rearing habitat analyses indicate that Alternative 4 may have a minor adverse effect, as rearing habitat may decrease on average by 5% across all water year types in comparison to the No Action Alternative, and that there may be increases to habitat in the spring and reductions in habitat in the summer in Clear Creek.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for juvenile growth, smoltification, and predation vulnerability during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 72 below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating juveniles during November through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 80 below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature range for yearling growth, smoltification, and predation vulnerability are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 86 below

Whiskeytown Dam April through December. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F UILT for rearing and migrating yearlings are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 92 below Whiskeytown Dam for April through December.

Results for the four analyses are summarized in Table O-43. Table O-43, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 55.4°F to 68°F juvenile optimum temperature range under Alternative 4, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-43). For the 75.2°F UILT for rearing and migrating juveniles, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 55.4°F to 68°F yearling optimum temperature range, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 75.2°F UILT for rearing and migrating yearlings, there were no combinations (0%) with favorable results and two combinations (4.4%) with unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on spring-run Chinook salmon juvenile and yearling rearing and emigration in Clear Creek.

Summary

Alternative 4 relative to the No Action Alternative is expected to be beneficial during all water years for spring-run Chinook salmon fry rearing habitat but may have an adverse impact on juvenile spring-run Chinook salmon rearing habitat due to differences in flow. Differences in water temperatures are negligible so are not expected to affect fry and juvenile rearing and emigration.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon migrate into Clear Creek from April to August, and peak passage occurs in May and June (Clear Creek Technical Team 2018; Giovannetti et al 2013). Adults distribute throughout Clear Creek and hold in deep pools throughout the summer from Whiskeytown Dam (river mile 18.3) as far downstream as river mile 4.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

CalSim 3 Flows

During the April through August period of adult spring-run Chinook salmon immigration and holding, the mean monthly flows under Alternative 4 will be increased in April and May in all water years and reduced from June to August which range from 3% in July in all water years, up to 36% in June during a critically dry year. Average flows range from 112 cfs in July to 261 cfs in May (Table O-275).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during March through September are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 46 below Whiskeytown Dam.

Results for the analysis are summarized in Table O-44. Table O-44, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 37.9°F to 68°F successful adult migration range, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-44). These results suggest that there would be no water temperature-related effects of Alternative 4 on spring-run Chinook salmon adult upstream migration and holding in Clear Creek.

Summary

Alternative 4 relative to the No Action Alternative may have an adverse impact from June to August on upstream migrating and holding adult spring-run Chinook salmon due to differences in flow. There would be no water-temperature related effects of Alternative 4 relative to the No Action Alternative.

O.7.9.3 Bay-Delta

Juvenile–Yearling Rearing and Emigration

Juvenile spring-run Chinook salmon show two distinct out-migration patterns in the Central Valley: out-migrating to the Delta and ocean during their first year of life as YOY or holding over in their natal streams and out-migrating the following fall/winter as yearlings. YOY spring-run Chinook salmon presence in the Delta peaks during April and May, as suggested by the recoveries of Chinook salmon in the CVP and SWP salvage operations and the Chipps Island trawls of a size consistent with the predicted size of spring-run fish at that time of year.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Zone of Influence

Differences in hydrology under Alternative 4 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions. With incremental decreases in OMR under Alternative 4 and the No Action Alternative, proportional overlap at these three locations decreases, with more subtle changes along the San Joaquin River at Jersey Point compared to Turner Cut and Old River at Middle River. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under Alternative 4 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2, *Zone of Influence*).

Flow into Junctions

Differences in flow routing under Alternative 4 compared with the No Action Alternative may have effects on the flow into the Head of Old River and CVP junctions.

Under Alternative 4 in all OMR bins except -3,500, predicted proportion of flow entering the CVP is less than the No Action Alternative. Changes in predicted proportion of flow entering the CVP in OMR bins -3,500, -5,000, and <-5,500 was less than ± 0.0372, indicating a negligible difference between Alternative 4 and the No Action Alternative. However, in OMR bin -2,000 the change in predicted proportion of flow into CVP was -0.0676 indicating that slightly less flow will be routed into CVP under Alternative 4 than when compared to the No Action Alternative.

Under Alternative 4 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the Head of Old River (HOR) is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.026, indicating a negligible difference between Alternative 4 and the No Action Alternative.

For a detailed description of how flows under Alternative 4 may impact the flow at HOR and CVP, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2, *Flow into Junctions*).

Summary

Alternative 4 relative to the No Action is expected to influence flow into the HOR and CVP junctions. Under Alternative 4, no change to possibly less flow into CVP under OMR -2,000; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 4 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Spring-run Chinook Salmon

Salvage Density and Negative Binomial

Predictions from the salvage density and the negative binomial model for LAD spring-run Chinook salmon include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP and Table O-281 shows modeled mean monthly flows of the San Joaquin River at Vernalis. Refer to the tables for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of LAD spring-run Chinook salmon at SWP Banks Pumping Plant for all the months January through June for Alternative 4 was greater than predicted average monthly loss under the No Action Alternative for all water year types with up to a 117% increase in predicted loss for above normal water year types (Table O-45). Predicted average monthly loss of LAD spring-run Chinook salmon at CVP Jones Pumping Plant for all the months December through June for Alternative 4 was higher than predicted average monthly loss under the No Action Alternative for all water year types except for dry water year types that had a

decrease in predicted loss of 1%. Predicted average monthly loss at Jones for LAD spring-run under Alternative 4 compared to the No Action Alternative increased for wet, above normal, below normal, and critically dry water year types, with up to a 5% increase for below normal water year types (Table O-46). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly salvage of LAD spring-run Chinook salmon at the Delta fish collection facilities for the months of March through June under Alternative 4 was greater than predicted loss under the No Action Alternative for all water year types, with up to a 97% increase in predicted loss for above normal water year types. (Table O-47). For detailed information on average monthly salvage by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Summary

Alternative 4 relative to the No Action Alternative resulted in an increase of entrainment due to differences in flow. Average monthly loss and salvage of LAD spring-run Chinook salmon was greater for all months and most water years at both facilities, supported by results from the two quantitative models.

Potential Changes to Routing of Spring-run Chinook Salmon

ECO-PTM

Differences in flows under Alternative 4 compared with the No Action Alternative may have effects on juvenile Chinook salmon's routing to Interior Delta via Georgiana Slough in the Delta. This possible difference was evaluated using ECO-PTM, a quantitative model. Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under Alternative 4 ranged from less than the No Action Alternative (up to 7% less under <-5,500 cfs) to greater than the No Action Alternative (up to 12% greater under -3,500 cfs) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in the attachment. The decrease in routing to the Interior Delta could have a beneficial effect on outmigrating juveniles while the increase in routing could have an adverse effect on outmigrating juveniles. For a detailed description of how flows under Alternative 4 may impact spring-run Chinook salmon routing, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2).

Summary

Alternative 4 relative to the No Action using ECO-PTM suggest a potential adverse or beneficial impact dependent on OMR grouping due to differences in flow.

Potential Changes to Through Delta Survival of Spring-run Chinook Salmon

ECO-PTM

Differences in flows under Alternative 4 compared with the No Action Alternative may have effects on juvenile Chinook salmon's through-Delta survival. This possible difference was evaluated using ECO-PTM, a quantitative model. Mean through-Delta percent survival December through March under Alternative 4 ranged from less than the No Action Alternative (up to 5% less under -3,500 cfs) to greater than the No Action Alternative (up to 6% more under

<-5,500 cfs) (Attachment I.7, *ECO-PTM*). Survival through Delta-specific routes is discussed further in the attachment. The increase in survival under some OMR conditions could have a beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have an adverse effect on outmigrating juveniles. For a detailed description of how flows under Alternative 4 may impact spring-run Chinook salmon through-Delta survival, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2).

Delta Passage Model

Under Alternative 4, in all water year types except below normal, predicted mean survival of spring-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). The change in mean predicted survival to Chipps Island in all water year types is less than or equal to ± .0.002.

Summary

Alternative 4 relative to the No Action Alternative is expected to have a possible adverse to beneficial impact on survival of outmigrating juvenile spring-run Chinook salmon dependent on model due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have an adverse or beneficial impact dependent on OMR grouping (ECO-PTM), or no impact (DPM).

O.7.10 California Central Valley Steelhead DPS

O.7.10.1 Sacramento River

Spawning and Egg Incubation

Steelhead mostly use the Sacramento River as a migratory corridor for reaching other tributaries to spawn. Data on steelhead spawning in the mainstem Sacramento River is limited and likely restricted to the area upstream of Red Bluff (National Marine Fisheries Service 2009a). No steelhead specific spawner surveys occur in the upper Sacramento River. Data from recent surveys for the four runs of Chinook salmon have found carcasses of *O. mykiss* but the majority are thought to be resident trout adults (Killam 2022). Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional 2-4 weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In the Sacramento River, estimated incubation timing based on spawning is December through June.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 4, differences in mean spawning WUA are generally similar to or slightly lower than (less than 0.6%) the No Action Alternative across all water year types (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 4 and the No Action Alternative is a 0.05% increase in wet water years. The largest reduction in estimated spawning habitat is a -0.6% decrease in below normal water year types.

The monthly median value of spawning WUA under Alternative 4 is similar to the No Action Alternative January through April (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are relatively similar in January through March. In April, the median values of spawning WUA are higher across all alternatives when compared to the other spawning months. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently lowest in April when compared to other spawning months (Table O-266). This results in lower spawning WUA results because the steelhead spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 4,000 to 7,000 cfs).

The results of suitable habitat analysis using the SIT LCM habitat models suggest that spawning habitat for steelhead in the upper Sacramento River may increase in April under all alternatives compared to the other spawning months (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*. Lack of consistent spawner estimates for steelhead prevented Reclamation staff from calculating spawner limitation ratios for this species.

The results of the two spawning habitat analyses based on CalSim 3 flows suggest that Alternative 4 may have a negligible (less than 0.6%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. Out of the four months of steelhead spawning, April has the highest estimated spawning WUA across all alternatives.

Redd Dewatering Analysis

The results for Alternative 4 show a substantial reduction in mean redd dewatering potential from wetter to drier water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation reflects flow conditions for the winter and early spring months when steelhead spawning and incubation occurs. During wet winters and springs, periodic storms and high runoff increase flow fluctuations, which tend to result in greater redd dewatering. In drier years, flow fluctuations are reduced and fewer redds are dewatered. Mean redd dewatering potential is lower under Alternative 4 than the No Action Alternative, including a maximum reduction of 19.2% in dry water years. Other reductions are small, ranging from 2.0% for above normal years to 0.1% for critically dry water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). For individual month periods, median redd dewatering potential under Alternative 4 is highest for February spawning and lowest for April spawning (Attachment L.4, *Sacramento River Redd Dewatering Analysis*).

Overall, the results indicate that steelhead redd dewatering potential under Alternative 4 is lower or little different relative to the No Action Alternative in all water year types.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis* Table 134 for Keswick Dam and Table 136 for RBDD. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 140 for Keswick Dam and Table 142 for RBDD. Full results of the analysis assessing the percent of

months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 170 for Keswick Dam and Table 172 for RBDD.

Results for the three analyses are summarized in Table O-48. Table O-48, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 45.5°F to 55°F successful spawning range analysis, there were three and zero month-water year type combinations (13.3% and 0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-48). There were zero combinations (0%) with unfavorable results at Keswick Dam and RBDD. For the 59.9°F pathogen virulence threshold, there were zero and two combinations (0% and 6.7%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were zero and one combinations (0% and 3.3%) with unfavorable results at Keswick Dam and RBDD, respectively. For the 45°F to 52°F range for optimal egg incubation, there were one and zero combinations (2.9% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were six and two combinations (17.1% and 5.7%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be positive water temperature-related effects and negative effects of Alternative 4 on steelhead spawning and egg incubation in the Sacramento River.

Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on steelhead spawning behavior and redd dewatering from sudden drops in flow. Redd surveys are occurring during the pulse flow period and redd dewatering has not been observed.

Summary

There are expected adverse and beneficial impacts of seasonal operations on steelhead spawning and egg incubation based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are expected to have a negligible increase and/or decrease on spawning habitat area and may decrease redd dewatering potential during some water year types. There may be adverse impacts to spawning behavior from spring pulse flows. There may be redd dewatering following spring pulse flow events, though this has not been observed during redd surveys. The water temperature analysis indicates that there would be both beneficial and adverse impacts of Alternative 4 on steelhead spawning and egg incubation in the Sacramento River. Water temperatures outside the successful spawning range are expected to decrease in frequency under Alternative 4 relative to the No Action Alternative below Keswick Dam. Water temperatures outside of the optimal egg incubation range are expected to increase in frequency under Alternative 4 relative to the No Action Alternative below Keswick Dam.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in

the Sacramento River. The timing of juvenile outmigration depends on the watershed and water year. The RST monitoring station at Knight's Landing indicate outmigration into the Delta, with median passage starting in January and ending in May from 2006-2024 (Columbia Basin Research, University of Washington 2024).

Potential Changes to Steelhead from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 4, mean fry rearing WUA increases in critically dry water year types and decreases in all other water year types in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). WUA curves were not developed for steelhead, so the late fall-run Chinook salmon curves were used to quantify spring-run habitat. The largest increase in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 3.9% increase in critically dry water year types. The largest reduction in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 0.8% decrease in below normal water year types.

The monthly median value of fry rearing WUA under Alternative 4 has a 7% reduction in September in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The median values are similar throughout the other fry rearing months. The estimated fry rearing WUA values under the modeled alternatives are highly variable across the months, April through October, but are generally highest in April and October (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). WUA values of the fry rearing WUA curve are lowest in the range of approximately 7,000 cfs to 13,000 cfs in Segment 5 (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and flows in this range are more frequent during May through August (Table O-266).

The results of the steelhead fry rearing habitat analysis based on CalSim 3 flows suggest that Alternative 4, in comparison to the No Action Alternative, may have a minor (less than 4%) increase and/or decrease in estimated fry rearing habitat across all water year types. There are some differences in estimated rearing WUA habitat under Alternative 4 when looking at a monthly scale, with a minor (7%) reduction in estimated fry rearing habitat in September in comparison to the No Action Alternative.

Juvenile Rearing Habitat Analyses

Under Alternative 4, differences in mean juvenile rearing WUA constitute reductions in all water year types in comparison to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The upper and lower limits of the range in WUA values are determined by the ranges of the juvenile rearing WUA curves for late-fall run since there were no reliable WUA curves for steelhead (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The analysis includes all months because steelhead juveniles may reside in freshwater for a year or more before emigrating to the ocean. There are no increases in estimated juvenile rearing habitat under Alternative 4 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between Alternative 4 and the No Action Alternative is a 1.2% decrease in below normal water year types.

The monthly median values of juvenile rearing WUA under Alternative 4 are similar to the No Action Alternative throughout the year (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The juvenile rearing WUA values under the modeled alternatives are similar December through March, and gradually decrease until the lowest estimated values in July. The high WUA values with low variability in the third quartile for December through March result from the peaking of the WUA curve at the lowest flows (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and frequent low Keswick Dam flow releases during these months to build Shasta Reservoir storage (Table O-266). The wide range of values in the first quartile of these months reflects the high frequency and variability of higher flows in these wet months. The low juvenile rearing WUA values June through August result from releases in the summer months above 10,000 cfs and estimated peak juvenile rearing at flows below 5,000 cfs.

The results of the suitable habitat analysis using the SIT LCM habitat models indicate that steelhead juvenile instream rearing habitat in the upper Sacramento River have a 3.9% to –3.0% difference from January through December (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest increase in estimated habitat may occur in September and the greatest reduction in estimated habitat may occur in November under Alternative 4 in comparison to the No Action Alternative.

The results of the two steelhead juvenile rearing habitat analyses based on CalSim 3 flows suggest that Alternative 4, in comparison to the No Action Alternative, may have a minor (less than 2%) decrease in estimated steelhead juvenile rearing habitat across all water year types and that the greatest increase in estimated habitat may occur in September (3.9%) in the mainstem upper Sacramento River.

Fry Stranding Analysis

The analysis of fry stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. Mean stranding of steelhead fry under Alternative 4 shows large variation among water year types, with wet years having the highest stranding and dry water years the lowest (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Alternative 4 shows the highest stranding in February, with the median level trending down over the next three months (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The higher mean stranding levels for steelhead fry during February and wet water year types likely results because of periodic storms and high runoff that produce increased variability of flow. Steelhead fry rearing occurs primarily during late winter and spring. Mean stranding under Alternative 4 is lower than stranding under No Action Alternative for all water year types, including a reduction of 23.4% for dry water years. Reduction in other water year types range from 9.4% in critically dry years to 1.3% in above normal water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*).

Overall, mean stranding for steelhead fry is lower under Alternative 4 than under the No Action Alternative, including an especially large reduction for dry water year types.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperature range year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 182 for Keswick Dam and Table 184 for

RBDD. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 188 for Keswick Dam, Table 190 for Red Bluff Diversion Dam, and Table 192 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 55°F upper limit of successful smoltification during January through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 196 for Keswick Dam, Table 198 for Red Bluff Diversion Dam, and Table 200 for Hamilton City.

Results for the three analyses are summarized in Table O-49. Table O-49, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 66.2°F upper limit of optimum temperature range, there were zero and one month-water year type combinations (0% and 1.7% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-49). There were no combinations (0%) with unfavorable results at both locations. For the 59.9°F juvenile pathogen virulence threshold, there were one and seven combinations (1.7% and 11.7%, respectively) with favorable results depending on location. There were zero and three combinations (0% to 5.0%) with unfavorable results depending on location. For the 55°F upper limit of successful smoltification, there were zero to three combinations (0% to 12.0%) with favorable results depending on location. There were no combinations (0%) with unfavorable results depending on location. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 4 on steelhead juvenile rearing and emigration in the Sacramento River.

<u>Sacramento River Pulse Flows</u>

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

<u>Summary</u>

There are expected generally beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are expected to have a minor increase and/or decrease on fry and juvenile rearing habitat area. Changes in flows are expected to decrease fry stranding, with moderate decreases during dry water year types. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. Water temperatures above the smoltification upper limit are expected to decrease in frequency below Keswick Dam. The frequency of exceedance above the pathogen virulence threshold is expected to increase, decrease, or remain unchanged, depending on location, under Alternative 4 compared to the No Action Alternative.

Adult Upstream Migration and Holding

Adult steelhead enter the San Francisco Estuary from the Pacific Ocean and will either spawn within a few months of entering freshwater or stage in pools for more extended periods until the first high flows (Moyle 2002; Williams 2006). Historical data at the Fremont Weir have shown that adult steelhead migrate upstream in the Sacramento River during most months of the year, beginning in July, peaking in September, and continuing through March (Hallock 1989; McEwan 2001; Hallock et al. 1957).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

A flow threshold of 3,250 cfs has been used to evaluate the potential for adverse effects on steelhead migrating and holding adults in the Sacramento River (Bureau of Reclamation 2019). Flows in the Sacramento River rarely drop below this level, and adults have not been observed to experience passage delays, crowding, or other adverse effects at this flow. Therefore, it represents a reasonable threshold for evaluating the potential for adverse effects on migrating and holding adults.

During the steelhead adult upstream migration and holding period, CalSim 3 modeling of Sacramento River mean monthly flows at Wilkins Slough indicate that flows are expected to go below the minimum flow in September of critically dry water year types under the No Action Alternative but flows are expected to have a minor (3%) increase under Alternative 4 (Table O-268). Flows in the Sacramento River at Wilkins Slough range from about 3,250 cfs in September of critically dry water years to about 19,900 cfs in February of wet water years during the adult migration period. Flows in the Sacramento River at RBDD range from about 5,200 cfs in October of critically dry water years to almost 37,000 cfs in February of wet water years during the adult migration period (Table O-267). Under Alternative 4, Reclamation will operate minimum instream flows at 2,300 cfs in March, July, and August, and 3,250 cfs from September through February but the schedule may change in critically dry water years (WRO Order 90-5). Since peak adult migration occurs around September, there may be minor beneficial effects to adult steelhead in September of critically dry years if flows are reduced in the lower Sacramento River under Alternative 4.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range for minimal migration impairment during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 110 for Keswick Dam, Table 112 for Red Bluff Diversion Dam, and Table 114 for Hamilton City. Results for the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 118 for Keswick Dam, Table 120 for Red Bluff Diversion Dam, and Table 122 for Hamilton City. Results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for adult migration and holding during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 126 at Keswick Dam, Table 128 for Red Bluff Diversion Dam, and Table 130 for Hamilton City.

Results for the three analyses are summarized in Table O-50. Table O-50, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 41°F to 66.2°F range for minimal migration impairment, there were zero to one month-water year type combinations (0% to 2.2% of total combinations during the period) with favorable results depending on location (Table O-50). There were also zero to one month water-year type combinations (0% to 2.2%) with unfavorable results depending on location. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at any location. There were no combinations (0%) with unfavorable results depending on location. For the 59.9°F adult migration pathogen virulence threshold, there were zero to five combinations (0% to 11.1%) with favorable results depending on location. There were zero to one combinations (0% to 2.2%) with unfavorable results depending on location. These results suggest that there would be positive water temperature-related effects and negligible negative effects of Alternative 4 on steelhead adult upstream migration and holding in the Sacramento River.

Sacramento River Pulse Flows

There may be beneficial impacts of spring pulse flows on adult migration through decreased travel time.

Summary

There are expected beneficial impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under Alternative 4 compared to the No Action Alternative. Under Alternative 4, changes in flows are expected to have a negligible impact in the upper portions of the Sacramento River but may have a minor beneficial impact during peak migration in September of critically dry water year types, in the lower Sacramento River below Wilkins Slough. Spring pulse flow events may decrease travel time for adult migrants. Alternative 4 would primarily improve water temperature conditions for migrating and holding steelhead adults in the Sacramento River.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Similar to the section above for adult migration, a threshold of 3,250 cfs has been used to evaluate the potential for adverse effects (Bureau of Reclamation 2019). Flows in the Sacramento River rarely drop below this level, and adults have not been observed to experience passage delays, crowding, or other adverse effects at this flow. Therefore, it represents a reasonable threshold for evaluating the potential for adverse effects on migrating and holding adults.

During the steelhead kelt emigration period, approximately February through June, CalSim 3 modeling of Sacramento River mean monthly flows do not go below the threshold of 3,250 cfs at Keswick Dam, RBDD, Wilkins Slough or Hamilton City under Alternative 4 and the No Action Alternative (Table O-266 through Table O-269). These results suggest flows are adequate for kelt emigration in the Sacramento River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F migration impairment limit during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 146 for Keswick Dam, Table 148 for Red Bluff Diversion Dam, and Table 150 for Hamilton City. Full results for the percent of months with water temperature above the 69.8°F lethal limit to kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 154 for Keswick Dam, Table 156 for Red Bluff Diversion Dam, and Table 158 for Hamilton City. Full results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 162 for Keswick Dam, Table 164 for Red Bluff Diversion Dam, Table 166 for Hamilton City.

Results for the three analyses are summarized in Table O-51. Table O-51, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 66.2°F migration impairment limit, there were zero to three month water-year type combinations (0% to 12.0%) with favorable results depending on location (Table O-51). There were zero to one combination (0% to 4.0%) with unfavorable results depending on location. For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with favorable results at all locations. There were no combinations (0%) with unfavorable results depending at all locations. For the 59.9°F adult migration pathogen virulence threshold, there were zero to two combinations (0% to 8.0%) with favorable results depending on location. There were zero to two combinations (0% to 8.0%) with unfavorable results depending on location. These results suggest that there would be positive and negative water temperature-related effects of Alternative 4 on steelhead kelt emigration in the Sacramento River.

Sacramento River Pulse Flows

There may be beneficial impacts of spring pulse flows on kelt emigration through decreased travel time.

Summary

There are expected negligible impacts of seasonal operations on steelhead kelts based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are expected to be above the minimum flow to avoid crowding and passage delays from Keswick Dam to Hamilton City in the Sacramento River. Spring pulse flow events may decrease travel time for kelt emigration. Alternative 4 would cause beneficial and adverse water temperature-related impacts to emigrating kelts in the Sacramento River.

O.7.10.2 Clear Creek

Spawning and Egg Incubation

In Clear Creek, the temporal distribution of redd count data shows spawning December through April, with peak spawning January (Schaefer et al. 2019; Provins and Chamberlain 2019a, 2019b, 2020). Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional 2-4 weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In Clear Creek, estimated incubation timing based on spawning is late-December through late-May.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

Under Alternative 4, mean spawning WUA increases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The greatest increase in estimated spawning habitat is a 7.3% increase in dry water year types under Alternative 4 in comparison to the No Action Alternative. There are no anticipated reductions in mean spawning WUA under Alternative 4 in comparison to the No Action Alternative.

The mean values of spawning WUA by month are higher under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The four months of spawning are expected to have similar spawning WUA values.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that steelhead spawning habitat under Alternative 4 may have a minor decrease (1.0%) in January and March, and a minor increase (4.2%) in February in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

The two spawning habitat analyses based on CalSim 3 flows suggest that Alternative 4 may have a beneficial effect (up to 7.3% increase) in steelhead spawning habitat in Clear Creek across all water year types when compared to the No Action Alternative, and that spawning habitat will likely have a minor decrease in January/March and minor increase in February on a monthly scale in Clear Creek.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis* Table 138 for Clear Creek at Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during December through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 144 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 174 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-52. Table O-52, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 45°F to 55°F range for successful spawning, there was one month-water year type combinations (3.3% of total combinations during the period) with both favorable and unfavorable results below Whiskeytown Dam (Table O-52). For the 59.9°F adult pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 45°F to 52°F range for optimal egg incubation, there was one combination (2.9%) with favorable results and two combinations (5.7%) with unfavorable results below Whiskeytown Dam. These results suggest that there would be similar positive and negative water temperature-related effects of Alternative 4 on steelhead spawning and egg incubation in Clear Creek.

Summary

There are expected minor to moderate beneficial impacts of seasonal operations on steelhead spawning and egg incubation based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows may have a beneficial impact on spawning habitat area across all water year types. Water temperatures outside of the optimal egg incubation range are expected to have similar increases and decreases in frequency overall in Clear Creek below Whiskeytown Dam.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in Clear Creek. The timing of juvenile outmigration depends on the watershed and water year. The RST monitoring station in lower Clear Creek indicates outmigration into the Sacramento River with median passage starting in November and ending in June, with peak passage between April and June (Schraml and Chamberlain 2019a, 2019b, 2020, 2021).

Potential Changes to Steelhead from Seasonal Operations

Fry Rearing Habitat Analysis

Under Alternative 4, mean fry rearing WUA decreases in critically dry water year types and increases in all other water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 1.3% increase in dry water year types. The only decrease in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 0.2% decrease in critically dry water year types.

The mean values of fry rearing WUA by month are slightly higher March through May and slightly lower February and June under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The five fry rearing months are expected to have similar fry rearing WUA values.

The results of the fry rearing habitat analysis suggest that Alternative 4 may have a negligible (less than 1.3%) increase and/or decrease in estimated steelhead fry rearing habitat across all water year types in Clear Creek.

Juvenile Rearing Habitat Analyses

Under Alternative 4, mean juvenile rearing WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under Alternative 4 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between Alternative 4 and the No Action Alternative is a 5% decrease in dry water year types. On average across all water year types, there is a 4.4% reduction in estimated juvenile rearing habitat under Alternative 4.

The mean values of juvenile rearing WUA by month are lower July through October and higher in November and December under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the six months, December is expected to have the highest juvenile rearing WUA values under Alternative 4.

The results of suitable habitat analysis using the SIT LCM habitat models indicate that instream juvenile rearing habitat for steelhead in Clear Creek may decrease 1.2-15.0% in February and June through October and may increase 5.8-10.4% November through January and March through May under Alternative 4 in comparison to the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). The greatest decrease in estimated juvenile rearing habitat may occur in June and the greatest increase in juvenile rearing habitat may occur in May.

The results of the two steelhead juvenile rearing habitat analyses based on CalSim 3 flows suggest that Alternative 4 may have a minor to moderate adverse effect, as rearing habitat may decrease 4.4% on average across all water year types in comparison to the No Action Alternative, and may increase and decrease throughout the year on a monthly scale. The steelhead juvenile rearing WUA analysis in Attachment O.1, *Clear Creek Weighted Usable Area Analysis* analyzed the period between July and December, but some juveniles may rear year-round in Clear Creek, up to four years before emigration to the ocean. The greatest decrease in estimated juvenile

rearing habitat may occur in July and the greatest increase in juvenile rearing habitat may occur in May.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperature range year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 186 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 194 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 55°F upper limit of successful smoltification during January through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 202 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-53. Table O-53, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 66.2°F upper limit of optimum water temperature range for juvenile steelhead growth, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-53). For the 59.9°F juvenile pathogen virulence threshold, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 55°F upper limit of successful smoltification, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on juvenile steelhead rearing and emigration in Clear Creek.

Summary

There are expected adverse impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are expected to have a decrease in juvenile rearing habitat area across all water year types. Water temperatures above the juvenile optimum temperature and pathogens and disease criteria are expected to slightly increase in frequency in Clear Creek below Whiskeytown Dam under Alternative 4.

Adult Upstream Migration and Holding

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During the period of adult steelhead migration and holding in Clear Creek, the mean monthly flows under Alternative 4 compared to the No Action Alternative are on average reduced August through October and increased November through January (Table O-275). Throughout the full simulation period, flows on average will range from roughly a 36% increase to 31% reduction

under Alternative 4. Flows are expected to generally be above 100 cfs throughout this period in Clear Creek, and unlikely to cause delays in migration and crowding for adult steelhead.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range for minimal migration impairment during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 116 for below Whiskeytown Dam. Results for the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 124 for below Whiskeytown Dam. Results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for adult migration and holding during July through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 32 for below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-54. Table O-54, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 41°F to 66.2°F range for minimal migration impairment, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-54). For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F pathogen virulence threshold for adult migration, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be no anticipated water temperature-related effects of Alternative 4 on steelhead adult upstream migration and holding in Clear Creek.

Summary

There are anticipated minor adverse impacts of seasonal operations on adult steelhead based on analyses of simulated flows and water temperature under Alternative 4 in comparison with the No Action Alternative. Under Alternative 4 compared to the No Action Alternative, Clear Creek flows are likely adequate for migrating adults. There are no anticipated water temperature-related effects of Alternative 4 relative to the No Action Alternative.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During the period of steelhead kelt emigration in Clear Creek, the mean monthly flows under Alternative 4 compared to the No Action Alternative will be reduced towards the tail ends of emigration and increased during peak emigration (Table O-275). Throughout the full simulation period, flows on average will have a 10% reduction in February and a 31% reduction in June under Alternative 4. Throughout the full simulation period, flows on average will have a 15-36% increase March through May under Alternative 4. Flows are above 100 cfs in Clear Creek throughout this period under Alternative 4. These results suggest there are negligible effects of flow to steelhead kelt emigration under Alternative 4.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F migration impairment limit during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 152 for below Whiskeytown Dam. Full results for the percent of months with water temperature above the 69.8°F lethal limit to kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 160 for below Whiskeytown Dam. Full results for the percent of months with water temperature above the 59.9°F pathogen virulence threshold for kelt emigrants during February through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 168 for below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-55. Table O-55, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 66.2°F kelt migration impairment limit, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-55). For the 69.8°F upper lethal limit to adult migrants, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F pathogen virulence threshold for adult migration, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible effects of Alternative 4 on steelhead kelt migration in Clear Creek.

Summary

There are anticipated negligible impacts of seasonal operations on steelhead kelts based on analyses of simulated flows and water temperature under Alternative 4 in comparison with the No Action Alternative. Under Alternative 4, flows are likely adequate for the small proportion of the population that emigrate as kelts in Clear Creek. Water temperatures above the three temperature criteria for kelts are not anticipated to change in frequency in Clear Creek below Whiskeytown Dam under Alternative 4 in comparison to the No Action Alternative.

O.7.10.3 Lower American River

Spawning and Egg Incubation

In the lower American River, redd surveys have reported spawning January through mid-April, with peak spawning in February (Sweeney et al. 2021). The median months of spawning from 2002-2021 were from January through March. Redd surveys on the lower American River do not occur until the first week of January, and there are reports from the Sacramento Water Forum (2015) that indicate spawning starts in late December. Therefore, the timing window of spawning on the lower American River was analyzed from late December until March.

Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional 2-4 weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). On the lower American River, egg incubation starts in late December and ends in late May, with peak incubation between February and April (Hannon pers. comm. 2023; Sacramento Water Forum 2015).

Potential Changes to Steelhead from Seasonal Operations

<u>Spawning Habitat—Flow Analyses</u>

Under Alternative 4, lower American River steelhead mean spawning WUA is highest in critically dry water years and falls sharply with wetter year types (Attachment M.3, *American River Weighted Usable Area Analysis*). This pattern of variation occurs because streamflow during the January through March spawning season of steelhead rises from dry to wetter water year types (Table O-277). The lower American River steelhead spawning WUA curve peaks at about 2,000 cfs (Attachment M.3, *American River Weighted Usable Area Analysis*) and flows under Alternative 4 are consistently well above this level in the wetter water years. February flows are especially high in all but critically dry water years and consequently February shows the lowest spawning WUA for all alternatives (Attachment M.3, *American River Weighted Usable Area Analysis*). Differences in mean spawning WUA between Alternative 4 and the No Action Alternative are small, ranging from 2.9% lower for dry water years to no change for wet years. Median spawning WUA under Alternative 4 is about the same as that under the No Action Alternative for all the three months of the spawning season (January through March) (Attachment M.3, *American River Weighted Usable Area Analysis*).

The results of the SIT LCM model for Alternative 4 show a decrease in spawning habitat (-3.5 to 5.7% changes) in comparison to the results for the No Action Alternative (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

Overall, the results indicate that there is little difference in mean spawning WUA for steelhead between Alternative 4 and the No Action Alternative.

Redd Dewatering Analysis

The results of the analysis for redd dewatering potential under Alternative 4 for lower American River steelhead indicate that redd dewatering is much greater in wetter water years than in drier water years (Attachment M.1, *American River Redd Dewatering Analysis*). This difference reflects the greater frequency of larger flow fluctuations in wetter years. Mean steelhead redd dewatering potential is similar or higher under Alternative 4 than under the No Action Alternative for all water year types, ranging from 0.2% lower in wet water years to 132.7% higher in critically dry water years. Redd dewatering is also much higher under Alternative 4 in dry and below normal water years, with 62.4% and 12.7% increases, respectively (Attachment M.1, *American River Redd Dewatering Analysis*). The magnitude of these changes may be somewhat misleading: in absolute terms, the increases range from 2.3% to 6.1%. For the individual months of steelhead spawning in the lower American River, median redd dewatering potential is highest and variability is greatest in February for both the No Action Alternative and Alternative 4 (Attachment M.1, *American River Redd Dewatering Analysis*). This occurs because flows during the two-month incubation period following February spawning exhibit greater declines than those for January and March (Table O-277). The median for February spawning under Alternative 4 is much higher than that under the No Action Alternative (Attachment M.1, *American River Redd Dewatering Analysis*).

Overall, the results indicate that Alternative 4 produces substantial increases in redd dewatering potential of steelhead relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 20 for Hazel Avenue and Table 22 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold for spawning adults during December through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 24 for Hazel Avenue and Table 26 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 40 for Hazel Avenue and Table 42 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold during December through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 44 for Hazel Avenue and Table 46 for Watt Avenue.

Results for the analysis are summarized in Table O-56. Table O-56 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 45°F to 55°F range for successful spawning there were zero month-water year type combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-56). There were three and one month-water year type combination (15% and 5%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the

59.9°F spawning pathogen virulence threshold, there were zero combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue. For the 45°F to 52°F range for optimal egg incubation there were there were one and zero month-water year type combinations (3.3% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were two and zero month-water year type combinations (6.7% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold, there were there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue, respectively. There was one month-water year type combinations (3.3%) with unfavorable results at both Hazel Avenue and Watt Avenue. These results suggest that Alternative 4 would have unfavorable water temperature-related effects (3.3% to 15%) to steelhead spawning and egg incubation in the lower American River.

Summary

There are expected minor adverse and substantial beneficial impacts of seasonal operations on steelhead spawning and egg incubation in the lower American River based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are expected to have a minor decrease on spawning habitat area and are expected to substantially increase redd dewatering potential. Alternative 4 is expected to increase the frequency of unfavorable conditions for steelhead spawning and egg incubation by up to 15% in the lower American River compared to the No Action Alternative.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Yearling rearing is year-round in the lower American River. Young of the year fry rearing is from February through May (Sacramento Water Forum 2015). The timing of juvenile outmigration depends on the watershed and water year. The RST monitoring station in the lower American River indicates outmigration into the Sacramento River with median passage starting in January and ending in May, with peak passage between March and May (Day 2022a).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

During steelhead rearing in the lower American River, the mean monthly flows under Alternative 4 compared to the No Action Alternative are reduced in the late summer, fall, and spring under critically dry water year types, which may reduce their rearing habitat (Table O-278, Table O-277). Reductions under Alternative 4 are anticipated in August through October and February through May of critically dry water year types. The greatest increase in flows under Alternative 4 occurs in July of a critically dry water year type (16% in the lower American River at H St). The greatest reduction occurs in March of a critically dry water year type (24% in the lower American River at H St). Throughout the full simulation period, flows on average are similar (less than 7% difference) under Alternative 4 compared to the No Action Alternative.

The CalSim 3 simulated flow results suggest that changes in flow in the lower American River under Alternative 4 compared to the No Action Alternative may have an adverse effect on both juvenile and fry rearing habitat during critically dry water year types. There are no reliable estimates for steelhead juvenile rearing habitat using weighted usable area analyses. U.S. Fish and Wildlife Service (1985) derives spawning and rearing weighted usable area on fall-run Chinook salmon, but this study did not assess steelhead and has not been peer reviewed.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 48 for Hazel Avenue and Table 50 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F rearing and outmigration pathogen virulence threshold year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 52 for Hazel Avenue and Table 54 for Watt Avenue. Full results of the analysis assessing water temperatures above the percent of months with water temperature above the 55°F limit of successful smoltification during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 56 for Hazel Avenue and Table 58 for Watt Avenue.

Results for the analysis are summarized in Table O-57. Table O-57 the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 66.2°F upper limit of optimum temperatures for juvenile steelhead growth, assuming maximum ration levels, there were four and one month-water year type combinations (6.7% and 1.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-57). There were two and four month-water year type combinations (3.3% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F juvenile rearing and outmigration pathogen virulence threshold, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There was one month-water year type combinations (1.7%) with unfavorable results at both Hazel Avenue and Watt Avenue,. For the 55°F limit of successful smoltification, there were zero and one month-water year type combinations (0% and 4%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero and one month-water year type combinations (0% and 4%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results suggest that there would be positive (1.7% to 6.7% favorable) and negative (1.7% to 6.7% unfavorable) water temperature-related effects to steelhead juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There are expected adverse and beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration in the lower American River based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4 in critically dry water year types, reductions in flows may decrease rearing habitat area. Water temperatures above the optimum juvenile growth criteria increase and decrease in frequency and temperatures above the smoltification criteria increase and decrease in frequency at Hazel Ave and Watt Ave.

Adult Upstream Migration and Holding

Adult steelhead enter the San Francisco Estuary from the Pacific Ocean and will either spawn within a few months of entering freshwater or stage in pools for more extended periods until the first high flows (Moyle 2002; Williams 2006). In the lower American River, adult steelhead migration may occur as early as July and through early April, with peak abundance in January and February (Sacramento Water Forum 2015; Hallock 1989; Hallock et al. 1957).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Flows in the lower American River below Nimbus Dam are expected to be adequate during peak adult migration and holding under Alternative 4 compared to the No Action Alternative (Table O-277 and Table O-278). Peak steelhead adult migration in the lower American River occurs between January and February (Sacramento Water Forum 2015), when flows are expected to be less than a 11% increase or decrease under Alternative 4 across all water year types (Table O-277 and Table O-278). The largest reductions in flow under Alternative 4 for adult migration occur in March of critically dry water year type. The largest increases in flow under Alternative 4 occur in July of a critically dry water year type. Flows in September and October of critically water year types are expected to be below 1,000 cfs under Alternative 4 but are likely still adequate for adult migration (Table O-278). Throughout the full simulation period, flows on average are similar (less than 5% difference) under Alternative 4 compared to the No Action Alternative.

These results of the CalSim 3 simulated flows suggest that there may be a negligible effect of Alternative 4 compared to the No Action Alternative on steelhead adult migration and holding in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range of minimal migration impairment for adult steelhead during July through April are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 8 for Hazel Avenue and Table 10 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through April are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 12 for Hazel Avenue and Table 14 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult upstream migration and holding pathogen virulence threshold during July through April are presented in Attachment M.2,

American River Water Temperature Analysis, Table 16 for Hazel Avenue and Table 18 for Watt Avenue.

Results for the three analyses are summarized in Table O-58. Table O-58 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 41°F to 66.2°F range of minimal migration impairment for adult steelhead under Alternative 4, there were four and one month-water year type combinations (8% and 2%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-58). There were two and one month-water year type combinations (4.0% and 2.0%, respectively%) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F upper lethal limit to adult migrants, there was one month-water year type combination (2.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were one and three month-water year type combinations (2.0% and 6.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F adult upstream migration and holding pathogen virulence threshold, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero and one month-water year type combinations (0.0% and 2%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that there would be positive (2% to 8% favorable) and negative (2% to 6% unfavorable) water temperature-related effects to steelhead adult upstream migration and holding in the lower American River at Hazel Avenue and Watt Avenue.

<u>Summary</u>

There are expected beneficial impacts of seasonal operations on adult steelhead based on analyses of simulated flows under Alternative 4 in comparison with the No Action Alternative. Under Alternative 4 compared to the No Action Alternative, there are likely adequate flows during peak adult migration and holding. Water temperatures outside the range of minimal migration impairment increase and decrease in frequency in the lower American River under Alternative 4 compared to the No Action Alternative.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, the timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Flows in the lower American River below Nimbus Dam are expected to be adequate during peak kelt emigration under Alternative 4 compared to the No Action Alternative (Table O-277 and Table O-278). The largest reductions in flow under Alternative 4 during kelt emigration occur in March of critically dry water year types. The largest increases in flow under Alternative 4 occur in May of dry water year types. Throughout the full simulation period, flows on average are similar (less than 5% difference) under Alternative 4 compared to the No Action Alternative.

These results of the CalSim 3 simulated flows suggest that there may be a negligible effect of Alternative 4 compared to the No Action Alternative on steelhead kelt emigration in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F limit of migration impairment for steelhead kelt emigration during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 28 for Hazel Avenue and Table 30 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F lethal limit for steelhead kelt emigration during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 32 for Hazel Avenue and Table 34 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F kelt emigration pathogen virulence threshold during February through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 36 for Hazel Avenue and Table 38 for Watt Avenue.

Results for the three analyses are summarized in Table O-59. Table O-59 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 66.2°F limit of migration impairment for steelhead kelt emigration under Alternative 4, there were zero month-water year type combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-59). There were zero and three month-water year type combinations (0.0% and 12.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 69.8°F lethal limit for steelhead kelt emigration there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue. For the 59.9°F kelt emigration pathogen virulence threshold there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were three and five month-water year type combinations (12.0% and 20.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. These results suggest that there would be negative (4% to 12% unfavorable) water temperature-related effects to steelhead kelt emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There are expected negligible impacts of seasonal operations on steelhead kelt emigration based on analyses of simulated flows under Alternative 4 in comparison with the No Action Alternative. Under Alternative 4 compared to the No Action Alternative, there are likely adequate flows for kelt emigration. Water temperatures above the three temperature criteria increase in frequency (4-12%) or remain unchanged (0%) in the lower American River under Alternative 4 in comparison to the No Action Alternative.

O.7.10.4 Bay-Delta

Juvenile Rearing and Emigration

While juvenile steelhead can be found in all waterways of the Delta, they are seen more frequently in the main channels to their natal river systems (National Marine Fisheries Service 2009a). The San Francisco Estuary is used as a short-term outmigration corridor for juvenile steelhead but the propensity of rearing in the Delta is currently unknown (Hayes and Kocik 2014, Chapman et al. 2015, Buchanan et al. 2021). The USFWS monitoring programs (Sacramento beach seines, Sacramento trawl, and Knight's Landing RST) indicate outmigration timing from the Sacramento River with first median passage in January and last median passage in May (Columbia Basin Research, University of Washington 2024). Outmigration from the San Joaquin River is monitored through the Mossdale Trawl, and median passage is April through May (Columbia Basin Research, University of Washington 2024).

Potential Changes to Steelhead from Seasonal Operations

Zone of Influence

Differences in hydrology under Alternative 4 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions. With incremental decreases in OMR under Alternative 4 and the No Action Alternative, proportional overlap at these three locations decreases, with more subtle changes along the San Joaquin River at Jersey Point compared to Turner Cut and Old River at Middle River. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under Alternative 4 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2, *Zone of Influence*).

Flow into Junctions

Differences in flow routing under Alternative 4 compared with the No Action Alternative may have effects on the flow into the Head of Old River and CVP junctions.

Under Alternative 4 in all OMR bins except -3,500, predicted proportion of flow entering the Central Valley Project is less than the No Action Alternative. Changes in predicted proportion of flow entering the CVP in OMR bins -3,500, -5,000, and <-5,500 was less than ± 0.0372, indicating a negligible difference between Alternative 4 and the No Action Alternative. However, in OMR bin -2,000 the change in predicted proportion of flow into CVP was -0.0676 indicating

that slightly less flow will be routed into CVP under Alternative 4 than when compared to the No Action Alternative.

Under Alternative 4 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the HOR is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.026, indicating a negligible difference between Alternative 4 and the No Action Alternative.

For a detailed description of how flows under Alternative 4 may impact the flow at HOR and CVP, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2, *Flow into Junctions*).

Summary

Alternative 4 relative to the No Action Alternative is expected to influence flow into the HOR and CVP junctions due to differences in water management. Under Alternative 4, no change to possibly less flow into CVP under OMR -2,000; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 4 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Steelhead

Salvage Density and Negative Binomial

Predictions from the salvage density and the negative binomial model for steelhead include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of steelhead at SWP Banks Pumping Plant for all the months December through April and all water year types Alternative 4 was lower than predicted average monthly loss under the No Action Alternative, with up to a 13% decrease in predicted loss for dry water year types (Table O-60). Predicted average monthly loss of steelhead at CVP Jones Pumping Plant for all the months October through April for Alternative 4 was lower than predicted average monthly loss under the No Action Alternative for wet, below normal, and dry water year types, with up to a 5% decrease in predicted loss for wet water year types. Predicted monthly loss at Jones for steelhead under Alternative 4 compared to the No Action Alternative increased for above normal, and dry water year types, with up to a 2% increase for both water year types (Table O-61). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Predicted average monthly salvage of juvenile steelhead at the Delta fish collection facilities for the months of December through June under Alternative 4 was higher than predicted loss under the No Action Alternative for all water year types, with up to a 60% increase for above normal water year types (Table O-62). For detailed information on average monthly salvage by water year type, see Attachment I.1, *Negative Binomial Model*.

Summary

The results of the two entrainment models suggest adverse and beneficial impacts of exports under Alternative 4 compared to the No Action Alternative, with increases and decreases in entrainment (depending on water year type) and the magnitude of changes varying between the two models. Alternative 4 relative to the No Action Alternative is expected to have a moderate to substantial increases in loss across all water year types (16-60%) on the entrainment of steelhead in the Delta at both fish facilities under the Negative Binomial model due to differences in exports. Alternative 4 relative to the No Action Alternative is expected to have minor to moderate decreases (1-13%) in steelhead loss across all water year types in the Delta at both fish facilities under the Salvage Density model due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have minor increases (2%) in steelhead loss in critically dry and above normal water year types at the CVP Jones Pumping Plant due to differences in flow.

Potential Changes to Routing and Through Delta Survival of Steelhead

ECO-PTM

Mean proportion of particles December through March routed to the Interior Delta, via Georgiana Slough, under Alternative 4 ranged from less than the No Action Alternative (up to 7% less under <-5,500 cfs) to greater than the No Action Alternative (up to 12% greater under -3,500 cfs) (Attachment I.7, *ECO-PTM*). Routing through other Delta-specific routes is discussed further in the attachment. The decrease in routing to the Interior Delta could have a beneficial effect on outmigrating juveniles while the increase in routing could have an adverse effect on outmigrating juveniles.

Mean through-Delta percent survival December through March under Alternative 4 ranged from less than the No Action Alternative (up to 5% less under -3,500 cfs) to greater than the No Action Alternative (up to 6% more under <-5,500 cfs) (Attachment I.7, *ECO-PTM*). Survival through Delta-specific routes is discussed further in the attachment. The increase in survival under some OMR conditions could have a beneficial effect on outmigrating juveniles while the decrease in survival under some OMR conditions could have an adverse effect on outmigrating juveniles.

For a detailed description of how flows under Alternative 4 may impact steelhead routing and through Delta survival, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2).

Summary

Alternative 4 relative to the No Action using ECO-PTM suggest a possible adverse or beneficial effect dependent on OMR grouping due to differences in flow.

O.7.10.5 San Joaquin River

Juvenile Emigration

The San Joaquin River is primarily documented as an outmigration corridor for juvenile steelhead (Buchanan et al. 2021). Outmigration from the San Joaquin River into the Delta is monitored through the Mossdale Trawl, and median passage is April through May (Columbia Basin Research, University of Washington 2024). RSTs in the lower Stanislaus River, a tributary to the San Joaquin River, suggests juvenile emigration into the San Joan Joaquin River starts in January and ends in June (Day 2022b).

Potential Changes to Steelhead from Seasonal Operations

Changes in flows from seasonal operations under Alternative 4 compared to the No Action Alternative may have a negligible effect on juvenile steelhead in the San Joaquin River. During the evaluated months in the juvenile emigration period, CalSim 3 estimates of mean monthly flows at Vernalis would generally be similar or increased under Alternative 4 compared to the No Action Alternative across all water year types (Table O-281). Throughout the full simulation period, average flows will range from 3,480 to 6,451 cfs under Alternative 4 during juvenile emigration.

Changes in water temperature from seasonal operations Alternative 4 compared to the No Action Alternative are likely to have a negligible effect on juvenile steelhead in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile emigration period (Figure O-15).

<u>Summary</u>

The results of these two simulation models suggest there are expected negligible impacts of seasonal operations on juvenile steelhead in the San Joaquin River under Alternative 4 relative to the No Action Alternative.

Adult Upstream Migration and Holding

Steelhead/rainbow trout of anadromous parentage occur at low numbers in all three major San Joaquin River tributaries. These tributaries have a higher percentage of resident rainbow trout compared to the Sacramento River and its tributaries (Zimmerman et al. 2009). Estimates of migrating adults in the San Joaquin River are made from the CDFW angler report cards and suggest that migration starts in July, peaks in December and January, and ends in March (California Department of Fish and Wildlife 2007).

Potential Changes to Steelhead from Seasonal Operations

Changes in flows from seasonal operations under Alternative 4 compared to the No Action Alternative may have a beneficial effect on adult steelhead migration and holding in the San Joaquin River in critically dry water year types. During the evaluated months in the adult migration period, CalSim 3 estimates of mean monthly flows at Vernalis would increase from July through September of critically dry water year types under Alternative 4 compared to the No Action Alternative (Table O-281). Throughout the full simulation period, average flows will range from 1,434 to 6,451 cfs under Alternative 4.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible effect on adult steelhead migration and holding in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the adult migration period (Figure O-15).

Summary

There are likely negligible to minor beneficial impacts of seasonal operations on adult steelhead migration and holding in the San Joaquin River based on analyses of simulated flows and water temperature under Alternative 4 in comparison with the No Action Alternative.

O.7.10.6 Stanislaus River

Spawning and Egg Incubation

Data on steelhead spawning in the Stanislaus River is limited, but adults appear to spawn primarily from January to April. In 2021, as part of the reasonable and prudent measure to accelerate steelhead monitoring and research in the National Marine Fisheries Service (2019) Biological Opinion, CDFW initiated the Stanislaus River Life Cycle Monitoring Program. Based on the initial redd survey report, which had a late start due to COVID-19 restrictions, spawning appears to start in February and last until April (Kok and Keller 2023). Although few steelhead spawning surveys have been conducted in the Stanislaus River, spawning *O. mykiss* has been documented upstream of the Highway 120 Bridge in Oakdale, between Goodwin Dam and the Oakdale Recreation Area.

Steelhead egg incubation varies with temperature and alevin typically hatch approximately 30 days post fertilization and remain in the gravel until the yolk sac is completely absorbed, for an additional two to four weeks (Shapovalov and Taft 1954, Reynolds et al. 1990, Sacramento Water Forum 2015). In the Stanislaus River, timing can only be estimated and would be January through late May.

Potential Changes to Steelhead from Seasonal Operations

Spawning Habitat—Flow Analyses

The spawning WUA results for Alternative 4 show consistent reductions in mean spawning WUA from drier to wetter water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the shape of the steelhead spawning WUA curves (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which show reduced WUA with increased flow, except at the lowest and highest flows (less than about 200 cfs and greater than about 800 cfs, respectively). CalSim 3 mean monthly flows below Goodwin Dam, which is immediately upstream of the WUA study reach, are 200 cfs or above in all water year types, with flow consistently increasing from critically dry to wet water years during all months of the December through April steelhead spawning period, except December (Table O-279). The mean spawning WUA estimates for Alternative 4 are below those for the No Action Alternative in all water year types, ranging from 1.2% lower in wet water years to 6.6% lower in below normal water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). The spawning WUA results for individual months show much lower median spawning WUA under Alternative 4 relative to the No Action Alternative in December through March and higher

median spawning WUA in April (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

The results of the SIT LCM model for Alternative 4 are similar to those described above for spawning WUA regarding the magnitude of differences between Alternative 4 and the No Action Alternative, but the SIT analysis shows relatively more increases in spawning habitat under Alternative 4 while the WUA analysis shows reductions for all water year types and all months except April (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*).

Overall, the results of the WUA analysis indicate that mean spawning WUA for steelhead is lower under Alternative 4 than under the No Action Alternative, whereas the SIT analysis indicate that mean spawning habitat increases under Alternative 4 in all months except for January.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 55°F range for successful spawning during December through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 16 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence threshold for spawning adults during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 18 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 52°F range for optimal egg incubation during December through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 32 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 54°F index value for egg incubation during December through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 34 Full results of the analysis assessing the 59.9°F fry pathogen virulence threshold during December through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 36 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-63. Table O-63 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 45°F to 55°F range for successful spawning under Alternative 4, there were zero month-water year type combinations (0.0%) with favorable results and one month-water year type combination (3.3%) with unfavorable results at Orange Blossom Bridge (Table O-63). For the 59.9°F spawning pathogen virulence threshold, there were zero month-water year type combinations (0%) with favorable and unfavorable results at Orange Blossom Bridge. For the 45°F to 52°F range for optimal egg incubation analysis, there was one month-water year type combination (2.5%) with favorable results and two month-water year type combinations (5.0%) with unfavorable results at Orange Blossom Bridge. For the 59.9°F fry pathogen virulence threshold analysis, there were zero month-water year type combinations (0.0%) with favorable results and one month-water year type combination (2.5%) with unfavorable results at Orange Blossom Bridge.

These results suggest that Alternative 4 would have negligible effects on steelhead spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

There are expected minor adverse and minor beneficial impacts of seasonal operations on steelhead spawning and egg incubation in the Stanislaus River based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are expected to have a minor increase and/or decrease in spawning habitat area. Water temperatures outside the four spawning and egg incubation criteria are expected to have negligible increases in frequency the Stanislaus River at Orange Blossom Bridge.

Juvenile Rearing and Emigration

Once steelhead embryos emerge out of their redds to become young-of-the-year fry, they rear in freshwater for one to four years before emigrating to the ocean. Juvenile rearing is year-round in the Stanislaus River. The timing of juvenile outmigration depends on the watershed and water year. RSTs in the lower Stanislaus River suggests juvenile emigration into the San Joan Joaquin River starts in January and ends in June (Day 2022b).

Potential Changes to Steelhead from Seasonal Operations

Rearing Habitat—WUA Analyses

The results for mean fry rearing WUA under Alternative 4 show general reductions from drier to wetter water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the steelhead fry WUA curves (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which show moderately reduced WUA with increased flow, especially in the Orange Blossom Bridge and Riverbank reaches, which are the longest segments. Mean fry rearing WUA under Alternative 4 is similar to or slightly higher than that for the No Action Alternative in all water year types. The differences range from 0.8% lower for critically dry water years to 3.2% higher for dry water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fry rearing period, median rearing WUA is higher under Alternative 4 than the No Action Alternative for April and similar for the other months (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

The results for juvenile rearing WUA under Alternative 4 show a minor increase in mean rearing WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in juvenile rearing WUA between Alternative 4 and the No Action Alternative are small, ranging from 0.2% higher for wet water years to 2.1% higher for critically dry water years. Juvenile rearing WUA is highest for Alternative 4 in February, April, and May (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in median rearing WUA between the Alternative 4 and the No Action Alternative are small in most months, but the median is lower for Alternative 4 in January and is much higher in February.

The SIT LCM model provides rearing habitat results for all juveniles, not separating out the fry stage from older juveniles. The instream juvenile rearing habitat results for Alternative 4 are similar to those described above for fry and juvenile rearing WUA, showing little difference in rearing habitat acreages between Alternative 4 and the No Action Alternative in all months,

except for a 5.6% increase for February (Attachment O.2, *CVPIA SIT LCM Habitat Estimates*). A large increase in February was also noted for the juvenile rearing WUA results above.

Overall, the rearing WUA results indicate that mean fry and juvenile rearing WUA for steelhead is largely similar under Alternative 4 to means under the No Action Alternative.

Rearing Habitat—ASH Analyses

The results of the Area of Suitable Habitat (ASH) analysis for fry and juvenile rearing for Alternative 4 show more variation in the means with the water year type than that found in the rearing WUA results described above. The ASH means consistently increase from drier to wetter water year types. This pattern of variation reflects the overall relationship between streamflow and ASH for both life stages determined from modeling and field studies (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in fry and juvenile ASH between Alternative 4 and the No Action Alternative are small, which is consistent with the results of the rearing WUA analyses. For fry rearing, the differences range from 2.6% lower for dry water years and to 1.2% higher for critically dry water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For juvenile rearing, the differences range from 0.3% lower for wet water years and to 2.0% higher for critically dry water years. For the individual months of the rearing periods, the median fry rearing ASH is similar between Alternative 4 and the No Action Alternative except in April, when the Alternative 4 median is lower. The median for juvenile rearing ASH is lower in January and April, higher in February, and roughly the same in the other months (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

Overall, the results indicate that steelhead fry and juvenile rearing ASH is largely similar under Alternative 4 relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F upper limit of optimal growth without food limitation year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 38 for Orange Blossom Bridge and Table 40 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 42 for Orange Blossom Bridge and Table 44 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperatures above the 55°F limit of successful smoltification during January through May are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 48 for Orange Blossom Bridge and Table 50 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-64. Table O-64 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 66.2°F upper limit of optimal growth without food limitation under Alternative 4, there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-64). There were zero and two month-water year type combinations (0.0% and 3.3%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 59.9°F juvenile pathogen virulence threshold, there were there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. There were one and three month-water year type combinations (1.7% and 5.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 55°F limit of successful smoltification, there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River. There were one and zero month-water year type combinations (4.0% and 0.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 4 would have negligible water temperature-related effects on steelhead juvenile rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

There are expected adverse and beneficial impacts of seasonal operations on steelhead juvenile rearing and emigration based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are expected to have an increase and/or decrease in fry and juvenile rearing habitat area, depending on water year type. Water temperatures above the three juvenile rearing and emigration criteria are expected to have negligible increases in frequency in the Stanislaus River under Alternative 4.

Adult Upstream Migration and Holding

In the Stanislaus River, *O. mykiss* greater than 16 inches have been seen migrating upstream through video monitoring as early as September and throughout March and can be recovered in the RST in Oakdale from November through April (Hellmair 2022; Eschenroeder et al. 2022).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Average flows in the Stanislaus River below Goodwin Dam are expected to be similar or increased during adult migration and holding under Alternative 4 compared to the No Action Alternative (Table O-279 and Table O-280). The largest reduction in flow is a 26% decrease under Alternative 4 in January of an above normal water year type. The largest increase in flow is a 45% increase under Alternative 4 in February of a dry water year type. Average flows are expected to be lowest in September and November under both the No Action Alternative and Alternative 4 during the adult migration and holding period. The major differences in these two months are a 17% increase in below normal water year types in September under Alternative 4. Throughout the full simulation period under Alternative 4 compared to the No Action

Alternative, flows on average increase (more than 5% difference) in December and February in the Stanislaus River below Goodwin Dam. Throughout the full simulation period under Alternative 4 compared to the No Action Alternative, flows on average increase (more than 5% difference) in July and August in the Stanislaus River below Goodwin Dam. The other adult migration months have similar flows (less than a 5% difference) in the Stanislaus River under Alternative 4.

These results of the CalSim 3 simulated flows suggest that there may be a minor beneficial effect of Alternative 4 compared to the No Action Alternative on steelhead adult migration and holding in the Stanislaus River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 41°F to 66.2°F range of minimal migration impairment for adult steelhead during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 4 for Orange Blossom Bridge and Table 6 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F upper lethal limit to adult migrants during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 8 for Orange Blossom Bridge and Table 10 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult upstream migration and holding pathogen virulence threshold during July through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 12 for Orange Blossom Bridge and Table 14 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-65. Table O-65 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 41°F to 66.2°F range of minimal migration impairment for adult steelhead, there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River (Table O-65). There were also zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River. For the 69.8°F upper lethal limit to adult migrants there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River. For the 59.9°F adult upstream migration and holding pathogen virulence threshold there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River.

These results suggest that Alternative 4 would have negligible water temperature-related effects on steelhead adult upstream migration and holding in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

There are expected beneficial impacts of seasonal operations in the Stanislaus River on adult steelhead based on analyses of simulated flows and water temperature under Alternative 4 compared to the No Action Alternative. Under Alternative 4 compared to the No Action Alternative, there are potential beneficial impacts of increased flow in the fall of drier water year types for adult migration and holding. Water temperatures outside the range or above the adult migration and holding criteria are not anticipated to increase or decrease in frequency under Alternative 4 compared to the No Action Alternative.

Kelt Emigration

Steelhead can spawn more than once, with post-spawn kelts (typically females) moving back downstream through the Delta after completion of spawning in their natal streams. Some adults will change their life-history strategy post-spawn, as demonstrated in Battle Creek, where kelts chose to stay in freshwater rather than emigrate to the ocean (Null et al. 2013). Rates of iteroparity in the Central Valley are generally considered low (Eschenroeder et al. 2022), and so much of the available information on repeat spawning for steelhead comes from the Pacific Northwest. In these steelhead populations, the timing of kelt emigration starts in February, peaks March through May, and ends by early June (Mayer et al. 2008).

Potential Changes to Steelhead from Seasonal Operations

CalSim 3 Flows

Average flows in the Stanislaus River below Goodwin Dam are expected to be similar during kelt emigration under Alternative 4 compared to the No Action Alternative, with a minor increase in February and a minor decrease in April (Table O-279 and Table O-280). The largest reduction in flow is a 21% decrease under Alternative 4 in April of a below normal water year type, when flows under the No Action Alternative are 846 cfs. The largest increase in flow is a 45% increase under Alternative 4 in February of a dry water year type, when flows under the No Action Alternative are 200-250 cfs. Flows are expected to be lowest in March and February of drier water year types under the No Action Alternative and Alternative 4. The largest differences in these two months are 43-45% increases in February of dry and critically dry water year types under Alternative 4.

These results of the CalSim 3 simulated flows suggest that there are anticipated beneficial effects of Alternative 4 compared to the No Action Alternative on steelhead kelt emigration in the Stanislaus River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66.2°F limit of migration impairment for steelhead kelt emigration during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 20 for Orange Blossom Bridge and Table 22 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 69.8°F lethal limit for steelhead kelt emigration during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 24 for Orange Blossom Bridge and Table 26 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F kelt emigration pathogen virulence threshold during February through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 28 for Orange Blossom Bridge and Table 30 for above the confluence with the San Joaquin River.

Results for the three analyses are summarized in Table O-66. Table O-66 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 66.2°F limit of migration impairment for steelhead kelt emigration under Alternative 4, there were zero month-water year type combinations (0.0%) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-66). There were zero and two month-water year type combinations (0.0% and 8.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 69.8°F lethal limit for steelhead kelt emigration there were zero month-water year type combinations (0.0%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively. For the 59.9°F kelt emigration pathogen virulence threshold there were zero month-water year type combinations (0.0%) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River. There were one and three month-water year type combinations (4.0% and 12.0%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 4 would have negative water temperature-related effects to steelhead kelt emigration in the Stanislaus River.

Summary

There are expected minor beneficial and minor adverse impacts of seasonal operations in the Stanislaus River on steelhead kelts based on analyses of simulated flows and water temperature under Alternative 4 compared to the No Action Alternative. Under Alternative 4 compared to the No Action Alternative, there are potential minor beneficial impacts of flow for kelt emigration in drier water year types. Water temperatures above the limit of migration impairment and pathogens and disease threshold are expected to increase in frequency under Alternative 4 compared to the No Action Alternative.

O.7.11 Southern DPS Green Sturgeon

O.7.11.1 Sacramento River

Spawning and Egg Incubation

Southern DPS green sturgeon adults spawn primarily from April through July, although they periodically spawn in late summer and fall (as late as October). Northern DPS green sturgeon eggs hatch about a week after fertilization (at 60ºF), and incubation time of Southern DPS green sturgeon eggs is assumed to be similar (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). Because the incubation time for green sturgeon is so short, the effects analysis period for incubating eggs is considered to be the same as the spawning period, April through July, occasionally extending to October.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

CalSim 3 Flows

During the April through July green sturgeon spawning period, CalSim 3 estimates of mean monthly flows at RBDD (RM 244) under the No Action Alternative and Alternative 4 range from about 5,000 cfs for April of critically dry water years to about 15,000 cfs in April of wet water years at RBDD and from about 5,000 cfs in April of critically dry water years and over 17,000 cfs in April of wet water years at Hamilton City (Table O-267 and Table O-269). Mean flows during most of this period at both locations are moderate (~8,000 cfs to ~13,000 cfs). At both locations, flows between Alternative 4 and the No Action Alternative remain similar in most months, but flows are moderately lower for Alternative 4 in May through July during critically dry water years (up to 8%) at RBDD and for July during critically dry water years at Hamilton City (up to 6%) (Table O-267 and Table O-269). During the August through October period, when green sturgeon spawning occurs in occasional years, the flows under both alternatives at both locations tend to be lower than those in April through July, but the mean flows would be close to or above 5,000 cfs for all water year types in all three months. A moderate reduction in mean flows from the No Action Alternative to Alternative 4 is predicted for August of critically dry water years at RBDD; however, the resulting Alternative 4 mean flows are greater than 7,000 cfs and would not be expected to have an adverse effect on spawning habitat. A moderate increase in flows under Alternative 4 is predicted in October of critically dry water years at both locations (up to 10%). Moderate increases in mean flow from No Action Alternative to Alternative 4 in October may or may not be substantial enough to have a positive effect on larval green sturgeon. September spawning occurs only sporadically, so any effect on the green sturgeon population would be minor (National Marine Fisheries Service 2018a). Flow levels at RBDD and Hamilton City are likely to be suitable for green sturgeon spawning and egg incubation, and no adverse effects are expected to result.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 49.3°F to 63.7°F range for spawning initiation during April through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 208 for Bend Bridge and Table 210 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 52.3°F to 60.8°F range supporting egg incubation during April

through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 216 for Bend Bridge and Table 218 for Hamilton City.

Results for the two analyses are summarized in Table O-67. Table O-67, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 49.3°F to 63.7°F spawning initiation range, there were zero and one month-water year type combinations (0% and 5.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-67). There were zero and two combinations (0% and 10.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. For the 52.3°F to 60.8°F range for egg incubation, there were zero combinations (0%) with favorable results at Bend Bridge and Hamilton City. There were one and zero combinations (5.0% and 0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive and negative water temperature-related effects of Alternative 4 on green sturgeon spawning and egg incubation.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on spawning habitats due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have beneficial and adverse water temperature-related impacts on spawning depending on location, month, and water year type.

Larval and Juvenile Rearing and Emigration

The green sturgeon spawning period is from April through July, so the larval period is considered to be April through September. The green sturgeon juvenile stage begins when metamorphosis of the larva is complete, typically at about 45 days post hatch. The juveniles rear in the Sacramento River from about May through December. During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near the Cow Creek confluence to the Delta (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). Effects of flow and water temperature on green sturgeon larvae and juveniles may occur from April through December in the Sacramento River when analyzing the two life stages together.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

CalSim 3 Flows

CalSim 3 modeling for the Sacramento River at RBDD indicates that mean monthly flows during the April through September period of larval rearing remain similar between Alternative 4 and the No Action Alternative. Reduced flows are predicted for May through August of critically dry years (up to 8%) (Table O-267). Reductions in flow from the No Action Alternative to Alternative 4 during critically dry years could potentially adversely affect green sturgeon larvae because, as discussed in Section O.1.3.2.5, *Green Sturgeon, Southern DPS*, there appears to be a positive relationship between annual outflow and abundance of white sturgeon larvae and juveniles, but the applicability of the relationship to green sturgeon is uncertain. Resulting

reduced flows remain above 7,000 cfs for all four months and would not be expected to have an adverse impact on larvae.

CalSim 3 modeling for the Sacramento River at Hamilton City indicates that mean monthly flows during the period of juvenile rearing and emigration, May through December, are higher in October of critically dry years (10%) and November of critically dry years (up to 13%) (Table O-269). Increases in flow could positively affect green sturgeon juveniles under Alternative 4 because, as discussed in Section O.1.3.2.5, *Green Sturgeon, Southern DPS*, there may be a positive relationship between annual outflow and abundance of juvenile green sturgeon.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 64.4°F upper threshold for larvae from May through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 220 for Bend Bridge and Table 222 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 66.2°F range of optimal juvenile bioenergetic performance during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 224 for Bend Bridge and Table 226 for Hamilton City.

Results for the two analyses are summarized in Table O-68. Table O-68 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 64.4°F upper water temperature limit for newly hatched larvae, there were one and two month-water year type combinations (5.0% and 10.0% of total combinations during the period, respectively) with favorable results at Bend Bridge and Hamilton City, respectively (Table O-68). There were zero and one combinations (0% and 5.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. For the 59°F to 66.2°F range of optimal juvenile bioenergetic performance, there were one and two combinations (6.7% and 13.3%, respectively) with favorable and unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be positive and negative water temperature-related effects of Alternative 4 on green sturgeon larval and juvenile rearing and emigration.

Summary

Alternative 4 relative to No Action Alternative is expected to have negligible impacts or possible beneficial impacts on rearing and emigration habitats. Alternative 4 relative to No Action Alternative is expected to have beneficial and adverse water temperature-related impacts on rearing and emigration depending on location, month, and water year type.

Adult Upstream Migration and Holding

Green sturgeon adults enter the Sacramento River from the Delta as early as February to make their way upstream to spawn in deep pools from the GCID oxbow (near Hamilton City) to the Cow Creek confluence. After spawning, the adults hold in the river for varying amounts of time, but typically emigrate back to the San Francisco Estuary and the ocean from about October through December (Section O.1.3.2.5, *Green Sturgeon, Southern DPS*). With the extended adult

holding period, effects of flow and water temperature on adult upstream migration and holding may occur from February through December.

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

CalSim 3 Flows

Flows during the February through December period of green sturgeon immigration, spawning and holding are generally similar at RBDD and Hamilton City, except for the moderate increases and decreases discussed in Section O.7.14.1.1, *Spawning and Egg Incubation* and Section O.7.14.1.2, *Larval and Juvenile Rearing and Emigration* under Alternative 4 versus No Action Alternative (Table O-267 and Table O-269). Wilkins Slough shows increased flows during April of critically dry years (8%), October of critically dry years (up to 14%), and November of below normal and critically dry years (up to 17%) (Table O-268). A decrease in flows occurs at Wilkins Slough during July of critically dry years (5%). Flow differences in all three locations are not expected to substantially affect upstream passage of migrating green sturgeon, and the October and November flow increases under Alternative 4 at all three locations could result in improved habitat quality in holding pool habitats, positively affecting holding adults.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52°F to 69.4°F range for adult migration during April through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 204 for Bend Bridge and Table 206 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 52°F to 73.4°F range for adult holding year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 212 for Bend Bridge and Table 214 for Hamilton City.

Results for the two analyses are summarized in Table O-69. Table O-69, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 52°F to 69.4°F range for adult migration, there were no month-water year type combinations (0% of total combinations during the period, respectively) with favorable or unfavorable results at both Bend Bridge and Hamilton City, respectively (Table O-69). For the 59°F to 73.4°F range for adult holding, there was one month water-year type combination (1.7%) with favorable and unfavorable results at Bend Bridge and Hamilton City. There were six and zero combinations (10.0% and 0.0%, respectively) with unfavorable results at Bend Bridge and Hamilton City, respectively. These results suggest that there would be negative water temperature-related effects of Alternative 4 on green sturgeon adult upstream migration and holding.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts to possible beneficial impacts on upstream migration and holding habitats due to differences in flow. Alternative 4 is expected to result in water temperature-related adverse impacts on upstream migration and holding depending on location, month, and water year type.

O.7.11.2 San Joaquin River

Green sturgeon are also present in the San Joaquin River, but at considerably lower numbers than white sturgeon. Anglers have reported catching green sturgeon in the San Joaquin River and one adult green sturgeon was captured by Reclamation in April of 2020 (Root et al., 2020 [research note]). Although the reported presence of green sturgeon in the San Joaquin River coincides with the spawning migration period of green sturgeon within the Sacramento River, no evidence of spawning has been detected (Section O.1.8.2.3, *Green Sturgeon, Southern DPS*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

Since green sturgeon spawning has not been confirmed in the San Joaquin River, life stage analyses were not performed. It is assumed that adult green sturgeon could be in the San Joaquin River during all months of the year.

During the evaluated months, CalSim 3 estimates of mean monthly flows at Vernalis under Alternative 4 range from about 681 cfs for July of critically dry water years with TUCP without VA to about 13,087 cfs for February of wet water years (Table O-281). Generally, flows remain similar between the No Action Alternative and Alternative 4. Increased flows are predicted under Alternative 4 for June through September of critically dry water years (up to 22%) (Table O-281). Increased flows under Alternative 4 during summer months may have a positive effect on adult green sturgeon.

Summary

Alternative 4 is expected to have possible beneficial impacts on adult green sturgeon relative to the No Action Alternative. Due to the lack of information about green sturgeon life stages in the San Joaquin River, a temperature analysis was not done for this species in this geography.

O.7.11.3 Bay-Delta

Larval and Juvenile Rearing and Emigration

After hatching, larvae and juveniles migrate downstream toward the Delta. Juveniles are believed to use the Delta for rearing for the first one to three years of their lives before moving out to the ocean and are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, especially within the central Delta and Suisun Bay/Marsh (Section O.1.9.1.5, *Green Sturgeon, Southern DPS*).

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

Differences in hydrology in the Delta under Alternative 4 compared with the No Action Alternative may have effects on flow routing into junctions and the hydrodynamic footprint of the export facilities. These possible differences were evaluated using several quantitative models which estimate the spatial extent of influence of exports under CVP and SWP diversions and estimate the proportion of flow entering a Delta junction: Zone of Influence and Flow into Junctions. In addition to these two analyses, a Delta Outflow vs. Sturgeon YCI regression analysis was done for the two sturgeon species to evaluate flow effects on sturgeon year class index.

Zone of Influence

Differences in hydrology under Alternative 4 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions. With incremental decreases in OMR under Alternative 4 and the No Action Alternative, proportional overlap at these three locations decreases, with more subtle changes along the San Joaquin River at Jersey Point compared to Turner Cut and Old River at Middle River. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under Alternative 4 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2, *Zone of Influence*).

Flow into Junctions

Under Alternative 4 in all OMR bins except -3,500, predicted proportion of flow entering the CVP is less than the No Action Alternative. Changes in predicted proportion of flow entering the CVP in OMR bins -3,500, -5,000, and <-5,500 was less than ± 0.0372, indicating a negligible difference between Alternative 4 and the No Action Alternative. However, in OMR bin -2,000 the change in predicted proportion of flow into CVP was -0.0676 indicating that slightly less flow will be routed into CVP under Alternative 4 than when compared to the No Action Alternative.

Under Alternative 4 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering HOR is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.026, indicating a negligible difference between Alternative 4 and the No Action Alternative.

Delta Outflow vs. Sturgeon YCI

The Delta Outflow Year-Class Strength regression analysis found statistically significant positive correlations between white sturgeon year-class strength and Delta outflow for April-May and March-July. The analysis is used as a surrogate for green sturgeon. For the April-May Delta outflow, the average overall YCI values would be generally similar between Alternative 4 (10.7) and the No Action Alternative (11.2) (Table O-70). The same is true for the March-July Delta outflow, with the average overall YCI value for Alternative 4 being 16.4 compared to 16.7 for the No Action Alternative (Table O-71). Effects of Alternative 4 on green sturgeon relative to the No Action Alternative are expected to be limited given the limited differences in average Delta flow conditions between the two alternatives over all water year types during the specified months. For more detailed information see summaries presented in Attachment J.2*, Sturgeon Year Class Index and Delta Outflow*.

Summary

Alternative 4 relative to No Action is expected to influence flow into the HOR and CVP junctions due to differences in water management. Under Alternative 4, potentially less flow into CVP under OMR -2,000; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 4 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where

there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI). Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on green sturgeon year class strength using white sturgeon as a proxy for green sturgeon due to differences in flow.

Potential Changes to Entrainment of Southern DPS Green Sturgeon

Differences in exports under Alternative 4 compared with the No Action Alternative may have effects on green sturgeon entrainment at the Delta Fish Collection Facilities. These potential differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for green sturgeon include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of green sturgeon at SWP Banks Pumping Plant for the months January, and March of all water year types under Alternative 4 was less than or equal to predicted average monthly loss under the No Action Alternative for all water year types except for a 12% increase for wet water year types. For all other water year types Alternative 4 had a lower or equal predicted loss of green sturgeon at Banks compared to the No Action Alternative with up to a 3% reduction in loss for below normal water year types (Table O-72). Predicted average monthly loss of green sturgeon at the CVP Jones Pumping Plant for June through July under Alternative 4 was equal or lower compared to the No Action Alternative for all water year types, with up to a 11% reduction in predicted loss for dry water year types (Table O-73). It should be noted that loss of green sturgeon at both facilities is rare and infrequent, with such low values of predicted loss that the percent differences may not be representative. For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Summary

Differences in exports between Alternative 4 and the No Action Alternative are expected to have negligible impacts on the entrainment of juvenile green sturgeon at both facilities. Modeled results from the quantitative model show possible beneficial and adverse impacts, but since green sturgeon are salvaged so rarely, the numbers may not be representative.

Adult Upstream Migration and Holding

Adult green sturgeon move through the Delta from February through April to get to spawning locations in the upper Sacramento River. Following their initial spawning run upriver, adults split into two out migration groups, the “early” out migration group may migrate immediately back downstream through the Delta during May and June, or the “late” out migration group may hold for a few weeks to months in the upper river before moving back downstream during November through January (Section O.1.9.1.5, *Green Sturgeon, Southern DPS*).

Potential Changes to Southern DPS Green Sturgeon from Seasonal Operations

Delta Outflow vs. Sturgeon YCI

The Delta outflow vs Sturgeon YCI regression analysis results apply to all life stages of green sturgeon found in the Bay Delta. The regression analysis, used as a surrogate for green sturgeon, found statistically significant positive correlations between white sturgeon year-class strength and Delta outflow for April-May and March-July. Under Alternative 4, April-May Delta outflow average overall YCI values would be 4.5% lower (Table O-70) and the March-July Delta outflow values would be 1.8% lower (Table O-71) compared to the No Action Alternative. Refer to the analysis in Section O.7.11.3.1, *Larval and Juvenile Rearing and Emigration* and Attachment J.2, *Sturgeon Year Class Index and Delta Outflow*, for additional details.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on green sturgeon year class strength due to differences in flow.

O.7.12 Delta Smelt

O.7.12.1 Bay-Delta

Adult Migration and Spawning

During winter, adult Delta smelt initiate upstream spawning migration in association with "first flush" flow events (Sommer et al. 2011). Others report this seasonal change as a multi-directional and more circumscribed dispersal movement to freshwater areas throughout the Delta region (Murphy and Hamilton 2013). By late winter-spring, after arriving in freshwater staging habitats, adult Delta smelt hold until spawning commences during favorable water temperatures (Bennett 2005; Grimaldo et al. 2009; Sommer et al. 2011; Damon et al. 2016). Delta smelt spawn over a wide area throughout much of the Delta, including the Sacramento River and San Joaquin River confluence, the upper Sacramento River, and Cache Slough as well as into Suisun Marsh and the Napa River as conditions allow (Brown et al. 2014; Murphy and Hamilton 2013). Spawning of Delta smelt has not been observed in the wild (Moyle et al. 2016).

Potential Changes to Delta Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 4 was similar to the No Action Alternative (Table O-270) during the adult Delta smelt migration and spawning period, only varying zero to two km from the No Action Alternative, likely having no to negligible effects on adult Delta smelt in the winter and spring.

USFWS Delta Smelt Life Cycle Model

The geometric mean of the expected rate of change in abundance across years (1995-2015), λ, for Alternative 4 was 0.88 (Attachment F.4., *Delta Smelt Life Cycle Model with Entrainment*). Like other Alternatives, the λ under Alternative 4 varied between water year types, from λ equal to 0.68 (-32% decline on average) for below normal, dry and critically dry water years, to λ equal to 1.18 (18% increase in λ on average) for wet and above normal years. Compared to the No Action Alternative, the results under Alternative 4 were similar in the direction and magnitude of the predicted trend, but Alternative 4 results were 3% to 8% lower in terms of population growth rates, depending on the water year type (Attachment F.4, *Delta Smelt Life Cycle Model with Entrainment*).

Revised Maunder and Deriso Life Cycle Model

Life cycle analysis with the MDR model for Alternative 4 showed negligible impact on Delta smelt population growth rates compared to the No Action Alternative. Differences in single-year λ values did not exceed +/-10% across all modeled years (1995-2015), and the geometric mean of λ was 0.75 for both Alternative 4 and the No Action Alternative (Attachment F.1, *Maunder and Deriso in R Model*).

Because the MDR is an integrated life cycle model, the effects of each alternative were evaluated quantitatively primarily based on year-to-year changes in the population growth rate metric. However, as a statistical model fitted to abundance data for multiple life-stages, it is possible to gain a qualitative understanding of the season-specific covariates with a statistically significant influence on each life-stage. Also, because the covariates are standardized prior to model fitting, their coefficients can be directly compared.

In the MDR model, survival from the sub-adult to adult stage can be influenced by winter covariates which are averaged across the December to February period. Model selection retained combined Old and Middle River flow (OMR) and mean Secchi depth at South Delta monitoring stations as significant covariates of sub-adult survival, with coefficients of 0.477 and 0.542, respectively. Although differences in hydrology between the Alternatives would be expected to influence turbidity, the relationship is complex and was not able to be addressed for this analysis. Within the MDR, impacts on sub-adult survival are therefore related only to differences in OMR between the Alternatives. Mean winter OMR differed negligibly from the No Action Alternative for Alternative 4 (-1.7% change), further indicating minimal potential for impacts on sub-adult Delta smelt survival via the modeled pathway.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the winter in the low salinity zone showed significant relationships for five zooplankton taxa; *Daphnia* adults, decapod larvae, *Eurytemora affinis* adults, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, for *Daphnia* adults the expected CPUE did not change for all water year types. Results for decapod larvae were negligible when rounded to the nearest whole integer (values were 0) across all WYT and scenarios. *E. affinis* adults had the largest expected CPUE increase of 1% during the wet and below normal water year type and did not change during the above normal, dry, and critically dry water year type. Other calanoid copepod

adults had the largest expected CPUE increase of 6% during the below normal water year type and did not change during the above normal, dry, and critically dry water year type. Other calanoid copepodites had the largest expected CPUE increase of 2% during below normal water year type and did not change during the above normal and critically dry water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflow under Alternative 4 during the winter were generally only slightly (<5%) different from the No Action Alternative for most water year types (Table O-272) resulting in only minor changes in zooplankton CPUE.

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for five zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, cladocerans (except *Daphnia*) expected CPUE did not change during the dry and critically dry water year type and the largest expected CPUE decrease of 4% during the above normal water year type. *E. affinis* adults had the largest expected CPUE increase of 1% during the critically dry water year type and the smallest expected CPUE decrease of 2% during the above normal and below normal water year type. Harpacticoids had no expected change in CPUE during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. The CPUE of other calanoid copepod adults was not expected to change during the critically dry water year type and had the largest expected CPUE decrease of 3% during the above normal and below normal water year types. Other calanoid copepod copepodites had the largest expected CPUE increase of 1% during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 4 during the spring were generally only slightly (<5%) different from the No Action Alternative for most water year types, except outflow decreased in May for most water year types (Table O-272) resulting in minor decreases in zooplankton CPUE.

<u>Summary</u>

Alternative 4 relative to the No Action Alternative is expected to have adverse impacts on adult Delta smelt migration and spawning due to differences in flow. Compared to the No Action Alternative, CPUE of Delta smelt prey species was only slightly (<5%) different during both winter and spring. Results from the revised Maunder and Deriso life cycle model indicate that under Alternative 4 there would be minimal potential impacts on sub-adult to adult Delta smelt survival. Compared to the No Action Alternative, the USFWS lifecycle model results for Alternative 4 ranged 4 to 8% lower in terms of population growth rates depending on the water year type when compared to the No Action Alternative. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the winter and spring which is expected to have no impact on adult Delta smelt migration and spawning.

Potential Changes to Entrainment of Delta Smelt

Alternative 4 relative to the No Action Alternative may affect the entrainment of adult Delta Smelt due to differences in flow. Entrainment varies annually and depends on a combination of hydrology, turbidity, and export rates (see Smith et al. 2021). Historic salvage shows adult Delta smelt are entrained in the Delta Fish Collection Facilities, however in more recent years fewer fish have been entrained likely due to a combination of changes to operations and the continued decline of the Delta smelt population. While the USFWS life cycle model does incorporate entrainment, it was not used to evaluate entrainment of adult Delta smelt. Instead, OMR flows were used to evaluate changes between Alternative 4 and the No Action Alternative.

CalSim 3 OMR Values

In general, OMR combined flows were more negative under Alternative 4 when compared to the No Action Alternative from February to May, which would have adverse impacts on entrainment of adult Delta smelt but less negative in December, January and June which would have beneficial effects on entrainment of adult Delta smelt (Table O-273). The largest difference in OMR flows was in April during the above normal water year type (115% more negative) while largest increase in OMR flows was in December of wet years (24% more positive). In general, during the January to June period, OMR was more negative under Alternative 4 compared to No Action Alternative from February to May which would be detrimental for adult Delta smelt entrainment, while OMR was less negative in December, January and June which would be beneficial for adult Delta smelt entrainment.

Summary

Alternative 4 relative to the No Action Alternative is expected to have adverse and beneficial impacts on the entrainment of adult Delta smelt depending on the month due to differences in flow. OMR was more negative under Alternative 4 compared to No Action Alternative from February to May, which would be detrimental for adult Delta smelt entrainment, while OMR was less negative in December, January and June, which would be beneficial for adult Delta smelt entrainment.

Eggs and Larvae

Eggs hatch after an average of 10 days in the spring and planktonic larvae are transported (advected) from freshwater regions by the Sacramento River and tidal flows from March through May. The larval stage lasts for an average of 30 days. The nonpelagic habitats used by larval Delta smelt before they move into the pelagic areas are not known (Swanson et al. 1998; Sommer et al. 2011).

Potential Changes to Delta Smelt from Seasonal Operations

Differences in flows under Alternative 4 compared with the No Action Alternative may have effects on Delta smelt larvae including X2 position, population growth rate, and prey availability. These possible differences were evaluated using several quantitative models.

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 4 was similar to the No Action Alternative (Table O-270) during the larval Delta smelt period, only varying zero to two km from the No Action Alternative, likely having negligible effects on larval Delta smelt in the spring.

Revised Maunder and Deriso Life Cycle Model

Life cycle analysis with the Maunder and Deriso Model in R (MDR) did not identify any significant covariates of recruitment, and so did not evaluate effects on eggs or early larval stages.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for five zooplankton taxa. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, cladocerans (except *Daphnia*) expected CPUE did not change during the dry and critically dry water year type and the largest expected CPUE decrease of 4% during the above normal water year type. *E. affinis* adults had the largest expected CPUE increase of 1% during the critically dry water year type and the smallest expected CPUE decrease of 2% during the above normal and below normal water year type. Harpacticoids had no expected change in CPUE during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. The CPUE of other calanoid copepod adults was not expected to change during the critically dry water year type and had the largest expected CPUE decrease of 3% during the above normal and below normal water year types. Other calanoid copepod copepodites had the largest expected CPUE increase of 1% during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 4 during the spring were generally only slightly (<5%) different from the No Action Alternative for most water year types, except outflow decreased in May for most water year types (Table O-272) resulting in minor decreases in zooplankton CPUE.

Summary

Alternative 4 relative to the No Action Alternative is largely expected to have minor adverse impacts on Delta smelt larvae due to differences in flow. Compared to the No Action Alternative, CPUE of Delta smelt prey species is expected to slightly decrease under Alternative 4. Results from the revised Maunder and Deriso life cycle model indicate that under Alternative 4 there would be a slight adverse impact (approximately 1%) on the survival of post-larval Delta smelt. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the spring which are expected to have negligible impacts on larval Delta smelt.

Potential Changes to Entrainment of Delta Smelt

Alternative 4 compared with the No Action Alternative may affect the entrainment of Delta smelt larvae due to differences in flow. This possible difference was evaluated using a quantitative model.

Particle Tracking Model (PTM)

Inflow Bins.

Depending on inflow conditions, an average of 0 to 12% of particles injected within the Sacramento River region would be entrained at export facilities under Alternative 4, compared to 0 to 14% under the No Action Alternative. The average percentage of particles entrained at exports ranged from 12% lower than for the No Action Alternative under "medlo" inflow conditions (14% under the No Action Alternative *vs* 12% under Alternative 4) to 70% higher than for the No Action Alternative under "medhi" inflow conditions (but note that the absolute entrainment remained low at around 2% and close to 1% entrainment under the No Action Alternative).

Depending on inflow conditions, an average of 53 to 91% of particles injected within the San Joaquin River region would be entrained at export facilities under Alternative 4, compared to 45 to 87% under the No Action Alternative. Differences in potential entrainment between Alternative 4 and the No Action Alternative ranged from -1% under "medlo" inflow conditions to +27% under "medhi" inflow conditions. Although not discussed here in detail, a similar pattern was observed for other injection regions with moderate potential for particles entrainment. Alternative 4 would lead to minor reductions in the average percentage of particles entrained compared to the No Action Alternative under "medlo" inflow conditions (-7% for the Central Delta injection region or -6% for the Mokelumne River injection region) and to the largest increases in potential entrainment under "medhi" inflow conditions compared to the No Action Alternative (+71% for the Central Delta injection region or +66% for the Mokelumne River injection region).

Depending on inflow conditions, an average of 0 to 4% of particles injected within the Yolo Bypass region would be entrained at export facilities under Alternative 4, compared to 0 to 5% under the No Action Alternative. Differences in potential entrainment between Alternative 4 and the No Action Alternative ranged from -32% under "hilo" inflow conditions to +74% under "medhi" inflow conditions (note, however, that average entrainment for this injection region remained low at around between 0 and 4%.

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), there was a difference between the average percentage of particles entrained under Alternative 4 and under the No Action Alternative (-1 to +27%).

OMR bins.

Depending on OMR flow conditions, an average of 57 to 80% of particles injected within the San Joaquin River region would be entrained at export facilities under Alternative 4, compared to 57 to 87% under the No Action Alternative. Potential entrainment ranged from 8% lower under Alternative 4 than under the No Action alternative for the -5000 OMR bin (80% *vs* 87%) to 9% higher for the -3500 bin (74 *vs* 68%). Although not discussed here in detail, a similar pattern was observed for other injection regions with moderate potential for particles entrainment at export facilities (Mokelumne River, Sacramento River, Central Delta): Alternative 4 would generally lead to substantial reductions in the average percentage of particles entrained compared to the No Action Alternative for the most negative OMR index (-5000: -35 to -58%), minor decreases to moderate increases under the less negative OMR index (-2000: -4 to +25%), and increases for intermediate OMR index (-3500: +33 to +49%).

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), regardless of OMR flow conditions, there was generally little difference between the average percentage of particles entrained under Alternative 4 and under the No Action Alternative (-2 to +1%).

Summary

Alternative 4 relative to the No Action Alternative for injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta) is expected to have a negligible to adverse impact on the entrainment of larval Delta Smelt. Alternative 4 relative to the No Action Alternative is expected for injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta) to have negligible impacts on the entrainment of larval Delta smelt, with some increased and reduced entrainment depending on OMR grouping due to differences in flows.

Juveniles

During and after larval rearing in freshwater, many young Delta smelt move with river and tidal currents during the early summer to remain in favorable rearing habitats, often moving into low salinity ($\leq$ 6 psu) areas to avoid seasonally warm and highly transparent waters that typify many areas in the central Delta (Nobriga et al. 2008). Juvenile Delta smelt rearing habitat is correlated with salinity, particularly the position of the LSZ, and other habitat attributes like turbidity and temperature. Delta smelt also rear in upstream areas such as the Cache Slough complex and Sacramento Deep Water Ship Channel, depending on habitat conditions (Sommer and Mejia 2013). Studies indicate that in fall, prior to spawning, juvenile and sub-adult Delta smelt tend to remain in the LSZ (Sommer et al. 2011), though they can be found in the lower San Joaquin River, Suisun and San Pablo bays, the Sacramento River and San Joaquin River confluence, Cache Slough, and the lower Sacramento River (Murphy and Hamilton 2013).

Potential Changes to Delta Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 4 was similar the No Action Alternative (Table O-270) and varied from zero to two km during the juvenile Delta smelt rearing period for below normal, dry and critically dry water year types, likely having no effects on juvenile Delta smelt in the summer and fall. However, the position of X2 was two to five km further landward during wet and above normal water year types in the fall, likely having an adverse effect on juvenile Delta smelt during the fall.

Habitat Suitability Index

Juvenile Delta smelt summer and fall habitat was estimated for different water year types (wet, above normal, below normal, dry, and critical) using the Bever et al. (2016) habitat suitability index (Bever HSI) and the Bever HSI with a water temperature threshold of 22° Celsius (22C HSI), where the Bever HSI value is multiplied by zero when water temperature is greater than 22° C and by one when water temperature is less than or equal to 22° C. The temperature threshold of 22ºC was used based on sub-lethal physiological and behavioral effects observed in multiple studies (Davis et al. 2022; Hammock et al. 2022; Komoroske et al. 2021; Lewis et al. 2021; Davis et al. 2019; Komoroske et al. 2015). Under Alternative 4, mean Bever HSI for

subregions targeted by the summer fall habitat action (Yolo Bypass, which includes Cache Slough and Sacramento Deepwater Shipping Channel; Lower Sacramento River; Confluence; Suisun Marsh; northwest Suisun Bay) was 3% to 6% lower than under the No Action Alternative, depending on water year type. Under Alternative 4, the mean 22C HSI for the summer fall habitat action subregions was 8% lower to less than 1% higher than under the No Action Alternative, depending on water year type. The largest differences under Alternative 4 are predicted during the dry water year for mean Bever HSI (6% lower) and during the critical water year for mean 22C HSI (8% lower). The smallest differences are predicted during the above normal water year for mean Bever HSI (1% lower) and for mean 22C HSI (< 1% lower).

The results of the HSI analyses suggest that Alternative 4 may result in minor increases (< 1%) and decreases (1-8%) in suitable habitat depending on water year type and the application of a temperature threshold in comparison to the No Action Alternative and would likely have negligible to minor adverse impacts on juvenile Delta smelt summer and fall habitat.

Revised Maunder and Deriso Life Cycle Model

Summer outflow, the only variable within the Maunder and Deriso Model in R (MDR) with influence on the larval life-stage, was approximately 1% lower under Alternative 4 than under the No Action Alternative, and so minimal impact on post-larval survival would be expected (Attachment F.1, *Maunder and Deriso in R Model*).

The preferred set of covariates identified through extensive model selection did not include any parameters that differed between alternatives (Attachment F.1, Maunder and Deriso in R Model). Mean Delta water temperature and Secchi depth were the selected parameters for the fall period, which correspond to juvenile survival in the MDR model. Although hydrological differences between the alternatives would potentially impact these variables, the relationships between flow, temperature and turbidity are complex, and were not able to be modeled for this exercise. As such, juvenile Delta smelt survival under Alternative 4 was the same as under the No Action Alternative.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the fall showed significant relationships for two taxa; *E. affinis* adults and mysids. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, for *E. affinis* there was no expected change in CPUE across all water year types.. However, the expected CPUE for *E. affinis* during the fall was very low (one to three individuals per cubic meter) and unlikely to impact Delta smelt juveniles. Mysids had the largest expected CPUE increase of 8% during the above normal water year type and was not expected to change for all other water year types. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 4 during the fall were generally only minorly (<5%) different from the No Action Alternative for most water year types (Table O-272) resulting in only minor changes in zooplankton CPUE.

Summary

Alternative 4 relative to the No Action Alternative is expected to have minor impacts on juvenile Delta smelt due to differences in flow. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the summer and fall, which is expected to have negligible impacts on juvenile Delta smelt. The results of the HSI analyses suggest that Alternative 4 depending on water year type and the application of a temperature threshold in comparison to the No Action Alternative would likely have minor adverse impacts on juvenile Delta smelt summer and fall habitat. Results from the revised Maunder and Deriso life cycle model did not include any parameters that differed between alternatives and therefore survival under Alternative 4 was the same as under the No Action Alternative. Compared to the No Action Alternative, CPUE of Delta smelt prey species was not related to outflow in the summer and the CPUE is expected to slightly change compared to the No Action Alternative during the fall.

Potential Changes to Entrainment of Delta Smelt

Alternative 4 relative to the No Action Alternative may affect the entrainment of juvenile Delta smelt due to differences in flow. Entrainment varies annually and depends on a combination of hydrology, turbidity, and export rates (see Smith et al. 2021). Historic salvage shows juvenile Delta smelt are entrained in the Delta Fish Collection Facilities, however in more recent years fewer fish have been entrained likely due to a combination of changes to operations and the continued decline of the Delta smelt population. While the USFWS life cycle model does incorporate entrainment, it was not used to evaluate entrainment of adult Delta smelt. Instead, OMR flows were used to evaluate changes between Alternative 4 and the No Action Alternative.

CalSim 3 OMR Values

OMR combined flows ranged from no differences to less negative under Alternative 4 when compared to the No Action Alternative from June to November, which would have negligible to positive effects on entrainment of juvenile Delta smelt (Table O-273). The largest difference in OMR flows under Alternative 4 compared with the No Action Alternative were in June during the dry water year type (10% less negative), while OMR flows were more negative in September during the above normal water year type (21% more negative) compared to the No Action Alternative. In general, during the June to November period, OMR was less negative under Alternative 4 compared to No Action Alternative in June and similar to the No Action Alternative from July to November, which would have negligible effects.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible to beneficial impacts on the entrainment of juvenile Delta smelt due to differences in flow. OMR flow for Alternative 4 was less negative in June, compared to the No Action Alternative, which would have beneficial impacts for entrainment of juvenile Delta smelt. OMR flow for Alternative 4 was similar to the No Action Alternative from July to November, which would have negligible impacts.

O.7.13 Longfin Smelt

O.7.13.1 Bay Delta

Adult Migration and Spawning

Longfin smelt are anadromous and spawn in fresh or low-salinity water in the Bay-Delta (Grimaldo et al. 2017), generally at 2 years of age (Moyle 2002). A portion of the population migrate from the ocean into the San Francisco Estuary and move upstream to spawn during late fall through winter, with most spawning occurring from November through April (California Department of Fish and Wildlife 2009a). Spawning locations have been estimated using field observations of gravid females and yolk-sac larvae (Grimaldo et al. 2017, Lewis et al. 2019) and through particle-tracking modeling (Gross et al. 2022) to suggest spawning extends farther seaward than previously thought (Moyle 2002). Based on these studies, longfin smelt appear to spawn in the low-salinity zone where brackish and freshwaters meet (Grimaldo et al. 2017), and in tidal wetlands of south San Francisco Bay and San Pablo Bay when hydrological conditions favor spawning in more seaward regions (Lewis et al. 2020, Grimaldo et al. 2020). These regions include marshes of the Petaluma watershed, Napa-Sonoma watershed, Sacramento-San Joaquin watershed, and Coyote Creek watershed (Lewis et al. 2020, Hobbs et al. 2015).

Potential Changes to Longfin Smelt from Seasonal Operations

<u>CalSim 3 X2 Modeled X2 Position</u>

The position of X2 under Alternative 4 was similar to the No Action Alternative (Table O-270) during the adult longfin smelt migration and spawning period, only varying zero to two km from the No Action Alternative, likely having negligible impacts on adult longfin smelt in the fall, winter and spring.

<u>Zooplankton CPUE-Outflow Analysis</u>

Analysis of CPUE with outflow during the fall showed significant relationships for two taxa; *E. affinis* adults and mysids. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, for *E. affinis* there was no expected change in CPUE across all water year types. However, the expected CPUE for *E. affinis* during the fall was very low (one to three individuals per cubic meter) and unlikely to impact longfin smelt. Mysids had the largest expected CPUE increase of 8% during the above normal water year type and was not expected to change for all other water year types. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 4 during the fall were generally only minorly (<5%) different from the No Action Alternative for most water year types (Table O-272) resulting in only minor changes in zooplankton CPUE.

Analysis of CPUE with outflow during the winter in the low salinity zone showed significant relationships for five zooplankton taxa; *Daphnia* adults, decapod larvae, *Eurytemora affinis* adults, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, for *Daphnia* adults the expected CPUE did not change for all water year types. Results for decapod larvae were negligible when rounded to the nearest

whole integer (values were 0) across all WYT and scenarios. *E. affinis* adults had the largest expected CPUE increase of 1% during the wet and below normal water year type and did not change during the above normal, dry, and critically dry water year type. Other calanoid copepod adults had the largest expected CPUE increase of 6% during the below normal water year type and did not change during the above normal, dry, and critically dry water year type. Other calanoid copepodites had the largest expected CPUE increase of 2% during below normal water year type and did not change during the above normal and critically dry water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflow under Alternative 4 during the winter were generally only slightly (<5%) different from the No Action Alternative for most water year types (Table O-272) resulting in only minor changes in zooplankton CPUE.

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for five zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, cladocerans (except *Daphnia*) expected CPUE did not change during the dry and critically dry water year type and the largest expected CPUE decrease of 4% during the above normal water year type. *E. affinis* adults had the largest expected CPUE increase of 1% during the critically dry water year type and the smallest expected CPUE decrease of 2% during the above normal and below normal water year type. Harpacticoids had no expected change in CPUE during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. The CPUE of other calanoid copepod adults was not expected to change during the critically dry water year type and had the largest expected CPUE decrease of 3% during the above normal and below normal water year types. Other calanoid copepod copepodites had the largest expected CPUE increase of 1% during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 4 during the spring were generally only slightly (<5%) different from the No Action Alternative for most water year types, except outflow decreased in May for most water year types (Table O-272) resulting in minor decreases in zooplankton CPUE.

<u>Summary</u>

Alternative 4 relative to the No Action Alternative is expected to have minor impacts on adult longfin smelt migration and spawning due to differences in flow. Compared to the No Action Alternative, CPUE of longfin smelt prey species is expected to minorly increase and decrease under Alternative 4 during the fall, winter, and spring, depending on water year type. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative which are expected to have a negligible impact on adult longfin smelt migration and spawning in the fall, winter, and spring.

Potential Changes to Entrainment of Longfin Smelt

Differences in flow between Alternative 4 and the No Action Alternative may affect the entrainment of adult longfin smelt. Entrainment varies annually and depends on a combination of hydrology and export rates.

CalSim 3 Modeled X2 Position

The position of X2 under Alternative 4 was similar to the No Action Alternative (Table O-270) during the adult longfin smelt migration and spawning period, only varying zero to two km from the No Action Alternative.

CalSim 3 Modeled OMR Flow

Total exports during the adult longfin smelt migration and spawning period under Alternative 4 were lower during December and higher in February, and April across all water year types and March for the wet and above normal water year type when compared to the No Action Alternative (Table O-273). OMR flow values were less negative in December and more negative in February and April across all water year types and March for the wet and above normal water year type when compared to the No Action Alternative. OMR values were still under the -5000 cfs threshold value. Compared to the No Action Alternative, under Alternative 4, there are likely minor beneficial impacts during the early winter and minor adverse impacts during late winter and spring.

Summary

Alternative 4 relative to the No Action Alternative is expected to have adverse to beneficial impacts on entrainment of adult longfin smelt during migration and spawning due to differences in flow. Compared to the No Action Alternative, the position of X2 only varied 0-1 km under Alternative 4, likely having a negligible impact on adult longfin smelt. Compared to the No Action Alternative, exports decreased in the December and increased in the February and April, while OMR values were less negative in December and more negative in February and April likely resulting in minor adverse and minor beneficial impacts depending on the month.

Eggs and Larvae

In the San Francisco Estuary, most longfin smelt larvae hatch between December and May, and rarely outside of this range (Baxter 1999). Longfin smelt larvae are most abundant in the water column usually from January through April (Bureau of Reclamation 2008). Larval longfin smelt rear in low salinity to brackish water (2–12 ppt; Grimaldo et al. 2017) and in tidal wetlands of San Pablo Bay (Sonoma Creek, Napa River, and Petaluma River) and south San Francisco Bay (Alviso Marsh Complex and salt pond restoration areas) (Hobbs et al. 2015, Lewis et al. 2020). The spatial distribution of these larvae reflects the year-to-year variation in freshwater outflow which affects the geographic location of the low-salinity zone during the winter and spring (Feyrer et al. 2004, Grimaldo et al. 2020). During high outflow years, the low salinity zone can extend into San Pablo Bay. Within the low-salinity zone and adjacent waters, larvae have been commonly collected in both littoral (nearshore) and pelagic (offshore) habitats.

Potential Changes to Longfin Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 4 was similar to the No Action Alternative (Table O-270) during the larval longfin smelt period, only varying zero to two km from the No Action Alternative, likely having negligible impacts on larval longfin smelt in the spring.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for five zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, cladocerans (except *Daphnia*) expected CPUE did not change during the dry and critically dry water year type and the largest expected CPUE decrease of 4% during the above normal water year type. *E. affinis* adults had the largest expected CPUE increase of 1% during the critically dry water year type and the smallest expected CPUE decrease of 2% during the above normal and below normal water year type. Harpacticoids had no expected change in CPUE during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. The CPUE of other calanoid copepod adults was not expected to change during the critically dry water year type and had the largest expected CPUE decrease of 3% during the above normal and below normal water year types. Other calanoid copepod copepodites had the largest expected CPUE increase of 1% during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 4 during the spring were generally only slightly (<5%) different from the No Action Alternative for most water year types, except outflow decreased in May for most water year types (Table O-272) resulting in minor decreases in zooplankton CPUE.

Summary

Alternative 4 is expected to have minor impacts on longfin smelt eggs and larvae due to differences in flow. Compared to the No Action Alternative, CPUE of longfin smelt prey species is expected to minorly increase and decrease under Alternative 4 during the spring, depending water year type. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the spring which are expected to have negligible impacts on larval longfin smelt.

Potential Changes to Entrainment of Longfin Smelt

Alternative may affect the entrainment of larval longfin smelt. This possible difference was evaluated using a quantitative model.

Particle Tracking Model (PTM)

Inflow Bins.

Depending on inflow conditions, an average of 1 to 19% (SO) or 1 to 16% (NB) of particles injected within the Sacramento River region would be entrained at export facilities under Alternative 4, compared to 1 to 16% (SO and NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 15% lower (SO) or 16% lower (NB) under “medlo” conditions to 19% higher (SO) or 22% higher (NB) under “lohi” conditions for Alternative 4 compared to the No Action Alternative.

Depending on inflow conditions, an average of 0 to 4% (SO and NB) of particles injected within the Western Delta region would be entrained at export facilities under Alternative 4, compared to 0 to 4% (SO) and 0 to 3% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 36% lower (SO) or 44% lower (NB) than the No Action Alternative for Alternative 4 under "medmed" conditions to 82% higher (SO) or 155% higher (NB) under "hihi" conditions. Note however that under these conditions the overall percentage of particles entrained would remain extremely low (close to 0 for both Alternative 4 and the No Action Alternative).

Depending on inflow conditions, an average of 0 to 9% (SO) or 0 to 7% (NB) of particles injected within the Yolo Bypass region would be entrained at export facilities under Alternative 4, compared to 0 to 7% (SO) and 0 to 5% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 17% lower (SO) or 20% lower (NB) under "medlo" conditions to 31% higher under "hihi" conditions (SO) or 37% higher under "lohi" conditions (NB) for Alternative 4 compared to the No Action Alternative. However, note that the overall percentage of particles entrained would remain extremely low under such conditions (close to 0 for both Alternative 4 and the No Action Alternative).

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), there was a negligible difference between the average percentage of particles entrained under Alternative 4 and under the No Action Alternative (-2 to +2% NB and SO).

OMR bins.

Depending on OMR flow conditions, an average of 26 to 66% (SO) or 23 to 64% (NB) of particles injected within the Central Delta region would be entrained at export facilities under Alternative 4, compared to 24 to 81% (SO) and 22 to 79% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 18% lower (SO) or 19% lower (NB) under Alternative 4 than under the No Action Alternative for the -5500 OMR bin to 17% higher (both SO and NB) for the -3500 OMR bin.

Depending on OMR flow conditions, an average of 25 to 69% (SO) or 22 to 66% (NB) of particles injected within the Mokelumne River region would be entrained at export facilities under Alternative 4, compared to 23 to 78% (SO) and 21 to 75% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 12% lower (SO) and 13% lower (NB) under Alternative 4 than under the No Action Alternative for the -5500 OMR bin to 17% higher (both SO and NB) for the -3500 OMR bin.

Depending on OMR flow conditions, an average of 2 to 10% (SO) or 1 to 8% (NB) of particles injected within the Yolo Bypass region would be entrained at export facilities under Alternative 4, compared to 2 to 16% (SO) or 1 to 13% (NB) under the No Action Alternative. The average percentage of particles entrained at exports ranged from 38% lower (SO) or 39% lower (NB) under Alternative 4 than under the No Action Alternative for the -5500 OMR bin to 19% higher (SO) and 22% higher (NB) for the -3500 OMR bin.

For injections regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), regardless of OMR flow conditions, there was generally little difference between the average percentage of particles entrained under Alternative 4 and under the No Action Alternative (-2 to +2% NB and SO).

Summary

The percentage of particles entrained at exports were generally similar between surface-oriented particles representative of yolk-sac larval longfin smelt and neutrally buoyant particles representative of >10mm larval longfin smelt. For injection regions with high potential for entrainment at export facilities (Old and Middle River, Southern Delta), Alternative 4 compared to the No Action Alternative is expected to have a negligible impact on the entrainment of larval longfin smelt, for all inflow groupings and OMR groupings.

Juveniles

Juveniles have been detected throughout the San Francisco Estuary and rarely in some Delta tributaries (Merz et al. 2013). Juveniles gradually move seaward as they grow and as water temperatures increase in the late spring and early summer (Rosenfield and Baxter 2007; Tobias and Randall 2021). Seasonal patterns in abundance and occurrence in the nearshore ocean suggest that the population is at least partially anadromous (Rosenfield and Baxter 2007; Garwood 2017). The detection of longfin smelt within the estuary throughout the year and geochemical analysis of otoliths suggests longfin smelt in the San Francisco Estuary utilize several life history strategies (Lewis et al. 2019).

Potential Changes to Longfin Smelt from Seasonal Operations

CalSim 3 X2 Modeled X2 Position

The position of X2 under Alternative 4 was similar to the No Action Alternative (Table O-270) during the juvenile longfin smelt period, only varying 0-2 km from the No Action Alternative, likely having negligible impacts on juvenile longfin smelt in the spring and summer.

Longfin Smelt Abundance-Outflow Analysis

Juvenile Longfin Smelt abundance as represented by the Fall Midwater Trawl index of abundance is predicted to be equal to or less than 5% lower under Alternative 4 than the No Action Alternative, regardless of water year type (Attachment J.1, *Longfin Smelt Outflow*, Table 3). The difference in predicted abundance under Alternative 4 ranges from 0% (no difference) during wet and below normal years to 1% lower during above normal, dry, and critical water years compared to predicted abundance under the No Action Alternative.

Zooplankton CPUE-Outflow Analysis

Analysis of CPUE with outflow during the spring in the low salinity zone showed significant relationships for five zooplankton taxa; cladocerans (except *Daphnia*), *Eurytemora affinis* adults, harpacticoids, other calanoid adults, and other calanoid copepodites. In general, CPUE tended to decrease as the water year type became drier and outflow decreased. Under Alternative 4, when compared to the No Action Alternative, cladocerans (except *Daphnia*) expected CPUE did not change during the dry and critically dry water year type and the largest expected CPUE decrease of 4% during the above normal water year type. *E. affinis* adults had the largest expected CPUE

increase of 1% during the critically dry water year type and the smallest expected CPUE decrease of 2% during the above normal and below normal water year type. Harpacticoids had no expected change in CPUE during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. The CPUE of other calanoid copepod adults was not expected to change during the critically dry water year type and had the largest expected CPUE decrease of 3% during the above normal and below normal water year types. Other calanoid copepod copepodites had the largest expected CPUE increase of 1% during the critically dry water year type and the largest expected CPUE decrease of 2% during the above normal and below normal water year type. (Attachment J.3, *Zooplankton-Delta Outflow Analysis*). The CalSim 3 simulated average Delta outflows under Alternative 4 during the spring were generally only slightly (<5%) different from the No Action Alternative for most water year types, except outflow decreased in May for most water year types (Table O-272) resulting in minor decreases in zooplankton CPUE.

Summary

Alternative 4 is expected to have negligible to minor adverse impact on juvenile longfin smelt, relative to the No Action Alternative. Juvenile longfin smelt abundance as represented by the Fall Midwater Trawl index of abundance is predicted to be no different to minorly lower under Alternative 4 than it is for the No Action Alternative. Compared to the No Action Alternative, CPUE of longfin smelt prey species is expected to minorly decrease under Alternative 4 during the spring. CalSim 3 results indicate that the position of X2 did not greatly differ from the No Action Alternative during the spring and summer which is expected to have a negligible impact on juvenile longfin smelt.

Potential Changes to Entrainment of Longfin Smelt

Longfin Smelt Outflow Entrainment

Changes in OMR flows under Alternative 4 compared with the No Action Alternative may have an impact on LFS salvage. Compared to the No Action Alternative, predicted salvage increases ranged from 23% during the critically dry water year type to 185% during the above normal water year type. Alternative 4 had the more negative mean April-May OMR values compared to the No Action Alternative across all water year types and therefore higher predicted salvage. Overall modeling for Alternative 4 suggests that longfin smelt salvage would increase substantially when compared to the No Action Alternative. (Attachment I.4, *Longfin Smelt Salvage-OMR Relationship*).

Summary

Alternative 4 is expected to have an adverse impact on the entrainment of longfin smelt due to differences in flow.

O.7.14 Fall-run and Late Fall-run Chinook Salmon ESU

O.7.14.1 Sacramento River

Spawning and Egg/Alevin Incubation

Fall-run Chinook salmon typically spawn in the Sacramento River, primarily between Keswick Dam and RBDD from October through December, with incubation occurring from October through April. Peak spawning time for late fall-run Chinook salmon generally is from January through April (National Marine Fisheries Service 2009a), with incubation typically lasting for approximately 2 to 4 months between April and June (Moyle 2002). See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under Alternative 4, differences in mean spawning WUA are generally lower than the No Action Alternative across the water year types, except in critically dry water years (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 4 and the No Action Alternative is a 1.1% increase in critically dry water years. The largest reduction in estimated spawning habitat is a -1.4% decrease in below normal water year types.

The monthly median value of spawning WUA under Alternative 4 is similar to the No Action Alternative throughout all of the spawning months (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are relatively similar in September and October, and slightly lower in November and December. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are consistently highest in December when compared to other spawning months (Table O-266). This results in lower spawning WUA results because the fall-run Chinook salmon spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 3,000 to 6,000 cfs).

The results of the spawning habitat analysis based on CalSim 3 simulated flows suggest that Alternative 4 may have a minor (less than 2%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. Out of the four months of potential fall-run Chinook salmon spawning, September and October have the highest estimated spawning WUA across all alternatives.

Fall-run Chinook Salmon: Redd Dewatering Analysis

Fall-run Chinook salmon mean redd dewatering potential under Alternative 4 increases from drier to wetter water year types (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). Most egg incubation of fall-run Chinook salmon occurs during fall and winter, when periodic storms and high runoff in wetter years result in increased flow fluctuations, increasing risk of redd dewatering. In drier winters, flow fluctuations are reduced and fewer redds are dewatered. Most differences in mean fall-run Chinook salmon redd dewatering potential between Alternative 4 and the No Action Alternative are small, except for a reduction of 20.7% in redd dewatering for

above normal water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). Other differences range from 6.77.3% lower in wet water years to 6.8% higher in critically dry water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). The apparent magnitude of the relative differences for fall-run are misleading because of the generally small levels of redd dewatering potential. For instance, for above normal water years the reduction is from 14.5% to 11.5%, an absolute difference of 3.0%, and for critically dry years the increase is from 6.3% to 6.7%, an absolute difference of 0.4%.

Overall, the results indicate that fall-run Chinook salmon redd dewatering potential under Alternative 4 is similar to that under the No Action Alternative.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 235 for Keswick Dam and Table 236 for RBDD. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 238 for Keswick Dam and Table 239 for RBDD. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during December through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 241 for Keswick Dam and Table 242 for RBDD.

Results for the three analyses are summarized in Table O-74. Table O-74, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 42.1°F to 55°F spawning initiation range analysis, there were one and zero month-water year type combinations (5.0% and 0% of total combinations during the period) with favorable results at both Keswick Dam and RBDD (Table O-74). There was zero and one combinations (0.0% and 5.0%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 59.9°F pathogen virulence threshold, there also was one combination (5.0%) with favorable results at both Keswick Dam and RBDD and no combinations with unfavorable results at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were no combinations (0%) with favorable or unfavorable results at both locations. These results suggest that there would be negligible positive and negative water temperature-related effects of Alternative 4 on fall-run Chinook salmon spawning and egg/alevin in the Sacramento River.

Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on redd dewatering from sudden drops in flow. However, redd surveys occur during the pulse flow period and redd dewatering has not been observed.

Fall-run Chinook Salmon: Summary

The change in seasonal operations in the Sacramento River between Alternative 4 and the No Action Alternative are expected to have minor impacts on fall-run Chinook salmon spawning habitat and incubation. Under Alternative 4, changes in flows may have a minor increase and decreases in spawning habitat area in all water year types. The potential for redd dewatering would be similar to the No Action Alternative. There may be redd dewatering following spring pulse flow events, though this has not been observed during redd surveys. Under Alternative 4, there would be favorable and unfavorable water temperature conditions for fall-run Chinook salmon spawning and egg/alevin incubation in the Sacramento River.

Late Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under Alternative 4, differences in mean spawning WUA are generally lower than the No Action Alternative across the water year types, except in critically dry water years (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat between Alternative 4 and the No Action Alternative is a 1.1% increase in critically dry water years. The largest reduction in estimated spawning habitat is a 1.4% decrease in below normal water year types.

The monthly median value of spawning WUA under Alternative 4 is similar to the No Action Alternative throughout all of the spawning months (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). Spawning WUA median values for all the modeled alternatives are also relatively similar across all three spawning months. The CalSim 3 simulated average flows in the Sacramento River below Keswick Dam are highest in February but all three months are above 8,000 cfs (Table O-266). This results in spawning WUA results that are approximately the same across all three months because the late fall-run Chinook salmon spawning WUA curves (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*), peak at relatively low flows (approximately 3,000 to 6,000 cfs).

The results of the spawning habitat analysis based on CalSim 3 simulated flows suggest that Alternative 4 may have a negligible (less than 1.5%) increase and/or decrease in estimated spawning habitat across all water year types when compared to the No Action Alternative in the mainstem upper Sacramento River. The three months of potential late fall-run Chinook salmon spawning have similar estimated spawning WUA across all alternatives.

Late Fall-run Chinook Salmon: Redd Dewatering Analysis

The results for Alternative 4 show substantial increases in percentage of late fall-run Chinook salmon redds dewatered with water year type, varying from high redd dewatering in wet water years to low redd dewatering in critically dry water years (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). This pattern of variation reflects flow conditions for the winter and spring months when late fall-run Chinook salmon spawning and incubation occurs (Table O-266). During wet winters and springs, periodic storms and high runoff increase flow and flow variability, which tends to result in greater redd dewatering. In drier years, flow fluctuations are reduced and fewer redds are dewatered. Mean redd dewatering potential is similar between Alternative 4 and the No Action Alternative in all water year types except for critically dry water years, for which redd dewatering is 15.6% higher under Alternative 4 (Attachment L.4, *Sacramento River Redd Dewatering Analysis*). Other differences range from 3.1% lower for

critically dry water years to 4.5% higher for wet years. Note that the 15.5% increase for critically dry years represents an absolute difference in redd dewatering of 0.4%.

Overall, the results indicate that late fall-run Chinook salmon redd dewatering potential is similar between Alternative 4 and the No Action Alternative, except for increased redd dewatering in critically dry water years.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 267 for Keswick Dam and Table 268 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 270 for Keswick Dam and Table 271 for below Clear Creek. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 273 for Keswick Dam and Table 274 for below Clear Creek.

Results for the three analyses are summarized in Table O-75. Table O-75, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 42.1°F to 55°F spawning initiation range analysis, there were zero month-water year type combinations (0%) with favorable and unfavorable results at Keswick Dam and Clear Creek, respectively (Table O-75). For the 59.9°F pathogen virulence threshold, there were no combinations (0%) with favorable or unfavorable results at both locations. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were two and four combinations (10.0% and 20.0%, respectively) with favorable results at Keswick Dam and Clear Creek, respectively. There were zero combinations (0%) with unfavorable results at both locations. These results suggest that there would generally be negligible effects of Alternative 4 on late fall-run Chinook salmon spawning and egg incubation, with a beneficial effect for egg incubation and fry emergence below Clear Creek.

Late Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on spawning behavior and redd dewatering from sudden drops in flow. However, redd surveys occur during the pulse flow period and redd dewatering has not been observed.

Late Fall-run Chinook Salmon: Summary

The change in seasonal operations in the Sacramento River between Alternative 4 and the No Action Alternative are expected to have minor impacts on late fall-run Chinook salmon spawning habitat and incubation. Under Alternative 4, flows would be similar to the No Action Alternative in all water year types and so would have similar effects to spawning habitat and redd dewatering. There may be changes to spawning behavior and redd dewatering with spring pulse

flow events, but redd dewatering has not been observed during the pulse flow period. Under Alternative 4, conditions caused by water temperatures for spawning initiation and pathogen virulence would be similar to the No Action Alternative. Egg incubation and emergence would have more favorable conditions when compared with the No Action Alternative.

Juvenile Rearing and Emigration

The majority of young fall-run Chinook salmon migrate to the ocean during the first few months following emergence, mostly between January through June. Late fall-run Chinook salmon juveniles typically enter the ocean after 7 to 13 months of rearing in freshwater, generally between October and February. See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Fry Rearing Habitat Analysis

Under Alternative 4, mean fry rearing WUA decreases in below normal, dry, and critically dry water year types and increases in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 0.3% increase in wet water year types. The largest reduction in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 0.9% decrease in dry water year types.

The monthly median value of fry rearing WUA under Alternative 4 is similar to the No Action Alternative throughout the fry rearing period of December through March (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The results during these four months show little variation in the third quartile of the WUA distributions. This occurs because the fry rearing WUA curves peak at the lowest flows encountered in the river (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and Keswick Dam flow releases are frequently low during these months in critically dry years when Shasta Reservoir is operated to rebuild storage volume (Table O-266). The first quartile is much wider because a greater range of flows affect the fry rearing WUA values below the median.

The results of the fall-run Chinook salmon fry rearing habitat analysis suggest that Alternative 4 in comparison to the No Action Alternative may have a negligible (less than 1%) increase and/or decrease in estimated fry rearing habitat in all water year types and no large increases or decreases in estimated habitat on a monthly scale.

Fall-run Chinook Salmon: Juvenile Rearing Habitat Analyses

Under Alternative 4, mean juvenile rearing WUA increases in above normal, dry, and critically dry water year types and decreases in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated juvenile rearing habitat between Alternative 4 and the No Action Alternative is a 2% increase in critically dry water year types. The largest reduction in estimated juvenile rearing habitat between Alternative 4 and the No Action Alternative is a 0.7% decrease in below normal water year types.

The monthly median value of fry rearing WUA under Alternative 4 is similar from February through June (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The fry rearing WUA values under the modeled alternatives are similar across the months of February and March, and gradually decrease until the lowest estimated values in June. As discussed previously for fry rearing WUA, the high WUA values with low variability in the third quartile for February and March result from the peaking of the WUA curve at the lowest flows (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*) and frequent low Keswick Dam flow releases during these months to build Shasta Reservoir storage (Table O-266). The wide range of values in the first quartile of these months reflects the high frequency and variability of higher flows in these wet months. The lowest juvenile rearing WUA values in June result from releases in the summer months above 10,000 cfs and estimated peak juvenile rearing at flows below 5,000 cfs.

The results of the fall-run Chinook salmon juvenile rearing habitat analysis suggest that Alternative 4 compared to the No Action Alternative may have a minor (less than 2%) increases and/or decrease in estimated juvenile rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in the mainstem upper Sacramento River.

Fall-run Chinook Salmon: Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. Alternative 4 shows a large but variable increase in stranding of fall-run Chinook salmon fry from critically dry to wet water year types, with a minor reduction in stranding from dry to below normal water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Fall-run Chinook salmon fry rearing occurs primarily during winter and early spring. Alternative 4 shows the highest median stranding in February and lowest median stranding in March, with intermediate levels in December and January (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). The higher mean stranding levels for fall-run fry during February and wet water year types likely results from periodic storms and high runoff that produce increased variability of flow. Mean fall-run fry stranding under Alternative 4 is lower than that under the No Action Alternative in all water year types, ranging from 7.2% lower in wet water years to 0.8% lower in critically dry water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*).

Overall, fall-run Chinook salmon juvenile stranding for fry is lower under Alternative 4, than under the No Action Alternative.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 247 for Keswick Dam, Table 248 for Red Bluff Diversion Dam, and Table 249 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 251 for Keswick Dam, Table 251 for Red Bluff Diversion Dam, and Table 253 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F

juvenile pathogen virulence threshold during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 255 for Keswick Dam, Table 256 for Red Bluff Diversion Dam, and Table 257 for Hamilton City.

Results for the three analyses are summarized in Table O-76. Table O-76, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with favorable results at all three locations (Table O-76). There were zero to two combinations (0% to 10.0%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were zero to two combinations (0% to 10.0%) with favorable results depending on location. There would be zero to two combination (0% to 10.0%) with unfavorable results depending on location. These results suggest that there would be positive and negative water temperature-related effects of Alternative 4 on fall-run Chinook salmon juvenile rearing and emigration.

Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

Fall-run Chinook Salmon: Summary

The change in seasonal operations between Alternative 4 and the No Action Alternative are expected to result in minor increase and/or decrease on fall-run Chinook salmon fry and juvenile rearing habitat. Under Alternative 4, flows would be similar to the No Action Alternative in all water year types. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. Alternative 4 would cause beneficial and adverse water temperature-related impacts to fall-run Chinook salmon juvenile rearing and emigration in the Sacramento River.

Late Fall-run Chinook Salmon: Fry Rearing Habitat Analysis

Under Alternative 4, mean fry rearing WUA increase in above normal and critically dry water year types and decrease in all other water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 1.9% increase in critically dry water year types. The largest reduction in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 0.3% decrease in below normal water year types.

The monthly median value of fry rearing WUA under Alternative 4 is similar to the No Action Alternative throughout the fry rearing period, March through June (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The fry rearing median WUA values under the modeled alternatives are similar across the months of May and June, and highest in March. The lower fry

rearing WUA values in May and June result from releases in the summer months above 7,000 cfs (Table O-266) and estimated peak fry rearing at flows below 5,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The results of the late fall-run Chinook salmon fry rearing habitat analysis suggest that Alternative 4 compared to the No Action Alternative may have a minor (less than 2%) increase and/or decrease in estimated fry rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in the mainstem upper Sacramento River.

Late Fall-run Chinook Salmon: Fry Stranding Analysis

The analysis of juvenile stranding is focused on fry because they are expected to be more vulnerable to stranding than the older juveniles, who are stronger swimmers. Mean stranding of late fall-run fry Chinook salmon under Alternative 4 shows minor and inconsistent variation with water year type; wet years have the highest stranding and dry years the lowest, with stranding in critically dry years similar to stranding in below normal and above normal water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Late fall-run Chinook salmon fry rearing occurs primarily during spring. Alternative 4 shows the highest median stranding in March, the lowest stranding in May, and similar stranding in April and June (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*). Mean fry stranding of late fall-run Chinook salmon is lower for all water year types under Alternative 4 than under the No Action Alternative. The reductions range from 1.0% for above normal water years to 21.8% for dry water years (Attachment L.5, *Sacramento River Juvenile Stranding Analysis*).

Overall, late fall-run Chinook salmon juvenile stranding for fry is lower under Alternative 4 as compared to the No Action Alternative for all water year types and is much lower for dry water years.

Late Fall-run Chinook Salmon: Juvenile Rearing Habitat Analysis

Under Alternative 4, mean juvenile rearing WUA increases in all water year types compared to the No Action Alternative (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). The largest increase in estimated fry rearing habitat between Alternative 4 and the No Action Alternative is a 5.7% increase in critically dry water year types. There are no anticipated reductions in mean juvenile rearing WUA under Alternative 4 in comparison to the No Action Alternative.

The monthly median value of juvenile rearing WUA under Alternative 4 is similar to the No Action Alternative throughout the juvenile rearing period, May through September (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*). During the juvenile rearing period, the median WUA values steadily decline from May to the lowest median WUA values in July. The lower juvenile rearing WUA values in June and July result from releases in the summer months above 7,000 cfs (Table O-266) and estimated peak juvenile rearing at flows below 5,000 cfs (Attachment O.3, *Sacramento River Weighted Usable Area Analysis*).

The results of the late fall-run Chinook salmon juvenile rearing habitat analysis suggest that Alternative 4 compared to the No Action Alternative may have a minor (less than 6%) increase in estimated juvenile rearing habitat across all water year types and no large increases or decreases in estimated habitat on a monthly scale in the mainstem upper Sacramento River.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 279 for Keswick Dam, Table 280 for Red Bluff Diversion Dam, and Table 281 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 283for Keswick Dam, Table 284 for Red Bluff Diversion Dam, and Table 285 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 287 for Keswick Dam, Table 288 for Red Bluff Diversion Dam, and Table 289 for Hamilton City.

Results for the three analyses are summarized in Table O-77. Table O-77, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 55.4°F to 68°F juvenile optimum temperature range, there were zero to two month-water year type combinations (0% to 3.6% of total combinations during the period) with favorable results depending on location (Table O-77). There were zero to five combinations (0% to 9.1%) with unfavorable results depending on location. For the 75.2°F UILT for rearing and migrating juveniles, there would be no combinations with either favorable or unfavorable results at any location. For the 59.9°F juvenile pathogen virulence threshold, there were one to seven combinations (1.8% to 12.7%) with favorable results depending on location. There would be zero to three combinations (0% to 5.5%) with unfavorable results depending on location. These results suggest that there would be positive and negative water temperature-related effects of Alternative 4 on late fall-run Chinook salmon juvenile rearing and emigration.

Late Fall-run Chinook Salmon: Sacramento River Pulse Flows

There may be unintentional adverse impacts of spring pulse flows on fry stranding and predation from sudden drops in flow. There may be beneficial impacts from decreased travel time for juvenile outmigration.

Late Fall-run Chinook Salmon: Summary

The change in seasonal operations in the Sacramento River between Alternative 4 and the No Action Alternative are expected to have minor adverse impacts on late fall-run Chinook salmon fry and juvenile rearing habitat. Under Alternative 4, flows would be similar to the No Action Alternative in all water year types and so would have similar impacts to fry and juvenile rearing habitat. The frequency of fry stranding would be similar to the No Action Alternative with minor increases and decreases in stranding. Fry stranding may occur following spring pulse flow events. There may be decreased travel times for juvenile outmigration during spring pulse flow events. Alternative 4 would cause beneficial and adverse water temperature-related impacts to late fall-run Chinook salmon juvenile rearing and emigration in the Sacramento River.

Adult Upstream Migration and Holding

Fall-run Chinook salmon migrate upstream past RBDD on the Sacramento River from July to December, and late fall-run Chinook salmon migrate upstream past RBDD from October through December (National Marine Fisheries Service 2009a). Adult late fall-run Chinook salmon typically hold in the river for one month to three months before spawning, while fall-run Chinook salmon generally spawn shortly after entering freshwater. See Section O.1.3.2 for additional information.

Potential Changes to Fall-run and Late Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

During the July through December period of fall-run and late fall-run Chinook salmon adult migration and holding, the mean monthly flows under Alternative 4 at Sacramento River below Keswick Dam, below RBDD, and at Hamilton City would mostly vary between being similar to moderately higher (up to 18%) in October, November and December in dry and critically dry water years compared to the No Action Alternative. However, during critically dry water years in July and August, there would be minor decreases in flow at these same locations. Flows at Wilkins Slough suggest decreases July through October for some water year types and increases October through December and April.

Expected flow values are at their lowest between July and December of critically dry years in December below Keswick Dam (~3,400 cfs), in October below Red Bluff Diversion Dam (~5,200 cfs), in September at Wilkins Slough (~3,250 cfs), and in October at Hamilton City (~4,600 cfs)(Tables O-266 through O-269). Flows at in the Sacramento River under Alternative 4 would be high enough (> 3,250 cfs) to allow upstream passage.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 227 for Keswick Dam, Table 228 for Red Bluff Diversion Dam, and Table 229 for Hamilton City. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 231 for Keswick Dam, Table 232 for Red Bluff Diversion Dam, and Table 233 for Hamilton City.

Results are summarized in Table O-78. Table O-78, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 37.9°F to 68°F successful adult migration range analysis, there were zero to two month-water year type combinations (0% to 6.7% of total combinations during the period) with favorable results depending on location (Table O-78). There were zero to one combinations (0% to 3.3%) with unfavorable results depending on location. For the 59.9°F adult pathogen virulence threshold analysis, there would be zero to five combinations (0% to 16.7%)

with favorable results and zero to one combinations (0% to 3.3%) with unfavorable results depending on location. These results suggest that there would be positive effects of Alternative 4 on water temperature conditions for fall-run Chinook salmon adult migration and holding in the Sacramento River.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 259 for Keswick Dam, Table 260 for Red Bluff Diversion Dam, and Table 261 for Hamilton City. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 262 for Keswick Dam, Table 263 for Red Bluff Diversion Dam, and Table 264 for Hamilton City.

Results are summarized in Table O-79. Table O-79, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 37.9°F to 68°F successful adult migration range analysis, there were zero to two month-water year type combinations (0% to 5.0% of total combinations during the period) with favorable results depending on location (Table O-79). There were no combinations (0%) with unfavorable results at all locations. For the 59.9°F adult pathogen virulence threshold analysis, there would be zero to five combinations (0% to 12.5%) with favorable results depending on location and zero to one combinations (0% to 2.5%) with unfavorable results at all locations. These results suggest that there would be positive effects of Alternative 4 on water temperature conditions for late fall-run Chinook salmon adult migration and holding in the Sacramento River.

Sacramento River Pulse Flows

Fall-run and late fall-run adult migration is outside the spring pulse flow period.

Summary

Under Alternative 4, conditions for adult fall-run and late fall-run Chinook salmon caused by water temperatures for successful migration are expected to be similar to the No Action Alternative, but with some more favorable conditions at Hamilton City. Below Keswick Dam and RBDD, fall-run and late fall-run Chinook salmon migrating adults would be exposed to more favorable conditions with respect to pathogen virulence. Migrating adult fall-run and late fall-run Chinook salmon would be experience both adverse and beneficial impacts from flow under Alternative 4 compared to the No Action Alternative.

O.7.14.2 Clear Creek

Spawning and Egg Incubation

Fall-run Chinook salmon typically spawn in Clear Creek from late September through early December, (Earley et al. 2013). Fall-run typically emerge from the gravel in December through March. Timing of peak late-fall spawning in the Sacramento River, January through April, was used as a proxy for Clear Creek. Late fall-run incubation and emergence is estimated to occur from March through June.

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Spawning Habitat—Flow Analysis

Under Alternative 4, mean spawning WUA increases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The largest increase in estimated spawning habitat is a 5% increase in critically dry water year types. There are no anticipated reductions in mean spawning WUA under Alternative 4 in comparison to the No Action Alternative.

The mean values of spawning WUA by month are higher in November and December and lower in October under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the three months, December is expected to have the highest spawning WUA values under Alternative 4.

The spawning habitat analysis indicates that Alternative 4 may have a minor to moderate beneficial effect (1.7-5% increase) in fall-run Chinook salmon estimated spawning habitat in Clear Creek across all water year types when compared to the No Action Alternative.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 237 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during October through January are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 240 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during December through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 243 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-80. Table O-80, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 42.1°F to 55°F spawning initiation range analysis, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-80). For the 59.9°F

pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were zero (0%) combinations with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be no water temperature-related effects of Alternative 4 on fall-run Chinook salmon spawning and egg/alevin incubation in Clear Creek.

Fall-run Chinook Salmon: Summary

Results suggest there may be a beneficial impact of seasonal operations on fall-run Chinook salmon spawning and egg incubation in Clear Creek based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows may have a beneficial impact on spawning habitat. There would be no impacts caused by water temperature conditions on spawning initiation, pathogen virulence, and egg incubation and fry emergence.

Late Fall-run Chinook Salmon: CalSim 3 Flows

For the period of late-fall run Chinook salmon spawning and egg incubation (January through June), there would be both adverse and beneficial impacts below Whiskeytown Dam under Alternative 4 compared to the No Action Alternative. Average flow among all water year types during this period would substantially increase in January (35%), March (27%), April (15%) and May (36%) but have a moderate decrease in February (10%) and substantially decrease in June (31%) (Table O-275).

Using peak spawning flows of 300-350 cfs from the fall-run Chinook salmon WUA curves as a proxy for potential late-fall-run Chinook salmon spawning habitat, changes under Alternative 4 suggest that when averaged across all water year types, flows would increase favorable spawning areas. Even with the slight decrease in average flows in February, flows would still remain above around 300 cfs on average across all water year types. There would be a substantial increase in spawning habitat available for late fall-run Chinook salmon as a result of flows in Clear Creek.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 269 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold during January through April are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 272 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F range for egg incubation and fry emergence during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 275 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-81. Table O-81, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 42.1°F to 55°F range for spawning initiation temperature analysis, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results below Whiskeytown Dam (Table O-81). For the 59.9°F pathogen virulence threshold, there were no month-water year type combinations (0%) with favorable or unfavorable results below Whiskeytown Dam. For the 42.8°F to 56°F range for egg incubation and fry emergence, there were no month-water year type combinations (0%) with favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on late fall-run Chinook salmon spawning and egg incubation in Clear Creek.

Late Fall-run Chinook Salmon: Summary

The change in seasonal operations in Clear Creek between Alternative 4 and the No Action Alternative is expected to have primarily beneficial effects on late-fall-run Chinook salmon spawning and egg incubation. Under Alternative 4, changes in flows provide mostly substantially beneficial conditions; however, flows in June create an adverse impacts to late incubation.

Juvenile Rearing and Emigration

The majority of young fall-run Chinook salmon migrate to the ocean during the first few months following emergence, mostly between January through June. Late fall-run Chinook salmon juveniles typically enter the ocean after 7 to 13 months of rearing in freshwater, generally between October and February (Moyle 2002).

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: Fry Rearing Habitat Analysis

Under Alternative 4, mean fry rearing WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean fry rearing WUA under Alternative 4 in comparison to the No Action Alternative. The greatest reduction in estimated fry rearing habitat is a 2.3% decrease in dry water year types under Alternative 4 in comparison to the No Action Alternative.

The mean values of fry rearing WUA by month are slightly lower under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). The four fry rearing months are expected to have similar fry rearing WUA values.

The results of the fry rearing habitat analysis indicate that Alternative 4 in comparison to the No Action Alternative may have a minor adverse impact (less than 3% decrease) in estimated fall-run Chinook salmon fry rearing habitat across all water year types in Clear Creek.

Fall-run Chinook Salmon: Juvenile Rearing Habitat Analyses

Under Alternative 4, mean juvenile rearing WUA decreases in all water year types in comparison to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). There are no anticipated increases in mean juvenile rearing WUA under Alternative 4 in comparison to the No Action Alternative. The largest reduction in estimated juvenile rearing habitat between Alternative 4 and the No Action Alternative is an 8.4% decrease in critically dry water year types. On average across all water year types, there is a 4.2% reduction in estimated juvenile rearing habitat under Alternative 4.

The mean values of juvenile rearing WUA by month are lower June through September and higher in May under Alternative 4 compared to the No Action Alternative (Attachment O.1, *Clear Creek Weighted Usable Area Analysis*). Out of the five months, May and June are expected to have the highest juvenile rearing WUA values.

The results of the juvenile rearing habitat analysis indicates that Alternative 4 in comparison to the No Action Alternative may have a minor to moderate adverse effect (up to 8.4% decrease) in fall-run Chinook salmon juvenile rearing habitat depending on the water year type.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 250 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F juvenile UILT during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 254 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F juvenile pathogen virulence threshold during March through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 258 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-82. Table O-82, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-82). For the 75.2°F UILT for rearing and migrating juveniles, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F juvenile pathogen virulence threshold, there were no month-water year type combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

Fall-run Chinook Salmon: Summary

Under Alternative 4, changes in flows are expected to have a minor decrease in estimated fall-run Chinook salmon fry rearing habitat across all water year types in Clear Creek. Additionally, the results of the juvenile rearing habitat analysis suggests that Alternative 4 may have an adverse impact compared to the No Action Alternative from decreased juvenile rearing habitat. Potential water temperature-related impacts (growth, smoltification, predation, and pathogen virulence) would be similar to the No Action Alternative on fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

Late Fall-run Chinook Salmon: CalSim 3 Flows

For the period late-fall juvenile rearing and emigration CalSim 3 modeling indicates that both negative and beneficial effects may occur below Whiskeytown Dam under Alternative 4 compared to the No Action Alternative. Average flow released would increase November through January and decrease June through October. The exception is during a critically dry water year during October with an increase of 15% (Table O-275). The largest decrease under Alternative 4 compared to the No Action Alternative occur June through August (an average of a 27% reduction among all water year types). A 31% reduction in average flow in June from 303 cfs to 208 cfs may have an adverse impact of rearing and emigration. Under Alternative 4 compared to the No Action Alternative, when all water year type simulations are averaged, flow released would increase November through January and March through May, and decrease in February and June through October

Under Alternative 4 from March through September during juvenile rearing periods for late-fall run Chinook salmon, flows would moderately increase from March to May (average of 31% across all water year types), but moderately decrease from June -September (average of 27%). Using the fall run WUA curves as a proxy for the late-fall run, optimal flows for maximum late-fall run juvenile rearing habitat is 300-400 cfs. The only month under Alternative 4 with flow within this range is February. CalSim 3 projects that under Alternative 4, late-fall run Chinook salmon juvenile rearing and emigration in Clear Creek would see both positive and negative impacts compared to the No Action Alternative, with the majority of months during the March through September rearing period having flows below the likely optimal range.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the analysis assessing the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 282 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the 75.2°F juvenile UILT during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 286 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the 59.9°F juvenile pathogen virulence threshold during April through February are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 290 for Clear Creek below Whiskeytown Dam.

Results for the three analyses are summarized in Table O-83. Table O-83, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 55.4°F to 68°F juvenile optimum temperature range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-83). For the 75.2°F UILT for rearing and migrating juveniles, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. For the 59.9°F juvenile pathogen virulence threshold, there were no month-water year type combinations (0%) with either favorable or unfavorable results ts below Whiskeytown Dam. These results suggest that there would be

negligible water temperature-related effects of Alternative 4 on late fall-run Chinook salmon juvenile rearing and emigration in Clear Creek.

Late Fall-run Chinook Salmon: Summary

The change in seasonal operations in Clear Creek between Alternative 4 and the No Action Alternative is expected to have both beneficial and adverse impacts on late fall-run Chinook salmon. An increase in flows would occur from March through May, a substantial beneficial impact, but there would be decreases from June through October, an adverse impact. There would be negligible water temperature-related impacts of Alternative 4 on late fall-run Chinook salmon rearing and emigration in Clear Creek.

Adult Upstream Migration and Holding

Fall-run Chinook salmon may arrive at Clear Creek before spawning from July through early December. Adult late fall-run Chinook salmon migrate and arrive slightly later and do not need to hold and mature before spawning from November into January.

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

Fall-run Chinook Salmon: CalSim 3 Flows

Average flows released to Clear Creek from Whiskeytown Dam would be substantially lower from July through October (up to 25%), and substantially higher from November and December (up to 30%; Table O-275). For the period of fall and late-fall adult migration and holding (July through December), there would be both substantial adverse and beneficial effects to fall-run Chinook salmon in Clear Creek under Alternative 4 compared to the No Action Alternative.

Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature outside the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 230 for Clear Creek below Whiskeytown Dam. Full results of the percent of months with water temperature above the 59.9°F adult pathogen virulence threshold analysis during July through December are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 234 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-84. Table O-84, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 37.9 F to 68°F successful adult migration range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-84). For the 59.9°F adult pathogen virulence threshold, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on fall-run Chinook salmon adult upstream migration and holding in Clear Creek.

Fall-run Chinook Salmon: Summary

The change in seasonal operations in Clear Creek between Alternative 4 and the No Action Alternative is expected to have adverse impacts and moderate to l beneficial impacts to fall-run Chinook salmon. Flows would decrease from July through October resulting in substantially adverse impacts, but flows would substantially increase in November and December, resulting in a substantial beneficial impact. There would be no water temperature impacts (adult migration and pathogen virulence) of Alternative 4 on fall-run Chinook salmon adult upstream migration and holding in Clear Creek.

Late Fall-run Chinook Salmon: CalSim 3 Flows

During the periods of late-fall run Chinook salmon adult migration (November through January), flows would be increased by an average of 27% among all water year types when compared to the No Action Alternative. The largest increase is in January with a 35% increase in average flows (222 cfs to 301cfs)(Table O-275). There would be a substantial increase in suitable migration and holding habitat available for adult late fall-run Chinook salmon as a result of flows in Clear Creek.

Late Fall-run Chinook Salmon: Water Temperature Analysis

Full results of the percent of months with water temperature above the 37.9°F to 68°F successful migration range analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 262 for Clear Creek below Whiskeytown Dam. Full results of the percent of months with water temperature outside the 59.9°F adult pathogen virulence threshold analysis during August through March are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 266 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-85. Table O-85, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 37.9°F to 68°F successful adult migration range, there were zero month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-85). For the 59.9°F adult pathogen virulence threshold, there were zero combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible effects of Alternative 4 on late fall-run Chinook salmon adult upstream migration and holding in Clear Creek.

Late Fall-run Chinook Salmon: Summary

Under Alternative 4, flows would be increased from November through January so there may be a beneficial impact of seasonal operations on late-fall-run Chinook salmon adult migration in Clear Creek based on analyses of simulated flows under Alternative 4 in comparison to the No Action Alternative. Water temperature results suggest that there would be negligible water temperature-related impacts from Alternative 4 on late fall-run Chinook salmon adult upstream migration and holding in Clear Creek

O.7.14.3 Lower American River

Spawning and Egg Incubation

Spawning occurs from about mid-October through early February, with peak spawning from mid-October through December. Chinook salmon spawning occurs within an 18-mile stretch from Paradise Beach to Nimbus Dam; however, most spawning occurs in the uppermost 3 miles (California Department of Fish and Wildlife 2012a). Chinook salmon egg and alevin incubation occurs in the lower American River from about mid-October through April. There is high variability from year to year; however, most incubation occurs from about mid-October through February.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Spawning Habitat—Flow Analysis

Under Alternative 4, fall-run Chinook salmon mean spawning WUA varies modestly among water year types, with no evident trend (Attachment M.3, *American River Weighted Usable Area Analysis*). The highest means are for above normal and below normal water year types and the lowest is for wet water years. Mean spawning WUA is lower under Alternative 4 than under the No Action Alternative for all water year types. The largest reduction is 5.5% for critically dry water years. The other reductions range between 1.1% lower and 0.5% lower (Attachment M.3, *American River Weighted Usable Area Analysis*). For all three months of the fall-run Chinook salmon spawning season, estimated median spawning WUA under Alternative 4 is similar to that under No Action Alternative (Attachment M.3, *American River Weighted Usable Area Analysis*). Spawning WUA for all alternatives is higher in October than in November or December because flows, on average, are lower in October (Table O-277). The fall-run Chinook salmon spawning WUA curve (Attachment M.3, *American River Weighted Usable Area Analysis*) peaks at relatively low flows (below 3,000 cfs).

Overall, fall-run Chinook salmon spawning WUA is similar under Alternative 4 to that under the No Action Alternative.

Redd Dewatering

The results of the analysis for fall-run Chinook salmon under Alternative 4 indicate that mean redd dewatering potential is greatest in wet water years and lowest in critically dry years (Attachment M.1, *American River Redd Dewatering Analysis*). The higher redd dewatering potential in wet water years reflects a greater frequency of large flow fluctuations in this water year type. Redd dewatering is higher under Alternative 4 than the No Action Alternative for all water year types, except for an 8.6% reduction in critically dry water years (Attachment M.1, *American River Redd Dewatering Analysis*). The largest increase is 38.9% for above normal water years. It should be noted, however, that the absolute difference in percent of redds dewatered between Alternative 4 and the No Action Alternative ranges from a 0.6% reduction in critically dry water years to a 4.4% increase in above normal water years . For the individual months of fall-run Chinook salmon spawning in the lower American River, redd dewatering potential increases from spawning in October to that in December, reflecting the increasingly higher flow levels and fluctuations over this period (Attachment M.1, *American River Redd Dewatering Analysis*).

Overall, redd dewatering potential is higher under Alternative 4 than the No Action Alternative, except for slightly lower redd dewatering for critically dry years. Differences are consistently much smaller on an absolute difference scale.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 42.1°F to 55°F range for spawning initiation during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 63 for Hazel Avenue and Table 64 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult spawning pathogen virulence threshold during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 65 for Hazel Avenue and Table 66 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence during October through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 67 for Hazel Avenue and Table 68 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F fry pathogen virulence threshold during October through March are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 69 for Hazel Avenue and Table 70 for Watt Avenue.

Results for the four analyses are summarized in Table O-86. Table O-86, as described in Section O.4.12.3.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 42.1°F to 55°F range for spawning initiation, there were zero month-water year type combinations (0%) with favorable results at both Hazel and Watt Avenue(Table O-86). There were two and zero combinations (5.7% and 0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for spawning adults, there were zero combinations (0%) with favorable and unfavorable results at both Hazel and Watt Avenue. For the 42.8°F to 56°F range for egg incubation and fry emergence analysis, there were one and zero month-water year type combinations (3.3% and 0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero and two month-water year type combinations (0% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 59.9°F fry pathogen virulence threshold analysis, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watts Avenue.

These results suggest that there would be positive (3.3%) and negative (5.7% to 6.7%) water temperature-related effects of Alternative 4 on fall-run Chinook salmon spawning and egg incubation in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Overall, seasonal operations in the lower American River on fall-run Chinook salmon spawning based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative are similar or have negligible differences. Fall-run Chinook salmon

spawning WUA is predicted to be similar under Alternative 4 to that under the No Action Alternative. Water temperature impacts are predicted to have both beneficial and adverse impacts at Hazel Avenue and Watt Avenue.

Juvenile Rearing and Emigration

Chinook salmon fry emergence occurs from January through mid-April, and juvenile rearing extends from January to about mid-July (Williams 2001). Most fall-run Chinook salmon out-migrate from the lower American River as fry from December to July; out-migration peaks in February and March (Snider and Titus 2002; Pacific States Marine Fisheries Commission 2014).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

For the period of juvenile rearing and emigration (December through July), CalSim 3 modeling indicates that flow released in the lower American River below Nimbus Dam under Alternative 4 compared to the No Action Alternative would generally be similar or negligible with both moderate adverse and beneficial effects during a critically dry year (Table O-277). In a critically dry year it is predicted that flows would decrease from February through March by around 5-23%, but flow would be increased in December, January, and July, 13%, 7%, and 14% respectively.

For the period of juvenile rearing and emigration (December through July) in the lower American River at H Street, CalSim 3 modeling of Alternative 4 compared to the No Action Alternative indicates that at H Street flow releases would generally be similar or negligible with both adverse and beneficial effects during a critically dry year (Table O-278). In a critically dry year it is predicted that flows would decrease from February through May by around 6-24%, but flow would be increased in December, January, and July, 13%, 8% and 16% respectively.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 71 for Hazel Avenue and Table 72 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F upper incipient lethal temperature (UILT) for juveniles during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 73 for Hazel Avenue and Table 74 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration during January through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 75 for Hazel Avenue and Table 76 for Watt Avenue.

Results for the three analyses are summarized in Table O-87. Table O-87 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability, there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Hazel and Watt Avenue, respectively (Table O-87). There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 75.2°F upper incipient lethal temperature (UILT) for juveniles, there were zero combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue. For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration, there were zero month-water year type combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue. There was one month-water year type combinations (4.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. These results suggest that Alternative 4 would have positive (4% favorable) and negative (4% unfavorable) water temperature-related effects on fall-run Chinook salmon juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

CalSim 3 modeling at on the lower American River below Nimbus Dam and at H Street have similar results to each other indicating that on average there would be negligible differences in flows during juvenile rearing an emigration, the exception is during a critically dry year when there is both adverse and beneficial impact with increase flows in December and July and reduced flows February -April. Water temperature modeling results are similar with occasional beneficial and adverse water temperature-related impacts on fall-run Chinook salmon juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Adult Upstream Migration and Holding

Adult fall-run Chinook salmon enter the lower American River from about mid-September through January, with peak migration from approximately mid-October through December (Williams 2001).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

CalSim 3 Flows

For the period of adult migration and holding (September through January) in the lower American River below Nimbus Dam, CalSim 3 modeling indicates that flow released from Folsom Reservoir Storage under Alternative 4 compared to the No Action Alternative would generally be similar or negligible with both adverse and beneficial effects during a critically dry year (Table O-277). In a critically dry year, it is predicted that flows would decrease September through November 8%-12% but flow would be increased in December by 8%.

For the period of adult migration and holding (September through January) in the lower American River at H Street, CalSim 3 modeling of Alternative 4 compared to the No Action Alternative indicates that at H Street flow releases would generally be similar or negligible with both adverse and beneficial effects during a critically dry year (Table O-278). In a critically dry year, it is predicted that flows would decrease September through November 10%-15% a moderate adverse effect, but flow would be increased in December by 8%.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 59 for Hazel Avenue and Table 60 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration during June through December are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 61 for Hazel Avenue and Table 62 for Watt Avenue.

Results for the two analyses are summarized in Table O-88. Table O-88, as described in Section O.4.12.3.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 37.9°F to 68°F successful migration range for adult fall-run Chinook salmon under, there were four and two month-water year type combinations (11.4% and 5.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-88). There were four and two month-water year type combination (11.4% and 5.7%, respectively) with unfavorable results at both Hazel Avenue and Watt Avenue, respectively. For the 59.9°F pathogen virulence threshold for adult migration, there were zero month-water year type combinations (0%) with favorable and unfavorable results at both Hazel Avenue and Watt Avenue. These results indicate that Alternative 4 would have positive (5.7% to 11.4% favorable) and negative (5.7% to 11.4% unfavorable) water temperature-related effects to fall-run Chinook salmon upstream migration and holding in the lower American River at Hazel Avenue and Watt Avenue.

Summary

CalSim 3 modeling on the lower American River below Nimbus Dam and at H Street have similar results indicating that on average there would be negligible differences in flows during adult migration and holding with the exception of during a critically dry year when there is both a moderate adverse and beneficial impact with increase flow in December but reduced flow from September through November. Water temperatures under Alternative 4 would have both beneficial and adverse impacts to fall-run Chinook salmon adult upstream migration in the lower American River relative to the No Action Alternative.

O.7.14.4 San Joaquin River

Fall-run Chinook salmon adults migrate upstream through the San Joaquin River at Vernalis between September and November. Juvenile fall-run Chinook salmon migrate downstream past Vernalis primarily January through May. See Section O.1.8.1 for additional information.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Changes in seasonal operations would result in minimal changes in flows in the San Joaquin River at Vernalis. Under the Alternative 4, average flows released at on the San Joaquin River near Vernalis would be similar (below 5%) to the No Action Alternative (Table O-281), except in June through September in critically dry water years when there would be minor to moderate increases in flows (6% to 22%).

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on fall-run Chinook salmon in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

There would be minimal impacts to migrating adults and juvenile fall-run Chinook salmon in the San Joaquin River at Vernalis. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.7.14.5 Bay-Delta

Juvenile Rearing and Emigration

Most fall-run Chinook salmon fry rear in freshwater from December through June, with out-migration as smolts occurring primarily from January through June, with presence in the Delta in December through July. In general, fall-run Chinook salmon fry abundance in the Delta increases following high winter flows. Smolts that arrive in the estuary after rearing upstream migrate quickly through the Delta and Suisun and San Pablo Bays. Late fall-run Chinook salmon outmigrants may be found in the Delta between December and April. See Section O.1.9.1 for additional information.

Potential Changes to Fall-run / Late Fall-run Chinook Salmon ESU from Seasonal Operations

<u>Zone of Influence</u>

Differences in hydrology under Alternative 4 compared with the No Action Alternative may have effects on the spatial extent of influence of exports under CVP and SWP diversions. With incremental decreases in OMR under Alternative 4 and the No Action Alternative, proportional overlap at these three locations decreases, with more subtle changes along the San Joaquin River at Jersey Point compared to Turner Cut and Old River at Middle River. Effects of pumping are smallest at the most upstream location (San Joaquin River at Jersey Point), and greater at Turner Cut, which is less influenced by riverine flow and thus more susceptible to changes in pumping. For a detailed description of how flows under Alternative 4 may impact the proportional overlap at Turner Cut, San Joaquin River at Jersey Point, and Old River at Middle River, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2, *Zone of Influence*).

<u>Flow into Junctions</u>

Differences in flow routing under Alternative 4 compared with the No Action Alternative may have effects on the flow into the Head of Old River and CVP junctions.

Under Alternative 4 in all OMR bins except -3,500, predicted proportion of flow entering the Central Valley Project is less than the No Action Alternative. Changes in predicted proportion of flow entering the CVP in OMR bins -3,500, -5,000, and <-5,500 was less than ± 0.0372, indicating a negligible difference between Alternative 4 and the No Action Alternative. However, in OMR bin -2,000 the change in predicted proportion of flow into CVP was -0.0676 indicating that slightly less flow will be routed into CVP under Alternative 4 than when compared to the No Action Alternative.

Under Alternative 4 in OMR bins -2,000 and <-5,500, predicted proportion of flow entering the HOR is less than the No Action Alternative. In OMR bins -3,500 and -5,000, the predicted proportion of flow entering the HOR is greater than the No Action Alternative. However, changes in predicted proportion of flow entering the HOR in all OMR bins was less than ± 0.026, indicating a negligible difference between Alternative 4 and the No Action Alternative.

For a detailed description of how flows under Alternative 4 may impact the flow at HOR and CVP, see Alternative 4, Sacramento River Winter-run Chinook Salmon ESU (Section O.7.8.2, *Flow into Junctions*).

Summary

Alternative 4 relative to the No Action is expected to influence flow into the HOR and CVP junctions due to differences in water management. Under Alternative 4, no change to possibly less flow into CVP under OMR -2,000; no change in flow into HOR under any OMR groupings. Impacts of pumping under both Alternative 4 and the No Action Alternative are smaller at the more upstream locations (e.g., San Joaquin River at Jersey Point) and greater at Turner Cut where there is less influence of riverine flow and thus more susceptible to changes in pumping (ZOI).

Potential Changes to Entrainment of Fall-run / Late Fall-run Chinook Salmon ESU

Differences in exports under Alternative 4 compared with the No Action Alternative may have effects on fall-run/ late fall-run Chinook salmon at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density model.

Fall-run Chinook Salmon: Salvage Density

Predictions from the salvage density model for fall-run Chinook salmon include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through July and all water year types under Alternative 4, was greater than predicted average monthly loss under the No Action Alternative. Predicted average monthly loss at Banks under Alternative 4, had a range from 29% higher for wet water year types to 77% higher for below normal water year types (Table O-89). Predicted average monthly loss of fall-run Chinook salmon at CVP Jones Pumping Plant for the months of November through August Alternative 4, was equal or higher than predicted average monthly loss under the No Action Alternative for all water year types except for dry water year types. The range of predicted loss for fall-run Chinook salmon at Jones under Alternative 4, compared to the No Action Alternative was from 1% lower in dry water year types to 4% higher for below normal water year types

(Table O-90). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Late Fall-run Chinook Salmon: Salvage Density

Predictions from the salvage density model for late fall-run Chinook salmon include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of late fall-run Chinook salmon at SWP Banks Pumping Plant for the months of December through April and all water year types Alternative 4 was lower than predicted average monthly loss under the No Action Alternative. Predicted average monthly loss at Banks under Alternative 4 had a range from 1% lower for critically dry water year types to 13% lower for dry water year types (Table O-91). Predicted average monthly loss of late fall-run Chinook salmon at CVP Jones Pumping Plant for the months of November through August under Alternative 4 was lower than predicted average monthly loss under the No Action Alternative for wet, below normal and dry water year types, predicted loss was higher for above normal and critically dry water year types. The range of predicted loss for late fall-run Chinook salmon at Jones Pumping Plant under Alternative 4 compared to the No Action Alternative was from 5% lower in wet water year types to 2% higher for above normal water year types (Table O-92). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Summary

The predicted monthly entrainment of fall-run Chinook salmon at Banks Pumping Plant is expected to be substantially increased under Alternative 4 compared to the No Action Alternative in all water year types, causing substantial impacts to fall-run Chinook salmon. The predicted monthly entrainment of fall-run Chinook salmon at the Jones Pumping Plant would be similar to the entrainment under the No Action in all water year types. Late fall-run Chinook salmon entrainment at Banks Pumping Plant would have increases and decreases but would be similar at Jones Pumping Plants under Alternative 4 compared with the No Action Alternative.

Potential Changes to Through Delta Survival of Fall-run / Late Fall-run Chinook Salmon ESU

Delta Passage Model

The DPM simulates migration of Chinook salmon smolts entering the Delta from the Sacramento River, Mokelumne River, and San Joaquin River and estimates survival to Chipps Island. For this application, only survival of fish entering the Delta from the Sacramento River are evaluated. The DPM uses available time-series data and values taken from empirical studies or other sources to parameterize model relationships and inform uncertainty, thereby using the greatest amount of data available to dynamically simulate responses of smolt survival to changes in water management. (Attachment I.6, *Delta Passage Model*). The major model functions in the DPM are listed under winter-run Chinook salmon (Section O.4.8.2).

The major model functions in the DPM are as follows.

- **Fall-run Chinook Salmon:** Under Alternative 4, in all water year types except critically dry and dry water years, predicted mean survival of fall-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). However, the change in mean predicted proportion survival to Chipps Island in all water year types is less than or equal to ± 0.002. There is not a substantial difference in predicted proportion of fall-run Chinook salmon surviving to Chipps Island between Alternative 4 and the No Action Alternative.
- **Late Fall-run Chinook Salmon:** Under Alternative 4, in all water year types except below normal and critically dry water years, predicted mean survival of late-fall-run Chinook salmon to Chipps Island is lower than when compared to the No Action Alternative (Attachment I.6, *Delta Passage Model*). The change in mean predicted survival to Chipps Island in all water year types less than or equal to ± 0.002. There is not a substantial difference in predicted proportion of late-fall-run Chinook salmon

Summary

Under Alternative 4, there would be changes in through Delta survival of both fall-run and late fall-run Chinook salmon through the Delta to Chipps Island compared to the No Action Alternative

O.7.14.6 Stanislaus River

Spawning and Egg Incubation

Peak spawning for fall-run Chinook salmon in the Stanislaus River typically occurs in November with roughly 7% of spawning occurring prior to November 1, and 2% prior to October 15. The few redds created during late September and early October are typically in the reach just below Goodwin Dam with spawning typically ending in December.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Spawning Habitat—Flow Analysis

The results for Alternative 4 show a consistent trend of reduction in mean spawning WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the shape of the fall-run Chinook salmon spawning WUA curves (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which show reduced WUA with increased flow, except at the lowest and highest flows (less than about 200 cfs to 500 cfs and greater than about 1,000 cfs, respectively). CalSim 3 mean monthly flows below Goodwin Dam, which is immediately upstream of the WUA study reach, are 200 cfs or above in all water year types, with flow generally increasing from critically dry to wet water years during all months of the October through December fall-run Chinook salmon spawning period, except December (Table O-279). The mean spawning WUA estimates for Alternative 4 are similar to those for the No Action Alternative, ranging from 2.7% lower in below normal water years to 0.4% higher in dry water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fall-run Chinook salmon spawning period, median spawning WUA under Alternative 4 is higher than the median under the No Action Alternative in November and December and is about the same in October (Attachment N.1, *Stanislaus River Habitat Availability Analysis*).

Overall, the results indicate that mean spawning WUA for fall-run Chinook are about the same for Alternative 4 and the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 42.1°F to 55°F range for spawning initiation during October through January are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 55 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F adult spawning pathogen virulence threshold during October through January are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 56 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 57 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F fry pathogen virulence threshold during December through March are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 58 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-93. Table O-93 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 42.1°F to 55°F range for spawning initiation there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge (Table O-93). For the 59.9°F adult spawning pathogen virulence threshold, there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 42.8°F to 56°F water temperature range for fall-run Chinook salmon egg incubation and fry emergence there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 59.9°F fry pathogen virulence threshold there were also no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge.

These results suggest that Alternative 4 would have negligible water temperature-related effects on fall-run Chinook salmon spawning and egg incubation.

Summary

Under Alternative 4 compared to the No Action Alternative, there are expected negligible impacts of seasonal operations in the Stanislaus River on fall-run Chinook spawning and egg incubation. The WUA and temperature model results indicate that mean spawning WUA for fall-run Chinook are about the same or would have negligible impacts under Alternative 4 compared to the No Action Alternative on fall-run Chinook salmon spawning and egg incubation. There would be similar conditions affecting spawning initiation, egg incubation and fry emergence, and pathogen virulence.

Juvenile Rearing and Emigration

Fall-run Chinook salmon juvenile rearing in the Stanislaus River typically occurs from January through May (Stanislaus River Fish Group 2004). Fry migration generally occurs from January through March, followed by smolt migration from April through May (Bureau of Reclamation 2012).

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

Rearing Habitat–WUA Flow Analyses

The results for fall-run Chinook salmon fry rearing WUA under Alternative 4 show a consistent trend from the highest mean rearing WUA in critically dry to the lowest in wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the fall-run Chinook salmon fry WUA curves, which show reduced WUA with increased flow, especially in the Orange Blossom Bridge and Riverbank reaches (Attachment N.1, *Stanislaus River Habitat Availability Analysis*), which are the longest river segments of the study. Mean fry rearing WUA under Alternative 4 is consistently higher than that under the No Action Alternative in all water year types, ranging from 2.7% higher in above normal water years to 7.2% higher in critically dry water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fry rearing period, fry rearing WUA is higher under Alternative 4 than under the No Action Alternative in all four months (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). The increase is especially large for February.

The results for juvenile rearing WUA under Alternative 4 shows little change in mean rearing WUA from critically dry to wet water year types (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Juvenile rearing WUA is higher under Alternative 4 than under the No Action Alternative for all water year types, ranging from 2.9% higher for wet water years to 5.5% higher for critically dry water years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the juvenile rearing period, the medians of juvenile rearing WUA are much lower in March than in other months (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Median juvenile rearing WUA is slightly higher under Alternative 4 than the No Action Alternatives in March, but there is little difference in the other months.

Overall, the results indicate that fry and juvenile rearing WUA for fall-run Chinook salmon is consistently but modestly higher under Alternative 4 than under the No Action Alternative.

Rearing Habitat—ASH Flow Analyses

The results of the Area of Suitable Habitat (ASH) analysis for fall-run Chinook salmon fry and juvenile rearing are quite different from the rearing WUA results described above. The mean ASH estimates vary strongly with water year type for both fry and juvenile fall-run Chinook salmon, consistently increasing from critically dry to wet years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). This pattern of variation reflects the overall relationship between flow and ASH for both life stages determined from modeling and field studies (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). Differences in fry and juvenile ASH between Alternative 4 and the No Action Alternative are moderate, which is consistent with the results of the rearing WUA analyses. For the fry, mean ASH is higher under Alternative 4

than the No Action Alternative for all water year types, ranging from 1.1% higher for wet years to 6.6% higher for critically dry water years. For the juveniles, mean ASH varies from 4.8% lower under Alternative 4 in below normal water years to 5.7% higher for critically dry years (Attachment N.1, *Stanislaus River Habitat Availability Analysis*). For the individual months of the fall-run Chinook salmon fry rearing period, median ASH under Alternative 4 relative to the No Action Alternative are higher in February, lower in April, and similar in March and May.

Overall, the results indicate that fry rearing ASH for fall-run Chinook salmon is somewhat higher under Alternative 4 than under the No Action Alternative, while juvenile rearing ASH is similar between the alternatives for all water year types combined.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 59 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 75.2°F upper incipient lethal temperature (UILT) for juveniles during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 60 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration during March through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 61 for Orange Blossom Bridge.

Results for the three analyses are summarized in Table O-94. Table O-94, as described in Section O.4.14.6, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 55.4°F to 68°F optimum temperature for juvenile growth, smoltification, and predation vulnerability there were two month-water year type combinations (10.0%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-94). For the 75.2°F upper incipient lethal temperature (UILT) for juvenile fall-run Chinook salmon there were no month-water year type combinations (0%) with favorable or unfavorable results at Orange Blossom Bridge. For the 59.9°F pathogen virulence water temperature threshold for fall-run Chinook salmon juvenile outmigration there was zero month-water year type combination (0.0%) with favorable results and one combination (5.0%) with unfavorable results at Orange Blossom Bridge. These results suggest that there would be positive water temperature-related effects of Alternative 4 on fall-run Chinook salmon juvenile rearing and emigration.

Summary

For the period of juvenile rearing and emigration of fall-run Chinook salmon in the Stanislaus River, CalSim 3 modeling under Alternative 4 compared to No Action Alternative suggest a mix of beneficial and adverse impacts may occur depending on water year type. The modeled median juvenile rearing WUA is slightly higher under Alternative 4 than the No Action Alternatives in March, but there is little difference in the other months. Fry rearing ASH for fall-run Chinook

salmon is somewhat higher under Alternative 4 than under the No Action Alternative a likely beneficial result. These results suggest that there would be beneficial impacts on fall-run Chinook salmon juvenile rearing and emigration. There would be similar conditions affecting spawning initiation, egg incubation and fry emergence, and pathogen virulence.

Adult Upstream Migration and Holding

Fall-run Chinook salmon adults generally migrate upstream from late September through December with peak migration from late October through early November in the Stanislaus River.

Potential Changes to Fall-run Chinook Salmon ESU from Seasonal Operations

For the period of adult migration and holding of fall-run Chinook salmon (September-December) in the Stanislaus River below Goodwin Dam, CalSim 3 modeling under Alternative 4 compared to No Action Alternative indicates that on average, among all water year types, only negligible differences in WUA would occur with a minor beneficial increase in December of 7% (Table O-279).

For the period of adult migration and holding of fall-run Chinook salmon (September-December) in the Stanislaus River at the mouth, CalSim 3 modeling under Alternative 4 compared to No Action Alternative indicates that on average, among all water year types, only negligible differences in WUA would occur with a minor beneficial increase in September of 5% on average and an increase of 29% in a critically dry water year (Table O-280).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 37.9°F to 68°F successful migration range during July through December are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 51 for Orange Blossom Bridge and Table 52 for above the confluence with the San Joaquin River. Full results of the analysis assessing the percent of months with water temperature above the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration during July through December are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 53 for Orange Blossom Bridge and 54 for above the confluence with the San Joaquin River.

Results for the two analyses are summarized in Table O-95. Table O-95, as described in Section O.4.14.6 reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was greater than 10%.

Under Alternative 4 for the 37.9°F to 68°F successful migration range there were no month-water year type combinations (0.0%) with favorable or unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River (Table O-95). For the 59.9°F pathogen virulence water temperature threshold for adult fall-run Chinook salmon migration there was also no month-water year type combinations (0.0%) with favorable or unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River.

These results suggest that Alternative 4 would have negligible water temperature-related effects on fall-run Chinook salmon upstream holding and migration in the Stanislaus River at Orange Blossom Bridge and above the confluence of the San Joaquin River.

Summary

For the period of adult migration and holding of fall-run Chinook salmon (September-December) in the Stanislaus River, CalSim 3 modeling under Alternative 4 compared to No Action Alternative indicates that on average, among all water year types, only negligible differences would occur at both Goodwin Dam and the mouth. Additionally, the water temperature model results indicate there would be negligible impacts under Alternative 4 compared to the No Action Alternative at Orange Blossom Bridge and above the confluence of the San Joaquin River. There would be similar water temperature conditions affecting spawning initiation, egg incubation and fry emergence, and pathogen virulence.

O.7.15 White Sturgeon

O.7.15.1 Sacramento River

Spawning and Egg Incubation

Spawning occurs in deep water in the middle and lower Sacramento River from near Verona (~RM 80) to just upstream of Colusa (~RM 156) from late February to early June, peaking during March and April, (Section O.1.3.2.6, *White Sturgeon*). Because the incubation time for white sturgeon is so short, the peak impacts analysis period for incubating eggs is also considered to be March and April.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

During the March and April spawning and egg incubation period for white sturgeon, CalSim 3 estimates of mean monthly flows at Wilkins Slough under Alternative 4 range from about 4,200 cfs for April of critically dry water years to about 18,000 cfs for March of wet water years (Table O-268). Because white sturgeon spawn in deep pools, these flow levels are likely to be adequate for spawning and egg incubation, so no adverse effects are expected to result. Differences in flows between Alternative 4 and the No Action Alternative are small in both months (up to 1%), but flows are moderately higher (8%) for Alternative 4 in April of critically dry water years (Table O-268). It is concluded that Alternative 4 would have similar flow effects on white sturgeon eggs and embryos relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 61°F upper limit for optimal egg incubation during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 291 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature above the 68°F upper limit for embryo hatching during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 292 for Hamilton City.

Results for the two analyses are summarized in Table O-96. Table O-96, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 61°F upper limit for optimal egg incubation, there were no month-water year type combinations (0.0%) with favorable and unfavorable results at Hamilton City (Table O-96). For the 68°F upper limit for embryo hatching, there were no combinations (0%) with favorable or unfavorable results at Hamilton City. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on white sturgeon spawning and egg incubation in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on spawning habitats due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have negligible water temperature-related impacts on spawning in the Sacramento River.

Larval and Juvenile Rearing and Emigration

The white sturgeon juvenile stage begins when metamorphosis of the larva is complete, typically at about 45 days post hatch (Heublein et al. 2017a, Deng et.al 2002). Therefore, since white sturgeon spawn from late February to early June, peaking in March and April, the larval period is considered to be March through June. Juvenile white sturgeon are believed to initiate a secondary dispersal (the primary dispersal occurring at the larval stage) in spring by actively swimming downstream during the night (Heublein et al. 2017a). The juvenile emigration period is considered to be April through July. Therefore, the effects analysis period for larvae and juvenile rearing and emigration is considered to be March through July.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

During the white sturgeon larval and juvenile rearing and emigration period, approximately March to July, CalSim 3 estimates of mean monthly flows at Wilkins Slough under Alternative 4 range from about 3,300 cfs for May of critically dry water years to about 18,000 cfs for March of wet water years (Table O-268). Differences in flows between Alternative 4 and the No Action Alternative are generally small in all four months of all water years (up to 5%), with a few exceptions. Flows would moderately decrease in July of critically dry years (up to 5%) (Table O-268). These flow levels are likely to be adequate for white sturgeon rearing and emigration; therefore, Alternative 4 would likely have a similar effect on larval and juvenile white sturgeon relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 66°F limit above which stress is observed in juvenile white sturgeon year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 293 for Hamilton City.

Results for the analysis are summarized in Table O-97. Table O-97, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 66.6°F stress limit for juvenile white sturgeon, there were three month-water year type combinations (5.0% of total combinations during the period) with favorable results and one combination (1.7%) with unfavorable results at Hamilton City (Table O-97). These results suggest that there would be negligible water temperature-related effects of Alternative 4 on white sturgeon larval and juvenile rearing and emigration in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on rearing and emigration habitats due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have negligible water temperature-related impacts on rearing and emigration in the Sacramento River.

Adult Upstream Migration and Holding

Adults ready for spawning likely move into the lower reaches of the Sacramento River during early winter to begin their upstream migration (Section O.1.3.2.6, *White Sturgeon*). Upstream migration appears to be rapid, with minimal holding time (Schaffter 1997, Heublein et al. 2017a). Based on rapid upstream migration, short egg incubation period, and larval presence in the Sacramento River; the adult upstream migration and holding period is considered to be December to February for this effects analysis.

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

During the white sturgeon adult upstream migration and holding period, approximately December to February, CalSim 3 estimates of mean monthly flows at Wilkins Slough under Alternative 4 range from about 6,400 cfs for January of critically dry water years to about 19,900 cfs for February of wet water years (Table O-268). CalSim 3 results indicate that differences in flows during December through February would generally be minimal (up to 5%) with Alternative 4 compared to the No Action Alternative (Table O-268). Therefore, Alternative 4 would have a similar effect on upmigrating and holding adult white sturgeon relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 77°F upper limit of suitable water temperature for adult white sturgeon during November through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 294 for Hamilton City.

Results for the analysis are summarized in Table O-98. Table O-98, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 77°F upper limit of suitable water temperature for adult white sturgeon, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results (Table O-98). These results suggest that there would be negligible water temperature-related effects of Alternative 4 on adult white sturgeon holding and migration in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on upstream migration and holding habitats. Alternative 4 relative to the No Action Alternative is expected to have negligible water temperature-related impacts on upstream migration and holding in the Sacramento River.

O.7.15.2 Lower American River

Limited quantitative information is available on the distribution and status of white sturgeon in the lower American River; however, small numbers of adults apparently use the lower American River, as evidenced by sturgeon report cards submitted to the CDFW by anglers in recent years (Section O.1.6.2.1, *Fish Evaluated in the Lower American River*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

Adult white sturgeon have been reported by anglers in the lower American River during all months of the year, peaking in March-April and November-December (California Department of Fish and Wildlife 2023i). During all months, CalSim 3 estimates of mean monthly flows below Nimbus Dam under Alternative 4 range from about 704 cfs for October of critically dry water years to about 12,284 cfs for February of wet water years (Table O-277). For the full simulation period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 6%) under Alternative 4 compared to the No Action Alternative (Table O-277).

During all months, CalSim 3 estimates of mean monthly flows at H Street under Alternative 4 range from about 583 cfs for October of critically dry water years to about 12,307 cfs for February of wet water years (Table O-277). For the full simulation period average, CalSim 3 results indicate that differences in flows during January through December would generally be minimal (up to 7%) under Alternative 4 compared to the No Action Alternative (Table O-277).

White sturgeon are not likely to be affected by changes in flow under Alternative 4 compared to the No Action Alternative due to their limited distribution in the lower American River.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 77°F upper limit of suitable water temperatures for adult white sturgeon year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 77 for Hazel Avenue and Table 78 for Watt Avenue.

Results for the analysis are summarized in Table O-99. Table O-99, as described in Section O.4.15.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 77°F upper limit of suitable water temperatures for adult white sturgeon, there were zero month-water year type combinations (0%) with favorable results at Hazel Avenue and Watt Avenue (Table O-99). There were also zero month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue.

These results suggest that Alternative 4 would have no water temperature-related effects on non-spawning white sturgeon in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on white sturgeon habitat due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have no water temperature-related impacts on white sturgeon habitat in the lower American River.

O.7.15.3 San Joaquin River

Little is known about white sturgeon populations inhabiting the San Joaquin River. White sturgeon spawning in the San Joaquin River was documented for the first time in 2011 and confirmed in 2012. Although the majority of sturgeon likely spawn in the Sacramento River, the results of these surveys confirm that white sturgeon do spawn in the San Joaquin River in both wet- and dry-year conditions and may be an important source of production for the white sturgeon population in the Sacramento–San Joaquin River system (Section O.1.8.2.4, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

Spawning Habitat—Flow Analysis

CalSim 3 Flows

Using the Sacramento River as a surrogate, it can be inferred that the spawning period for white sturgeon in the San Joaquin River also occurs in deep water from late February to early June, peaking during March and April, (Section O.1.8.2.4, *White Sturgeon*). Because the incubation time for white sturgeon is so short, the peak impacts analysis period for incubating eggs is also considered to be March and April. Since confirmed spawning events took place in the San Joaquin River, it is reasonable to assume that rearing larvae, emigrating juveniles, and migrating adults are also present in the San Joaquin River, but due to the lack of information on these life stages they are not part of this analysis.

During the evaluated months in the spawning period, CalSim 3 estimates of mean monthly flows at Vernalis under Alternative 4 range from about 2,060 cfs for March of critically dry water years to about 12,506 cfs for April of wet water years (Table O-281). CalSim 3 results indicate that differences in flows during March and April would generally be minimal (up to 1%) under Alternative 4 compared to the No Action Alternative (Table O-281). Due to spawning occurring in deep pools, it is not anticipated that flows under Alternative 4 would have an effect on white sturgeon spawning compared to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on white sturgeon in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on spawning white sturgeon due to differences in flow. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.7.15.4 Bay-Delta

Juvenile Rearing and Emigration

White sturgeon are believed to be most abundant within the Bay-Delta region. Juveniles can be found throughout the Delta year-round. Additionally, white sturgeon larvae have been observed to be flushed farther downstream in the Delta and Suisun Bay in high outflow years, but otherwise rear higher in the system (Section O.1.9.1.6, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

<u>CalSim 3 Flows</u>

During all months, CalSim 3 estimates of mean monthly flows in the Sacramento River at Rio Vista under Alternative 4 range from about 3,222 cfs for August of critically dry water years to about 104,637 cfs for February of wet water years (Table O-274). For all water year types, CalSim 3 results indicate that differences in flows would generally be minimal (up to 5%) under Alternative 4 compared to the No Action Alternative, with a couple exceptions. Flows under Alternative 4 for above normal water years would moderately decrease in July (7%) and moderately increase April of critically dry water years (Table O-274).

CalSim 3 estimates of mean monthly total exports of SWP and CVP under Alternative 4 range from 1,538 cfs for July of critically dry water years to about 10,840 cfs for August of wet water years (Table O-271). Exports would moderately to substantially increase in February, April, and May of all water year types (up to 37%) and moderately increase in March of wet water years (13%), March and September of above normal water years (up to 22%), and October and November of critically dry water years (up to 13%). Flows would moderately decrease in December for all water year type (up to11%), June of above normal below normal, and dry water year types (up to 11%) and July and August of critically dry water years (up to 12%) (Table

O-271). It is not anticipated that changes in exports under Alternative 4 would have an effect on white sturgeon juveniles compared to the No Action Alternative.

Delta Outflow vs Sturgeon YCI

Differences in year class strength between Alternative 4 and the No Action Alternative are expected to be negligible. For additional effects of spring Delta outflow vs white sturgeon YCI under Alternative 4, refer to the analysis in Section O.7.11.3.1, *[Green Sturgeon] Larval and Juvenile Rearing and Emigration* and Attachment J.2, *Sturgeon Year Class Index and Delta Outflow*, for additional details.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on white sturgeon year class strength due to differences in flow.

Potential Changes to Entrainment of White Sturgeon

Salvage Density

Predictions from the salvage density model for white sturgeon include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

At the CVP Jones Pumping Plant loss was similar in all water year types, whereas predicted average monthly loss of white sturgeon under Alternative 4 compared to the No Action Alternative at SWP Banks Pumping Plant was greater in wet and dry water year types and lower in below normal water year types; however, no loss is anticipated in critically dry year types at either facility (Tables O-100 and O-101). At the SWP Banks Pumping Plant predicted average monthly loss was up to 32% greater for January and May of dry water year types and as low as -9% for March, April, June, November, and December of below normal water year types (Table O-100). Historical loss of white sturgeon at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Summary

Differences in exports between Alternative 4 and the No Action Alternative are expected to have negligible impacts on the entrainment of juvenile white sturgeon at both facilities. Modeled results from the quantitative model show potential beneficial and adverse impacts, but since white sturgeon are salvaged so rarely, the numbers may not be representative.

Subadult and Adult Residency

White sturgeon are believed to be most abundant within the Bay-Delta region. Non-spawning adults can be found throughout the Delta year-round. When not undergoing spawning or ocean migrations, adults and subadults are usually most abundant in brackish portions of the Bay-Delta (Section O.1.9.1.6, *White Sturgeon*).

Potential Changes to White Sturgeon from Seasonal Operations

CalSim 3 Flows

Juveniles, subadults and non-spawning adults are in the Bay Delta year-round, refer to the CalSim 3 flow analysis in the juvenile life stage (Section O.7.15.5.1, *Juvenile Rearing and Emigration*) for changes in flow under Alternative 4 compared to the No Action Alternative.

Summary

Differences in exports between Alternative 4 and the No Action Alternative are expected to have negligible impacts on white sturgeon year class strength.

O.7.16 Native Minnows

O.7.16.1 Sacramento River

Sacramento Splittail, Hardhead, and Sacramento Hitch

- **Sacramento Splittail:** Historically, Sacramento splittail was widespread in the Sacramento River from Redding to the Delta (Rutter 1908, as cited in Moyle et al. 2004). This distribution has become somewhat reduced in recent years (Sommer et al. 1997, 2007b). During drier years there is evidence that spawning occurs farther upstream (Feyrer et al. 2005). Adult splittail migrate upstream in the lower Sacramento River to above the mouth of the Feather River and into the Sutter and Yolo Bypasses (Sommer et al. 1997; Feyrer et al. 2005; Sommer et al. 2007b). Each year, mainly during the spring spawning season, a small number of individuals have been documented at the Red Bluff Pumping Plant and the entrance to the GCID intake (Moyle et al. 2004).
- Most juvenile Sacramento splittail move from upstream areas downstream into the Delta from April through August (Meng and Moyle 1995; Sommer et al. 2007b). The production and recruitment of YOY Sacramento splittail is largely influenced by extent and duration of inundation of floodplain spawning habitats, with abundance spiking following wet years and declining after dry years (Sommer et al. 1997; Moyle et al. 2004; Feyrer et al. 2006).
- **Hardhead:** Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986). They migrate upstream and into tributary streams as far as 45 miles (72.4 km) to spawning sites. Spawning behavior has not been documented, but it is assumed to be similar to that of the pikeminnow, which deposit their eggs over gravel-bottomed riffles, runs, and at the head of pools (Moyle et al. 1995). Hardhead larvae and juveniles likely inhabit stream margins with abundant cover and move into deeper habitats as they grow larger. Juvenile and adult hardhead are present in the Sacramento River year-round.
- **Sacramento Hitch:** Sacramento hitch historically occurred in low-elevation streams throughout the Sacramento and San Joaquin Valleys and in the Delta (Moyle et al. 2015). Sacramento hitch were not known to occur in high abundance in the Sacramento watershed, but they are known to prefer shallow backwater areas and historically were observed in the upper and lower Sacramento River and north Delta (Brown and May 2006; Robinson and Safran 2014).

Moyle et al. (2015) summarized habitat and distribution: Spawning takes place mainly in riffles of streams tributary to lakes, river, and sloughs after flows increase in response to spring rains, but spawning requirements are in need of further documentation. Moyle et al. (2015) indicate that YOY hitch spend the next two months after hatching shoaling in shallow water or staying close to aquatic plants before moving out into more open water at around 50-mm fork length.

Potential Changes to Sacramento Splittail, Hardhead, and Sacramento Hitch from Seasonal Operations

CalSim 3 Flows

The greatest factor in determining native minnow spawning success and recruitment is the amount and duration that crucial floodplain spawning areas are inundated during the period of native minnow migration and spawning. In wet years flows over 22,500 cfs at Tisdale, the first flood control gate, would cause the Tisdale weir to begin spilling into the Sutter Bypass (California Department of Water Resources 2010). Adult migration generally occurs during the late winter with juvenile outmigration into the Delta occurring in spring/early summer. Exact migration, spawning and outmigration timing are not well understood for native minnows, so flows were examined for the months of December through May.

CalSim 3 modeling indicates that average flow released at Keswick Dam under Alternative 4 would generally be similar to flows under No Action Alternative December through May, the range of average flows for the full simulation period are from about 6,300 cfs (April) to 11,800 cfs (February) (Table O-266). Differences in average flows at Keswick Dam under Alternative 4 are from a 2% reduction (May) to a 1% increase (December) for the full simulation period (Table O-266). Native minnows need adequate flows to allow access to upstream spawning/rearing habitat, with minimal differences in flows under Alternative 4 the effect on flow to native minnow is likely negligible as compared to the No Action Alternative.

For the full simulation period, and the months of December through May, the difference in average CalSim 3 flow estimates under Alternative 4 compared to the No Action Alternative at Wilkins Slough are minimal, with a range of 1% decrease in flows for May to a 1% increase in December (Table O-268).With little difference in average CalSim 3 flow estimates at Wilkins Slough, Alternative 4 would have a negligible effect on native minnow spawning and migration as compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 75°F observed range of suitable water temperatures for Sacramento splittail during February through May are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 307 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 84.2°F range of preferred temperatures in lab and field observations for Sacramento hitch non-spawning adults year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Tables 308 for Keswick Dam, 309 for Red Bluff Diversion Dam, and 310 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 64°F optimal water temperature range for hardhead spawning during April through June are presented in Attachment

L.1, *Sacramento River Water Temperature Analysis*, Tables 311 for Keswick Dam and 312 for Red Bluff Diversion Dam. Full results of the analysis assessing the percent of months with water temperature outside the 57.2°F to 78.8°F commonly observed range of temperatures for non-spawning adult hardhead year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Tables 314 for Keswick Dam and 315 for Red Bluff Diversion Dam.

Results for the four analyses are summarized in Table O-102. Table O-102, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 45°F to 75°F observed range for suitable Sacramento splittail spawning, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at Hamilton City (Table O-102). For the 77°F to 84.2°F preferred range for non-spawning Sacramento hitch, there were no combinations (0%) with favorable or unfavorable results at any location analyzed. For the 59°F to 64°F optimal hardhead spawning range, there were no combinations (0%) with favorable results at both locations analyzed. There were zero and one combinations (0% and 6.7%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there were zero and five combinations (0% and 8.3%, respectively) with favorable results at Keswick Dam and RBDD, respectively. There were two and one combinations (3.3% and 1.7%, respectively) with unfavorable results at Keswick Dam and RBDD, respectively. These results suggest that there would be positive and negligible negative water temperature-related effects of Alternative 4 on native minnows in the Sacramento River.

Summary

Seasonal operations impact on native minnows would likely be negligible based on the CalSim 3 analysis. Alternative 4 compared to the No Action Alternative would not impact splittail or hitch, but would have beneficial and negligibly adverse effects on non-spawning adult hardhead in the Sacramento River.

O.7.16.2 Clear Creek

Hardhead

According to Moyle et al. 2015, hardhead mainly occupy canyon reaches and deep pools in Clear Creek. Hardhead are one of the non-target species regularly caught in the RSTs in lower Clear Creek (Schraml and Chamberlain 2019a, 2019b, 2020, and 2021). Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986).

Potential Changes to Hardhead from Seasonal Operations

CalSim 3 Flows

During the December through May period for adult migration and spawning flows in Clear Creek the CalSim 3 modeling results show that throughout the full simulation period, average flows in Clear Creek higher under Alternative 4 with the exception of a 10% reduction in February. Under Alternative 4 average flows in Clear Creek ranged from 220 cfs (April) to 301 cfs (January and February) (Table O-275). Even with a 10% reduction in February, flows would remain generally high during the period of hardhead spawning and migration so the effect of seasonal operations under Alternative 4 compared to the No Action Alternative would likely be negligible.

Hardhead are present in Clear Creek all months of the year. During the full simulation period and for all months utilizing the CalSim 3 modeling results, average flows under Alternative 4 had a range from 112 cfs (July) to 301 cfs (January and February) (Table O-275). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from 31% lower (June) to 36% higher (May) (Table O-275). With the decrease in flows in February, flows would still remain relatively high during the winter and spring, but during the fall a substantial reduction in flows would likely have a negative effect on hardhead occupying Clear Creek by limiting suitable habitat, and prey availability.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 64°F optimal water temperature range for hardhead spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 304 for Clear Creek below Whiskeytown Dam. Full results of the analysis assessing the percent of months with water temperature outside the 57.2°F to 78.8°F commonly observed range of temperatures for hardhead spawning year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 307 for Clear Creek below Whiskeytown Dam.

Results for the two analyses are summarized in Table O-103. Table O-103, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 59-64°F optimal hardhead spawning range, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results (Table O-103). For the 57.2°F to 78.8°F commonly observed range for non-spawning adult hardhead, there were no combinations (0%) with either favorable or unfavorable results below Whiskeytown Dam. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on native minnows in Clear Creek.

Summary

There are likely negligible impacts of seasonal operations on migrating and spawning adult hardhead in Clear Creek based on temperature and simulated flow analysis for Alternative 4 as compared to the No Action Alternative. However, a reduction in flows during the fall would likely have an adverse impact on juvenile and non-spawning adults occupying Clear Creek.

O.7.16.3 Lower American River

Hardhead and Sacramento Splittail

- **Hardhead:** The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are fairly common in the lower reaches of the lower American River. Hardhead are fairly common year-round in the lower reaches of the lower American River (Moyle 2002). Although migratory behavior of hardhead in the lower American River individuals is unknown, individuals from other large rivers, such as the Sacramento River, migrate into tributary streams during April and May. Hardhead typically spawn between April and May (Moyle 2002). Although hardhead early life history is largely unknown, young individuals likely remain along stream edges with dense cover and move into deeper water as they grow, which allows migrants to move back downstream in the current (Moyle 2002).

- **Sacramento Splittail:** Splittail likely spawn in the lower reaches of the lower American River (Sommer et al. 2008; Moyle et al. 2004). Because upstream migration is more directed and fish tend to swim farther upstream during wet years (Moyle 2002), more individuals are expected to use the lower American River in wet years. Although juvenile splittail are known to rear in upstream areas for a year or more (Baxter 1999), most move to the Delta after only a few weeks of rearing on floodplain habitat (Bureau of Reclamation 2008). Most juveniles move downstream into the Delta from April to August (Meng and Moyle 1995). The primary factor potentially limiting the lower American River population of Sacramento splittail is availability of inundated floodplains for spawning and rearing habitats (Moyle et al. 2004).

Potential Changes to Hardhead and Sacramento Splittail from Seasonal Operations

<u>CalSim 3 Flows</u>

During the December through May period for adult migration and spawning for flows in the lower American River below Nimbus Dam the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are minimal. Under Alternative 4 average flows in the lower American River at Nimbus ranged from 3,567 cfs (April) to 6,461 cfs (February) (Table O-277). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 2% reduction (March) to a 2% increase (January and February) (Table O-277). With minimal differences in flows native minnow migration and spawning would likely have a negligible affect under Alternative 4 compared to the No Action Alternative.

During the full simulation period, and all months, CalSim 3 estimates of mean monthly flows below Nimbus Dam under Alternative 4 are from 1,417 cfs (October) to 6,355 cfs (February) (Table O-277). The difference in average flows under Alternative 4 as compared to the No Action Alternative for the full simulation period range from a 6% reduction (September and October) to a 3% increase (November) (Table O-277). With minimal differences in flows native minnows occupying the lower American River would likely have a negligible affect under Alternative 4 compared to the No Action Alternative.

During the December through May period for adult migration and spawning for flows in the lower American River at H street the CalSim 3 modeling results show that throughout the full simulation period differences in average flows are minimal. Under Alternative 4 average flows in the lower American River at H street ranged from 3,488 cfs (April) to 6,351 cfs (February) for the period of December through May (Table O-278). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 2% reduction (March) to a 2% increase (January and February) (Table O-278). With minimal differences in flows native minnow migration and spawning would likely have a negligible affect under Alternative 4 compared to the No Action Alternative.

During all months, and for the full simulation period, CalSim 3 estimates of mean monthly flows at H Street under Alternative 4 range from 1,312 (October) to 6,351 cfs (February) (Table O-278). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 7% reduction (September) to a 3% increase (November) for the full simulation period (Table O-278). With minimal differences in flows native minnows occupying the lower American River would likely have a negligible affect under Alternative 4 compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 45°F to 75°F water temperature range observed for Sacramento splittail suitable spawning during February through May are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 87 for Hazel Avenue and Table 88 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the outside the 59°F to 64°F water temperature optimal range for hardhead spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 89 for Hazel Avenue and Table 90 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the outside the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 91 for Hazel Avenue and Table 92 for Watt Avenue.

Results for these three analyses are summarized in Table O-104. Table O-104, as described in Section O.4.16.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 45°F to 75°F temperature range observed for suitable spawning for Sacramento splittail under Alternative 4, there were zero month-water year type combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-104). There were also zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 59°F to 64°F water temperature optimal range for hardhead spawning under Alternative 4, there were one and two month-water year type combinations (6.7% and 13.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There was one month-water year type combinations (6.7%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were three and two month-water year type combinations (5.0% and 3.3%, respectively) with favorable results at both Hazel Avenue and Watt Avenue. There were one and

two month-water year type combinations (1.7% to 3.3%, respectively) with unfavorable results at both Hazel Avenue and Watt Avenue.

Overall, these results suggest that there would be positive and negative water temperatures-related effects of Alternative 4 on native minnows in the lower American River.

Summary

There are likely negligible impacts of seasonal operations on native minnow in the lower American River based on the difference in simulated flows for Alternative 4 compared to the No Action Alternative. However, the temperature analysis for the lower American River at Hazel and Watt Avenue shows that beneficial and adverse temperature related impacts are expected for hardhead spawning and non-spawning adults under Alternative 4. Water temperature related impacts on Sacramento splittail are likely negligible in the lower American River at Watt Ave and Hazel Ave. With negligible flow related impacts, and beneficial and adverse temperature related impacts, overall Alternative 4 would have a beneficial and adverse impact on native minnows in the lower American River as compared to the No Action Alternative.

O.7.16.4 Stanislaus River

Hardhead

The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are a frequent catch in the lower Stanislaus River (Bradbury and Hickey 2019). Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986).

Potential Changes to Hardhead from Seasonal Operations

CalSim 3 Flows

During the December through May period for adult migration and spawning for flows in the Stanislaus River at the confluence with the San Joaquin the CalSim 3 modeling results show that throughout the full simulation period average flows are similar for Alternative 4 compared to the No Action Alternative. Under Alternative 4 average flows in the Stanislaus River at the confluence ranged from 532 cfs (December) to 1,161 cfs (May) (Table O-280). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 3% reduction (May) to a 4% increase (December) for the full simulation period and months of December through May (Table O-280). With minimal differences in flows hardhead migration and spawning would likely have a negligible affect under Alternative 4 compared to the No Action Alternative.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the Stanislaus River at the confluence of the San Joaquin under Alternative 4 range from 346 cfs (July) to 1,161 cfs (May) (Table O-280). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 3% reduction (May) to a 7% increase (August) for the full simulation period and all months (Table O-280). Hardhead are present in the Stanislaus River all months of the year. With minimal differences in flows hardhead occupying the Stanislaus River would likely have a negligible affect under Alternative 4 compared to the No Action Alternative.

During the December through May period for adult migration and spawning for average flows in the Stanislaus River below Goodwin Dam the CalSim 3 modeling results show that throughout the full simulation period flows will be generally similar for Alternative 4 compared to the No Action Alternative. Under Alternative 4 average flows in the Stanislaus River below Goodwin Dam ranged from 527 cfs (December) to 1,048 cfs (February) for the months December through May (Table O-279). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 8% reduction (April) to a 7% increase (February) (Table O-279). Somewhat substantial decreases in flows during the crucial month of April, most notably in dry and below normal water year types may have a negative effect on hardhead spawning. Overall, flows are similar under Alternative 4 compared to the No Action Alternative, so the effect on hardhead spawning and migration would likely be negligible or slightly negative.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the Stanislaus River below Goodwin Dam under Alternative 4 had a range from 295 cfs (July) to 1,048 cfs (February) (Table O-279).The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 8% reduction (April) to a 10% increase (August) for the full simulation period, and all months (Table O-279). Hardhead are present in the Stanislaus River for all months of the year. Somewhat substantial decreases in flows during the crucial month of April, most notably in dry and below normal water year types may have a negative effect on hardhead spawning. Overall, flows are similar under Alternative 4 compared to the No Action Alternative, so the effect on hardhead occupying the Stanislaus River would likely be negligible.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the outside the 59°F to 64°F water temperature optimal range for hardhead spawning during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 868 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the outside the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 69 for Orange Blossom Bridge.

Results for these two analyses are summarized in Table O-105. Table O-105, as described in Section O.4.16.4, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 59°F to 64°F water temperature optimal range for hardhead spawning under Alternative 4, there was one month-water year type combination (6.7%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-105). For the 57.2°F to 78.8°F observed water temperature range for non-spawning adult hardhead, there were two month-water year type combinations (3.3%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge.

These results suggest that Alternative 4 would have negligible water temperature-related effects on native minnows in the Stanislaus River at Orange Blossom Bridge.

Summary

Utilizing the CalSim 3 flow analysis, Alternative 4 would have a negligible impact on hardhead in the Stanislaus River except for a few instances. Most notably, in dry water year types reduced flows in the Stanislaus River below Goodwin would have an adverse impact on hardhead under Alternative 4. However, based off the temperature analysis for the Stanislaus River the impact of temperature under Alternative 4 would be negligible. Given that the impact of temperature under Alternative 4 is negligible, but flow related impacts are just slightly negative, overall hardhead would likely have a negligible to a slightly adverse impact as compared to the No Action Alternative.

O.7.16.5 San Joaquin River

Sacramento Splittail, Hardhead, and Sacramento Hitch

- **Sacramento Splittail:** Historically, Sacramento splittail were widespread in the San Joaquin River and found upstream to Tulare and Buena Vista lakes, where they were harvested by native peoples (Moyle et al. 2004). Today, Sacramento splittail likely ascend the San Joaquin River to Salt Slough during wet years (Baxter 1999). During dry years, Sacramento splittail are uncommon in the San Joaquin River downstream of the Tuolumne River (Moyle et al. 2004).

  The population of Sacramento splittail is largely influenced by extent and period of inundation of floodplain spawning habitats, with abundance spiking following wet years and declining after dry years (Moyle et al. 2004).

- **Hardhead:** In the San Joaquin drainage, hardhead are present throughout tributary streams but are largely absent from the valley reaches of the San Joaquin River (Moyle et al. 2015, Moyle and Nichols 1973, Saiki 1984). Hardhead spawn mainly in April and May, but some may spawn as late as August in the foothill regions of the upper San Joaquin River (Wang 1986).

- **Sacramento Hitch:** Sacramento hitch historically occurred in low-elevation streams throughout the Sacramento and San Joaquin Valleys and in the Delta, but are now absent from the San Joaquin River and tributaries between Friant Dam and the Merced River (Moyle et al. 2015). Sacramento hitch are occasionally captured in low numbers in the lower San Joaquin River in the Mossdale trawl monitoring program (Interagency Ecological Program et al. 2022).

Potential Changes to Sacramento Splittail, Sacramento Hitch, and Hardhead from Seasonal Operations

During the December through May period for adult migration and spawning for average flows in the San Joaquin at Vernalis the CalSim 3 modeling results show that throughout the full simulation period flows are similar under Alternative 4 compared to the No Action Alternative. Under Alternative 4 average flows in the San Joaquin at Vernalis ranged from 2,890 cfs (December) to 6,451 cfs (February) (Table O-281). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 1% reduction (May) to a 1% increase (December) for the full simulation period and for months December through May

(Table O-281). Overall, flows are similar under Alternative 4 compared to the No Action Alternative, so the effect on native minnow spawning and migration would likely be negligible.

During all months, and for the full simulation period CalSim 3 estimates of mean monthly flows for the San Joaquin at Vernalis under Alternative 4 range from 1,434 cfs (August) to 6,451 cfs (February) (Table O-281). The difference in average flows under Alternative 4 compared to the No Action Alternative had a range from a 1% reduction (May) to a 3% increase (August) for the full simulation period, and all months (Table O-281). Presence of native minnows in the San Joaquin are not well known, but it is likely that many species are present year-round. Overall, flows are similar under Alternative 4 compared to the No Action Alternative, so the effect on native minnow occupying the San Joaquin River would likely be negligible.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on native minnows in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Based off the CalSim 3 flow analysis flows under Alternative 4, differences in predicted flows are minimal. Given that differences in predicted CalSim 3 flows are minor, the impact of seasonal operations for Alternative 4 as compared to the No Action Alternative would likely be negligible. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.7.16.6 Bay-Delta

Hardhead, Sacramento Hitch, and Sacramento Splittail

- **Hardhead:** The extant range of hardhead includes the Sacramento–San Joaquin River Basin, and are present in low abundance in the San Francisco Estuary and Delta. Brown and Michniuk (2007) electrofished parts of the Bay-Delta in the 1980's and 2000's and captured small numbers of hardhead. Retrieval of hardhead at the SWP/CVP south Delta fish salvage facilities remain relatively low (California Department of Water Resources 2020:4-62).
- **Sacramento Hitch:** The species is distributed in the Sacramento River Basin, in low numbers in the San Joaquin River Basin, and occasionally captured during monitoring programs in the Delta (Moyle et al. 2015; Interagency Ecological Program et al. 2022). Monitoring data suggests year round presence in the Delta (Interagency Ecological Program et al. 2022).
- **Sacramento Splittail:** Adult Sacramento splittail typically migrate upstream from brackish areas in January and February and spawn in freshwater, particularly on inundated floodplains when they are available, in March and April (Sommer et al. 1997; Moyle et al. 2004; Sommer et al. 2008). A substantial amount of splittail spawning occurs in the Yolo and Sutter Bypasses and the Cosumnes River area of the Delta (Moyle et al. 2004).

Although juvenile Sacramento splittail are known to rear in upstream areas for a year or more (Baxter 1999), most move to the Delta after only a few weeks or months of rearing in floodplain habitats along the rivers (Feyrer et al. 2006). Juveniles move downstream into the Delta from April to August (Meng and Moyle 1995; Feyrer et al. 2005). Sacramento splittail recruitment is largely limited by extent and period of inundation of floodplain spawning habitats, with abundance observed to spike following wet years and dip after dry years (Moyle et al. 2004).

Potential Changes to Sacramento Splittail, Sacramento Hitch, and Hardhead from Seasonal Operations

CalSim 3 Flows

For many species of native minnow, it has been shown that changes in export flows can lead to higher levels of entrainment which can potentially influence population dynamics. Certain species such as Sacramento splittail are known to utilize the Delta for many portions of their life history so flows into the Delta will have a strong effect on these fish by limiting habitat, prey availability and access to spawning areas. Since many native minnows occupy the Delta year-round, flows and exports were examined for all months of the year.

During all months and for the full simulation period, CalSim 3 estimates of average Delta outflow would be similar under Alternative 4 compared to the No Action Alternative. CalSim 3 estimates of average Delta outflow for all months have a range from 3,870 cfs (August) to 58,501 cfs (February) for Alternative 4 and for the full simulation period (Table O-272). Differences in average outflow under Alternative 4 as compared to the No Action Alternative would be from a 6% reduction (May) to a 6% increase (December) for the full simulation period and all months (Table O-272). Overall, flows are similar under Alternative 4 compared to the No Action Alternative, so the effect on native minnows in the Delta would be likely be negligible.

CalSim 3 estimates of mean monthly average flow for the total exports of SWP and CVP under Alternative 4 for the full simulation period, and all months, range from 5,171 cfs (April) to 8,215 cfs (February) (Table O-271). The range of average export flow difference under Alternative 4 compared to the No Action Alternative for the full simulation period, and all months, were from a 12% reduction in exports (December) to a 25% increase in exports (May) (Table O-271). Overall, average export flows are similar for Alternative 4 compared to the No Action Alternative, but substantial increases in exports would occur during a crucial period for native minnows spawning and migration. With increased average export flows for the months of April/May and for all water year types, entrainment would likely increase under Alternative 4, having a negative effect on native minnow populations as compared to the No Action Alternative.

Summary

Utilizing the CalSim 3 predicted flow analysis, Alternative 4 would have similar predicted Delta outflow as compared to the No Action Alternative. Since differences in Delta outflow are minor, the impact of outflow on native minnows would likely be negligible. However, while average export flows are similar for Alternative 4 compared to the No Action Alternative, substantial increases in exports would occur during a crucial period for native minnows spawning and migration. With increased average export flows for the months of April/May and for all water

year types, entrainment would likely increase under Alternative 4, having an adverse impact on native minnows when compared to the No Action Alternative.

Potential Changes to Entrainment of Sacramento Splittail, Sacramento Hitch, and Hardhead

Sacramento Splittail: Salvage Density

Predictions from the salvage density model for Sacramento splittail include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of Sacramento splittail at SWP Banks Pumping Plant for all months of the year and all water year types Alternative 4 was greater than predicted average monthly loss under the No Action Alternative for all but below normal water year types, with up to 62% higher for above normal water year types and 1% lower for below normal water year types (Table O-106). Predicted average monthly loss of Sacramento splittail at CVP Jones Pumping Plant for all months of the year and all water year types Alternative 4 was higher than predicted average monthly loss under the No Action Alternative for all water year types except for dry water year types. For all water year types Alternative 4 as compared to the No Action Alternative at Jones had a range from up to 3% higher for below normal water year types to 11% lower for dry water year types, it should also be noted that in critically dry water year types predicted loss only occurred for 6 months of the year (Table O-107). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Sacramento Hitch: Salvage Density

Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of Sacramento hitch at SWP Banks Pumping Plant for all months of the year and all water year types, Alternative 4 was higher than predicted average monthly loss under the No Action Alternative for all water year types except for dry water year types, there was no predicted loss for critically dry water year types. Predicted average monthly loss at Banks under Alternative 4 had a range from 4% lower for dry water year types to 177% higher for above normal water year types (Tables O-110). Predicted average monthly loss of Sacramento hitch at CVP Jones Pumping Plant for the months of March through April and all water year types Alternative 4 was equal or higher than predicted average monthly loss under the No Action Alternative. The range of predicted loss for Sacramento hitch at Jones under Alternative 4 compared to the No Action Alternative was from 0% in above normal water year types to 12% higher for wet water year types, no fish were predicted to be lost in dry and critically dry water year types. It should be noted that loss of Sacramento hitch at both facilities is rare and infrequent, with such low values of predicted loss, the percent differences may not be representative. (Table O-111). For detailed information on average monthly loss by water year type, see Attachment I.2, *Salvage Density Model Loss Simulation*.

Hardhead: Salvage Density

Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Whereas at the CVP Jones Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of hardhead of Alternative 4 compared to the No Action Alternative at SWP Banks Pumping Plant was greater all water year types, except in below normal and dry water year types when no fish are expected (Tables O-108 and O-109). At the SWP Banks Pumping Plant predicted average monthly loss was between 8% and 177% greater in September of critically dry water years and April of above normal water year, respectively (Table O-108). Historical loss of hardhead at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Summary

With higher exports for most months and water year types, higher levels of entrainment are predicted. While there are a few instances where predicted loss would be lower, most water year types and months have higher predicted loss for native minnows at both facilities for Alternative 4 as compared to the No Action Alternative.

O.7.17 Pacific Lamprey

O.7.17.1 Trinity River

Spawning and Egg Incubation

Pacific lamprey typically spawn from March through June, when daily mean water temperatures range from 50–64°F, with peak spawning occurring typically occurring in April and May and when water temperatures are approximately 57–59°F (Stone 2006, Brumo et al. 2009). Redds are typically constructed in gravel and cobble substrates within pool and run tailouts and low gradient riffles (Stone 2006, Brumo et al. 2009). Eggs are deposited in the redd and hatch after approximately 15 days, depending on water temperatures (Meeuwig et al. 2005, Brumo 2006). Egg-sac larvae spend another 15 days in redds before emergence. Water temperatures in excess of 65°F during incubation have been shown to reduce embryo survival (Meeuwig et al. 2005). The effects analysis period for spawning and egg incubation in the Trinity River is March through July.

Potential Changes to Pacific Lamprey from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 4 to flows under the No Action Alternative during spawning and egg incubation periods for Pacific lamprey. Differences in monthly average flows between Alternative 4 and the No Action Alternative greater than 5% in reduction of flows would occur in March of wet years (Table O-264). Under Alternative 4 compared to the No Action Alternative, flow decreases would occur during the Pacific lamprey spawning and egg incubation period. The reduction in flows in wet years would likely be negligible for spawning habitat and egg incubation as flows would remain above 1,881 cfs.

The flow decreases in March in below wet water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative. Modeled monthly average water temperatures under Alternative 4 would remain well below the upper water

temperature suggested for Pacific lamprey spawning and egg incubation of 65°F in the reach from Lewiston Dam to the North Fork Trinity River (Asarian et al. 2023).

Ammocoete Rearing and Emigration

After emergence from redds, eyeless Pacific lamprey larvae, known as ammocoetes, settle out of the water column and burrow into fine silt and sand substrates, often containing organic matter. Ammocoetes rear in these habitats for 4–10 years. Water temperature requirements for the life stage are not well described. Ammocoetes have been observed burrowed in substrates in streams with water temperatures up to 80°F (Claire 2004), and upper temperature tolerances are estimated to be around 83°F (Whitesel and Uh 2022). After Pacific lamprey metamorphose to the macropthalmia stage, individuals migrate to the ocean typically in conjunction with high flow events between fall and spring, but can occur year-round. The effects analysis period for ammocoete rearing is year-round and emigration is primarily fall through spring in the Trinity River

Potential Changes to Pacific Lamprey from Seasonal Operations

Under Alternative 4, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (Table O-264). The reduction in flows could have minor adverse impacts in the reduction of rearing habitat, and reduced flows during peak emigration periods in December of below normal years as flows decrease from 931 to 816 cfs. Alternative 4 monthly average flows will have negligible to minor adverse impacts on ammocoete rearing and emigration of Pacific lamprey when compared to the No Action Alternative.

The flow decreases in February and March of wet water years, November of above normal water years, and December of below normal water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam but there would be no substantial differences relative to the No Action Alternative. Modeled monthly average water temperatures under Alternative 4 would remain well below the upper water temperature threshold for Pacific lamprey ammocoete and emigration of 83°F in the reach from Lewiston Dam to the North Fork Trinity River (Asarian et al. 2023).

Adult Upstream Migration and Holding

Adult Pacific lamprey typically enter freshwater from winter to early summer, but in the Klamath River adults have been reported to enter year-round (Petersen Lewis 2009, Parker 2018). In general, adult Pacific lampreys have two life history types: ocean maturing where individuals likely spawn several weeks after entering freshwater, and stream maturing where individuals spend one year in freshwater prior to spawning (Clemens et al. 2013, Parker et al. 2019). In general, adult Pacific lamprey hold in interstitial spaces within large cobble and boulders and also in glides, runs, and riffles (Lampman 2011). Water temperature requirements for holding adult Pacific lampreys have not been fully evaluated, but adults have been observed in temperatures ranging from 60 to 84°F (Starcevich et al. 2014). The effects analysis period for adult upstream migration and holding in the Trinity River is year-round.

Potential Changes to Pacific Lamprey from Seasonal Operations

Under Alternative 4, monthly average flows would be similar or have greater than 5% reduction in flows compared to the No Action Alternative during February and March in wet years, November in above normal years, and December in below normal years (Table O-264). The reduction in flows in winter would likely have minor adverse impacts on the adult upstream migration as flows would remain above 1,726 cfs in wet years in February and March, and 816 cfs in below normal years in December. Alternative 4 monthly average flows will have minor adverse to negligible impacts on adult upstream migration and holding of Pacific lamprey when compared to the No Action Alternative.

The flow decreases in February and March of wet water years, November of above normal water years, and December of below normal water years may result in negligible changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam. Modeled monthly average water temperatures under Alternative 4 would remain well below the upper water temperature threshold for Pacific lamprey adult upstream migration and holding of 84°F in the reach from Lewiston Dam to the North Fork Trinity River (Asarian et al. 2023).

O.7.17.2 Sacramento River

Spawning and Egg Incubation

Pacific lamprey construct redds in shallow water (about 0.5 to 3.5 feet or 0.15 to 1 meter) gravel habitats in the upper river and spawning occurs from March through July with peak spawning typically occurring in early April (Gunckel et al. 2009; Schultz et al. 2014; Moyle et al. 2015). The eggs and pro-larvae incubate for about 30 to 45 days. Water flows and temperature impacts on eggs are March-August but are largely April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

<u>CalSim 3 Flows</u>

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam are largely similar to those under the No Action Alternative (Table O-266 and Table O-267). Impacts on Pacific lamprey spawning and egg incubation are expected to be minimal. Flows are almost unchanged at both locations from those under the No Action Alternative. The greatest changes in the spawning period are several flow decreases in critically dry years. However, flows are expected to remain high enough that redds should not face dewatering, and spawning and egg incubation will likely not see any serious adverse impacts. Most of these critically dry decreases come in months with more robust flows, compared to others that have weaker flow but see little change. While minor adverse impacts are possible in critically dry years, survival should not be affected and overall impacts across water-year types are expected to be minimal.

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities for Pacific lamprey during April through August are presented in Attachment L.1,

Sacramento River Water Temperature Analysis, Table 295 for Keswick Dam and Table 296 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-112. Table O-112, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were zero and one month-water year type combinations (0% and 4.0% of total combinations during the period, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-112). There were no combinations (0%) with unfavorable results at both Keswick Dam and RBDD. These results suggest that there would be negligible water temperature-related impacts of Alternative 4 on Pacific lamprey spawning and egg incubation in the Sacramento River.

Summary

Alternative 4 is expected to have minor adverse impacts on Pacific lamprey spawning and egg incubation relative to the No Action Alternative. Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey spawning and egg incubation in the Sacramento River.

Ammocoete Rearing and Emigration

After Pacific lamprey larvae (ammocoetes) emerge, they drift downstream and burrow into fine sediments to rear. Ammocoetes select habitats that are often off-channel, with low flow velocity and shallow depths; therefore, they are vulnerable to stranding by reductions in water level. After three or more years, the ammocoetes metamorphose to the macropthalmia (juvenile) stage and migrate downstream to the Delta and ocean. Data from rotary screw trapping at sites on the mainstem Sacramento River indicate that emigration of Pacific lamprey peaks from early winter through early summer, but some emigration is observed year-round at both the RBDD and the GCID diversion dam (Hanni et al. 2006).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Redd Bluff Diversion Dam and below Keswick Dam are mostly similar to those under the No Action Alternative (Table O-266 and Table O-267). Impacts on Pacific lamprey ammocoete rearing and emigration are likely to be minimal. Ammocoete rearing could see some minor adverse impacts in critically dry years, as flows decrease in some spring and summer months, but flow values are expected to remain high enough that survival should not be threatened. Increases in some fall and winter months could have slight beneficial impacts. Overall, ammocoete rearing would likely see some minimal beneficial and adverse impacts compared to the No Action Alternative. Juvenile emigration is likely to also see minimal impacts from flow changes under Alternative 4. Some slight flow increases in fall and winter months could have minimal beneficial impacts during the emigration period, but flows are largely similar to those under the No Action Alternative, and overall impacts are expected to be minimal.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific Lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 298 for Keswick Dam and Table 299 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-113. Table O-113, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results at both Keswick Dam and RBDD (Table O-113). These results suggest that there would be negligible water temperature-related impacts of Alternative 4 on Pacific lamprey ammocoete rearing and emigration in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration in the Sacramento River due to differences in water temperatures.

O.7.17.3 Clear Creek

Spawning and Egg Incubation

Pacific lamprey usually spawn in Clear Creek from March through July, depending on water temperatures and local conditions such as seasonal flow regimes. The adults construct redds similar to steelhead redds, and eggs incubate for 11 to 30 days, depending on the water temperature, prior to hatching. Although the extent of spawning is unknown, the species spawns in Clear Creek as evidenced by ammocoetes routinely collected in the screw trap at RM 1.7. Effects from water flows and temperature on eggs are likely felt March-August, and they likely peak in accordance with peak spawning April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in Clear Creek below Whiskeytown Dam under Alternative 4 would see a mix of increases and decreases compared to the No Action Alternative depending on month and water year type (Table O-275). Impacts of these flow changes on Pacific lamprey spawning would likely be mixed, with beneficial impacts from flow increases during the peak spawning period in March, April and May, and adverse impacts from flow decreases at the beginning and end of the spawning period during some or all water year types for February and June through August.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities for Pacific lamprey during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 288 for Clear Creek below Whiskeytown Dam.

Results for the analysis are summarized in Table O-114. Table O-114, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 50°F to 64°F observed range of high survival and low occurrence of embryonic developmental abnormalities, there were five month-water year type combinations (20.8% of total combinations during the period) with favorable results and no combinations (0%) with unfavorable results below Whiskeytown Dam (Table O-114). These results suggest that there would be positive water temperature-related impacts of Alternative 4 on Pacific lamprey spawning and egg incubation in Clear Creek.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial to adverse impacts on Pacific lamprey spawning and egg incubation due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have beneficial impacts on Pacific lamprey spawning and egg incubation in Clear Creek due to differences in water temperatures.

Ammocoete Rearing and Emigration

Pacific lamprey rearing takes place over a matter of years. Hatched embryos remain in the gravel for up to one more month as gill slits develop. The ammocoetes then spend three to seven years in soft sediments as filter feeders (USFWS 2019). Once ammocoetes have become juveniles, they begin to migrate towards the ocean in spring and possibly early summer. Effects from water temperature and flow on larval and juveniles are year-round due to their prolonged rearing in their home waters, with spring and summer flows during migratory periods being important as well.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in Clear Creek below Whiskeytown Dam under Alternative 4 would see a mix of increases and decreases compared to the No Action Alternative (Table O-275). Impacts on Pacific lamprey ammocoete rearing would likely be mixed, as rearing takes place over several years, and positive impacts during months and water years with increased flows would likely be balanced by negative impacts from those months and water year types with decreased flows. Juvenile emigration for Pacific lamprey would likely see some beneficial impacts under Alternative 4, as flows generally increase during the peak outmigration period in winter and spring months, with the exception of February, which sees flow decreases in wet, above normal, and below normal years.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific Lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 291 for Clear Creek below Whiskeytown Dam.

Results for the analysis are summarized in Table O-115. Table O-115, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results below Whiskeytown Dam (Table O-115). These results suggest that there would be negligible water temperature-related impacts of Alternative 4 on Pacific lamprey ammocoete rearing and emigration in Clear Creek.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial to adverse impacts on Pacific lamprey ammocoete rearing, and beneficial impacts on Pacific lamprey juvenile emigration. Differences in Alternative 4 is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration in Clear Creek due to differences in water temperatures.

O.7.17.4 Lower American River

Spawning and Egg Incubation

Hannon and Deason (2008) documented Pacific lamprey spawning in the lower American River from early January to late May, with peak spawning typically occurring in early April. Redds are built in shallow water environments and eggs incubate for several weeks before larvae emerge. Water temperature and flow impacts on eggs are likely January-June, with peak impacts April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the lower American River at H Street and below Nimbus Dam under Alternative 4 would see a mix of small increases and decreases compared to the No Action Alternative (Table O-277 and Table O-278). Impacts on Pacific lamprey spawning would likely be relatively minor, as few months see large changes (up to 14% increase below Nimbus) in flow compared to the No Action Alternative. The largest impacts would likely be during the middle of the spawning period in critically dry years, with March and April having the some of the largest relative decreases and would likely see the greatest adverse impacts. Generally, however, flow changes are fairly small in scope and are a mix of increases and decreases, so

overall impacts on spawning from changes due to Alternative 4 would likely be mixed beneficial and adverse depending on month and water year type, but largely minimal.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities during March through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 79 for Hazel Avenue and Table 80 for Watt Avenue.

Results for the analysis are summarized in Table O-116. Table O-116, as described in Section O.4.17.4.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities for Pacific lamprey spawning and egg incubation under Alternative 4, there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at both Hazel Avenue and Watt Avenue (Table O-116). There were three and one month-water year type combinations (12.0% and 4.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that Alternative 4 would have positive (4% favorable) and negative (4% to 12% unfavorable) water temperature-related impacts to Pacific lamprey spawning and egg incubation in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial to adverse impacts on Pacific lamprey spawning and egg incubation in the lower American River due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have beneficial and adverse impacts on Pacific lamprey spawning and egg incubation in the lower American River due to differences in water temperatures.

Ammocoete Rearing and Emigration

Pacific lamprey ammocoetes rear in the lower American River for all or part of their 3- to 7-year freshwater residence. Larvae spend a month maturing to ammocoetes before leaving spawning areas to find suitable rearing habitat, usually shallow, off-channel areas with low flow velocity where they will spend the next several years filter-feeding and maturing to juvenile stage. Once juveniles, they will begin migrating towards the ocean. Data from rotary screw trapping in the nearby Feather River suggest that out-migration of Pacific lamprey generally occurs from early winter through early summer (Hanni et al. 2006), although some out-migration likely occurs year-round, as observed at sites on the mainstem Sacramento River (Hanni et al. 2006) and in other river systems (Moyle 2002).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the lower American River at H Street and below Nimbus Dam under Alternative 4 would see a mix of increases and decreases compared to the No Action Alternative (Table O-277 and Table O-278). Impacts on Pacific lamprey ammocoete rearing are likely to be mixed as well, but overall minimal. As rearing takes place over a period of several years, ammocoetes are subject to the range of flow increases and decreases, but as they are predicted to largely be small in scope, rearing would likely not see many beneficial or adverse impacts. Decreased flows in some months of critically dry water years (up to 23% below Nimbus) could have an adverse impact on ammocoete rearing, especially since ammocoetes spend this period buried in off-channel pools that could be at risk of drying out in critically dry years, but the risk of this is difficult to assess. Impacts on Pacific lamprey juvenile emigration are likely to be mixed as well, depending on water year type, but are likely to be similarly minimal due to the small increases and decreases that characterize the months in the winter-early summer emigration window.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 48 for Hazel Avenue and Table 50 for Watt Avenue.

Results for the analysis are summarized in Table O-117. Table O-117, as described in Section O.4.17.4.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific lamprey ammocoete rearing and emigration under Alternative 4, there were zero and two month-water year type combinations (0.0% and 3.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-117). There were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 4, there would be positive (3.3% favorable) and negative (1.7% unfavorable) water temperature-related impacts to Pacific lamprey ammocoete rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial to adverse impacts on Pacific lamprey ammocoete rearing and emigration due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have positive and negative impacts on Pacific lamprey ammocoete rearing and emigration in the lower American River due to differences in water temperatures.

O.7.17.5 Stanislaus River

Spawning and Egg Incubation

Hannon and Deason (2008) have documented Pacific lampreys spawning in the lower American River from early January to late May, with peak spawning typically in early April. Spawning time is presumably similar in the Stanislaus River. Eggs are laid in redds constructed in shallow water, and incubation takes several weeks. Effects from water flows and temperature on eggs are present February-June, likely with a peak April-May.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Stanislaus River at the mouth and below Goodwin Dam under Alternative 4 will see a mix of increases and decreases relative to the No Action Alternative depending on month and water year type (Table O-279 and Table O-280). Impacts on Pacific lamprey spawning at the mouth would likely be minimal, as the relative flow changes are predicted to be fairly small, and the flow increases and decreases over the spawning period relative to the No Action Alternative impact. Below Goodwin Dam, impacts on Pacific lamprey spawning would likely be slightly adverse, as flows generally decrease during the peak spawning period of April and May, with some flows decreasing in March and June.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities during April through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 62 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-118. Table O-118, as described in Section O.4.17.5, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 with TUCP without VA for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities of Pacific lamprey, there were no month-water year type combinations (0.0%) with favorable or unfavorable results at both Orange Blossom Bridge and above the confluence of the San Joaquin River (Table O-118).

These results suggest that Alternative 4 would have negligible water temperature related impacts on Pacific lamprey spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

Alternative 4 relative to the No Action Alternative is expected to have minor adverse impacts on Pacific lamprey spawning and egg incubation due to flow differences. Alternative 4 relative to the No Action Alternative is expected to have negligible water temperature-related impacts on Pacific lamprey spawning and egg incubation in the Stanislaus River.

Ammocoete Rearing and Emigration

Pacific lamprey ammocoetes are expected to rear in the Stanislaus River for all or part of their three- to seven-year freshwater residence. Larvae usually spend a month in their spawning areas before becoming ammocoetes and moving to rearing habitat in shallow, off-channel areas. After several years, they become juveniles and migrate out to the ocean. Data from rotary screw trapping in the nearby Mokelumne and Tuolumne Rivers suggest that out-migration of Pacific lamprey generally occurs from early winter through early summer (Hanni et al. 2006). Catches of juvenile Pacific lampreys in trawl surveys of the mainstem San Joaquin River, near the mouth of the Stanislaus River at Mossdale, occurred during winter and spring. Some out-migration likely occurs year-round, as observed at sites on the mainstem Sacramento River (Hanni et al. 2006).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Stanislaus River at the mouth and below Goodwin Dam under Alternative 4 will see a mix of increases and decreases relative to the No Action Alternative depending on month and water year type (Table O-279 and Table O-280). Impacts on Pacific lamprey ammocoete rearing are likely to be mixed, with flow increases and decreases with their accompanying impacts but are likely adequate for this life stage. Impacts on juvenile emigration are similarly likely to be mixed. Flow increases in some winter months during the early part of the outmigration period; flows then see some decreases in spring months during the later part of the emigration period.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 63 for Orange Blossom Bridge and Table 64 for the Stanislaus River above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-119. Table O-119, as described in Section O.4.17.5, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Pacific lamprey, there were no month-water year type combinations (0.0%) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-119). There were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 4 would have negligible water temperature related impacts on Pacific lamprey ammocoete rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial to adverse impacts on Pacific lamprey ammocoete rearing and emigration due to flow differences. Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on Pacific lamprey ammocoete rearing and emigration in the Stanislaus River due to water temperature differences.

O.7.17.6 San Joaquin River

Ammocoete Rearing and Emigration

Pacific lamprey larvae, once emerged, spend roughly a month in spawning areas before becoming ammocoetes and moving to rearing habitat in shallow, off-channel waters with low flow velocity, where they will spend the following several years (roughly three to seven) maturing to the juvenile stage. Once juveniles, they begin a migration towards the ocean. Midwater trawl surveys in the San Joaquin River suggest that peak ammocoete out-migration occurs in January and February (Hanni et al. 2006). Ammocoetes are vulnerable to habitat loss due to the nature of their rearing habitat.

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 models predict that flows in the San Joaquin River at Vernalis under Alternative 4 will see a mix of increases and decreases relative to the No Action Alternative. Impacts from changes in flow on ammocoete rearing would likely be minimal (Table O-281). Slightly increased flows in summer months of critically dry water years would likely have some small beneficial impacts on the success of ammocoete rearing, though the extent of these impacts is difficult to determine. Flow changes under Alternative 4 compared to the No Action Alternative would likely have minimal impact on juvenile emigration, as flows see little change during the winter and spring months when outmigration is at its peak.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on Pacific lamprey in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 4 relative to the No Action Alternative are expected to have beneficial impacts on Pacific lamprey ammocoete rearing and emigration in the San Joaquin River due to differences in flow. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.7.17.7 Bay-Delta

Some Pacific lamprey ammocoetes likely spend part of their extended (3 to 7 years) freshwater residence rearing in the Delta, particularly in the upstream, freshwater portions (California Department of Water Resources et al. 2013). Ammocoetes are present year-round in all of the regions (California Department of Water Resources et al. 2013). Data from the Fall Midwater Trawl Survey in the lower Sacramento and San Joaquin Rivers and Suisun Bay suggest that peak out-migration of Pacific lamprey through the Delta coincides with high-flow events from fall

through spring (Hanni et al. 2006).Water temperature and flows affect resident ammocoetes year round and migrating juveniles fall-spring. Duration of estuarine adult migration and holding in the San Francisco Estuary is poorly understood, but some evidence suggests they may migrate as early as the fall and throughout the spawning season until late June (Moyle et al. 2015).

Potential Changes to Pacific Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Sacramento River at Rio Vista under Alternative 4 would see a mix of increases and decreases compared to the No Action Alternative (Table O-274). For impacts in the southern Delta, see the San Joaquin River section above, which discusses flow at Vernalis. Under Alternative 4, flows at Rio Vista would see a mix of increases and decreases but would be relatively unchanged compared to the No Action Alternative. Impacts on Pacific lamprey ammocoete rearing would likely be negligible, as flows are likely adequate for rearing. Impacts on juvenile emigration and adult migration would be beneficial in April of critically dry water year types.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial impacts on Pacific lamprey juvenile emigration and adult migration in April of critically dry water year types due to differences in flow. Impacts on ammocoete rearing are expected to be negligible.

Potential Changes to Entrainment of Pacific Lamprey

Salvage Density

Predictions from the salvage density model for Pacific lamprey include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for the alternatives, predicted average monthly loss of Pacific lamprey of Alternative 4 compared to the No Action Alternative at CVP Jones Pumping Plant were almost equal in all water year types (Tables O-120 and O-121). Historical loss of Pacific lamprey is infrequent; this is a driver of low values of predicted loss.

Summary

Alternative 4 and the No Action Alternative are expected to have similar impacts on the entrainment of Pacific lamprey at CVP Jones Pumping Plant, but the species is infrequent at the facility. No impacts at the SWP Banks Pumping Plant are expected.

O.7.18 Western River Lamprey

O.7.18.1 Sacramento River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April-May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Red Bluff Diversion Dam and below Keswick Dam are largely similar to those under the No Action Alternative (Table O-266 and Table O-267). Impacts on Western River lamprey spawning and egg incubation are expected to be minimal. Flows under Alternative 4 are largely the same as those under the No Action Alternative. The greatest changes in the spawning period are several flow decreases in critically dry years. However, flows are expected to remain high enough that redds should not face dewatering, and spawning and egg incubation will likely not see any serious adverse effects. Most of these critically dry decreases come in months with more robust flows, compared to others that have weaker flow but see little change. While slight adverse impacts are possible in critically dry years, survival should not be affected and overall impacts across water-year types are expected to be minimal due to the similarity to the flows of the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Western river lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 304 for Keswick Dam and Table 305 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-122. Table O-122, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 50°F to 64°F observed range of high survival and low occurrence embryonic developmental abnormalities, there was one and zero month-water year type combinations (3.3% and 0%, respectively) with favorable results at Keswick Dam and RBDD, respectively (Table O-122). There were no month-water year type combinations with unfavorable results at Keswick Dam and RBDD. These results suggest that there would be negligible water temperature-related impacts of Alternative 4 on Western River lamprey spawning and egg incubation in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible to minor adverse impacts on Western River lamprey spawning and egg incubation due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have negligible water-temperature-related impacts on Western River lamprey spawning and egg incubation in the Sacramento River.

Ammocoete Rearing and Emigration

Western river lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the Sacramento River below Redd Bluff Diversion Dam and below Keswick Dam are mostly similar to those under the No Action Alternative (Table O-266 and Table O-267). Impacts on Western River lamprey ammocoete rearing and emigration are likely to be minimal. Ammocoete rearing could see some minor adverse effects in critically dry years, as flows decrease in some spring and summer months, but flow values are expected to remain high enough that survival should not be threatened. Minor increases in some fall and winter months could have slight beneficial impacts. Overall, ammocoete rearing would likely see some minimal beneficial and adverse impacts compared to the No Action Alternative. Western River lamprey juvenile emigration is likely to also see minimal impacts from flow changes under Alternative 4. Some slight flow increases in fall and winter months during the emigration period could have minimal beneficial impacts during the emigration period, but flows are largely similar to those under the No Action Alternative, and overall impacts are expected to be minimal.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Western river lamprey year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 304 for Keswick Dam and Table 305 for Red Bluff Diversion Dam.

Results for the analysis are summarized in Table O-123. Table O-123, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 72°F observed range of high survival and low occurrence of developmental abnormalities, there were no month-water year type combinations (0% of total combinations during the period) with favorable and unfavorable results at both Keswick Dam and RBDD (Table O-123). These results suggest that there would be negligible water temperature-related impacts of Alternative 4 on Western river lamprey ammocoete rearing and emigration in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible to minor beneficial impacts on Western River lamprey ammocoete rearing and emigration due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on Western River lamprey ammocoete rearing and emigration in the Sacramento River due to differences in water temperatures.

O.7.18.2 Lower American River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April-May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates of monthly flows in the lower American River at H Street and below Nimbus Dam for Alternative 4 are somewhat similar to the No Action Alternative (Table O-277 and Table O-278). Impacts on Western River lamprey spawning are likely to be fairly small in scope due to there being little change for many months. The greatest impacts are likely to be in critically dry years (up to 23% below Nimbus), which see flow decreases in the majority of months. These decreases could have an adverse impact in March, April, and August, which would affect the beginning and end of the spawning period. While Alternative 4 would see increased flows for some water year types in April, May, and July, these would likely not have a great impact on spawning. Thus, the overall impact on spawning is likely to be slightly adverse due to the slight flow decreases in critically dry years.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in Western river lamprey during February through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 83 for Hazel Avenue and Table 84 for Watt Avenue.

Results for the analysis are summarized in Table O-124. Table O-124, as described in Section O.4.18.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in western river lamprey spawning and egg incubation under Alternative 4, there were zero and three month-water year type combinations (0.0% and 10.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-124). There were three and one month-water year type combinations (10.0% and 3.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 4, there would be positive (10% favorable) and negative (3.3% to 10% favorable) water temperature-related impacts to Western River lamprey spawning and egg incubation in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial to adverse impacts on spawning and egg incubation. Alternative 4 relative to the No Action Alternative is expected to have beneficial and adverse water-temperature-related impacts on Western River lamprey spawning and egg incubation in the lower American River.

Ammocoete Rearing and Emigration

Western River lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates for monthly flows in the lower American River at H Street and below Nimbus Dam for Alternative 4 are somewhat similar to the No Action Alternative (Table O-277 and Table O-278). Impacts on Western River lamprey ammocoete rearing are likely to be slightly adverse, as flows decrease in many months of critically dry years. While these decreases are not large, they happen at the most vulnerable times for ammocoetes, when conditions are driest. Impacts of flow changes from Alternative 4 on Western River lamprey juvenile emigration are likely to be minimal, as flows are fairly similar to those under the No Action Alternative. While flows do decrease in critically dry years compared to the No Action Alternative which has the potential to adversely affect emigration in the winter-early summer window, these decreases are relatively small and will likely not adversely affect emigration much more than flows under the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities in Western river lamprey year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 85 for Hazel Avenue and Table 86 for Watt Avenue.

Results for the analysis are summarized in Table O-125. Table O-125, as described in Section O.4.18.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 72°F upper limit for high survival and low occurrence of developmental abnormalities in Western river lamprey ammocoete rearing and emigration under Alternative 4, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-125). There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

These results suggest that under Alternative 4, there would be negligible water temperature-related impacts to Western River lamprey ammocoete rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible to minor adverse impacts on Western River lamprey ammocoete rearing and emigration due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have negligible water temperature-related impacts on Western River lamprey ammocoete rearing and emigration in the lower American River.

O.7.18.3 Stanislaus River

Spawning and Egg Incubation

The life history of river lamprey is understudied, especially in California (Moyle et al. 2015). Spawning is believed to occur February through May in small tributary streams (Moyle 2002), with peak spawning thought to mirror that of Pacific lamprey and occur in April. Redds are built at the upstream end of small riffles (Moyle 2002), and eggs hatch typically after several weeks. Water flow and temperature impacts on eggs may occur February-July but are likely primarily April-May.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates of monthly flows in the Stanislaus River at the mouth and below Goodwin Dam for Alternative 4 compared to the No Action Alternative are a mix of increases and decreases (Table O-279 and Table O-280). Impacts on Western River lamprey spawning are likely to be similarly mixed. Flow decreases in some water year types from April through June would likely have some adverse impacts on spawning, as April and May are peak spawning months. However, flows are expected to increase during June through August in critically dry

years, which would likely be beneficial to spawning, possibly increasing spawning success and decreasing egg mortality. Overall, impacts from flow changes on spawning are likely to be mixed, with some adverse impacts in the peak spawning period but beneficial impacts in critically dry summers.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 50°F to 64°F observed range of high survival and low occurrences of embryonic developmental abnormalities in Western river lamprey during February through July are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 65 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-126. Table O-126, as described in Section O.4.18.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 50°F to 64°F observed range for high survival and low occurrences of embryonic developmental abnormalities of Western river lamprey, there were zero month-water year type combinations (0.0%) with favorable results and one combination (3.3%) with unfavorable results at Orange Blossom Bridge (Table O-126).

These results suggest that Alternative 4 would have negligible water temperature related impacts on Western River lamprey spawning and egg incubation in the Stanislaus River at Orange Blossom Bridge.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial to adverse impacts on Western River lamprey spawning and egg incubation due to differences in flow. Alternative 4 relative to the No Action Alternative is expected to have negligible water temperature-related impacts on Western River lamprey spawning and egg incubation in the Stanislaus River.

Ammocoete Rearing and Emigration

Western River lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 estimates of monthly flows in the Stanislaus River at the mouth and below Goodwin Dam for Alternative 4 compared to the No Action Alternative are a mix of increases and decreases (Table O-279 and Table O-280). Impacts on Western River lamprey ammocoete rearing are likely to be mixed as well, with decreased flows in some spring and early summer months (depending on water year type) but increased flows for some water year types in other months, and a number of months seeing flow increases in critically dry years. These increases in critically dry years could be very beneficial to ammocoete rearing, decreasing the risk of ammocoete mortality when flows are typically lowest. Impacts of flow changes on juvenile emigration are likely to be mixed as well. Flow changes are not substantial for most water year types during winter-early summer outmigration period. Flow increases during drier years in February, while flow decreases during some water years in April and January. Effects are therefore mixed, with some beneficial impacts and some adverse impacts.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 72°F upper limit for high survival and low occurrence of developmental abnormalities in Western river lamprey year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 66 for Orange Blossom Bridge and Table 67 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-127. Table O-127, as described in Section O.4.18.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 72°F upper limit for high survival and low occurrence of developmental abnormalities for Western River lamprey, there were no month-water year type combinations (0.0%) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River (Table O-127). There were zero and one month-water year type combinations (0.0% and 1.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 4 would have negligible water temperature related impact on Western River lamprey ammocoete rearing and emigration in the Stanislaus River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial to adverse impacts on Western River lamprey ammocoete rearing and emigration. Alternative 4 and the No Action Alternative is expected to have negligible water temperature-related impacts on Western River lamprey ammocoete rearing and emigration in the Stanislaus River.

O.7.18.4 San Joaquin River

Ammocoete Rearing and Emigration

Western River lamprey rearing takes place over multiple years. After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juveniles (macropthalmia) migrate downstream in the following year from May to July (Moyle 2002). Ammocoete presence for years after spawning means they are affected by water flow and temperature variations year-round, and juveniles are partially dependent on May-July flows to help their migration out of rearing territory.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 estimates for monthly flows in the San Joaquin River at Vernalis for Alternative 4 are largely unchanged compared to the No Action Alternative (Table O-281). Impacts on Western River lamprey ammocoete rearing are likely to be slightly beneficial. Increased flows during summer months of critically dry years would be beneficial and would decrease the risk of ammocoete habitat being dewatered, increasing success and survival. Otherwise, impacts on ammocoete rearing are likely to be minimal as flows are largely unchanged. Impacts on Western River lamprey juvenile emigration are likely to be minimal. Flows during the emigration period are mostly unchanged compared to the No Action Alternative, and there would be no impact on emigration.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on Western River lamprey in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

<u>Summary</u>

Alternative 4 relative to the No Action Alternative is expected to have beneficial impacts on Western River lamprey ammocoete rearing and emigration in the San Joaquin River due to differences in flow. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year and likely to have negligible impacts.

O.7.18.5 Bay-Delta

The Sacramento and San Joaquin River Basins are at the southern edge of the range for Western River lamprey (Moyle et al. 2009). While their population abundance is poorly understood, they are frequently caught in the Delta Juvenile Fish Monitoring Program in the winter months through trawls at Sherwood Harbor, Mossdale, and Chipps Island (Interagency Ecological Program et al. 2022). Ammocoetes spend an unknown amount of time as ammocoetes (likely 3-5 years) in silt-sand backwater eddies and have been documented during dredging studies in the Delta (Lamprey Technical Workgroup 2021; Moyle et al. 2015). Adults typically start their migration back into their natal habitats in the fall.

Potential Changes to Western River Lamprey from Seasonal Operations

CalSim 3 Flows

CalSim 3 models predict that flows in the Bay-Delta under Alternative 4 would see a mix of increases and decreases compared to the No Action Alternative (Table O-274). For impacts in the southern Delta, see the San Joaquin River section above, which discusses flow at Vernalis. Under Alternative 4, flows at Rio Vista would see a mix of increases and decreases but would be relatively unchanged compared to the No Action Alternative. Similar to Pacific lamprey, impacts on Western river lamprey ammocoete rearing would likely be negligible, as flows are likely adequate for rearing. Impacts on juvenile emigration would be beneficial in April of critically dry water year types. Impacts on adult migration would be negligible, as flows are similar (less than a 5% difference) throughout the fall of critically dry water year types.

Summary

Alternative 4 relative to the No Action Alternative is expected to have beneficial impacts on Western river lamprey juvenile emigration in April of critically dry water year types and negligible impacts on adult migration due to differences in flow. Impacts on ammocoete rearing is expected to be negligible.

Potential Changes to Entrainment of Western River Lamprey

Salvage Density

Predictions from the salvage density model for Western River lamprey include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Whereas at the SWP Banks Pumping Plant no loss was anticipated for any water year types for any alternative, predicted average monthly loss of Western River lamprey of Alternative 4 compared to the No Action Alternative at CVP Jones Pumping Plant was minor in all water year types, except in dry water year types when no fish are expected (Tables O-128 and O-129). At the CVP Jones Pumping Plant predicted average monthly loss was up to 3% greater in February through March of critically dry water year types and as low as -3% less in January of below normal water year types (Table O-129). Historical loss of Western river lamprey is infrequent; this is a driver of low values of predicted loss.

Summary

Alternative 4 relative to the No Action Alternative is expected to have adverse and beneficial impacts on the entrainment of Western river lamprey at CVP Jones Pumping Plant due to differences in exports, but the species is infrequent at the facility. No impacts at the SWP Banks Pumping Plant are expected.

O.7.19 Striped Bass

O.7.19.1 Sacramento River

Spawning and Egg Incubation

It is believed that striped bass do not spawn or rear in the Sacramento River upstream of RBDD (Tehama-Colusa Canal Authority 2008). Most spawning in the Sacramento River occurs in the lower river between Colusa and the confluence of the Sacramento and Feather Rivers (Moyle 2002). About one-half to two-thirds of adults spawn in the Sacramento River and the remainder spawn in the Delta (Leet et al. 2001). After spawning, most adult striped bass move downstream into brackish and salt water for summer and fall (Moyle 2002).

Eggs are free-floating and negatively buoyant and hatch as they drift downstream, with larvae occurring in shallow and open waters of the lower reaches of the Sacramento and San Joaquin rivers, the Delta, Suisun Bay, Montezuma Slough, and Carquinez Strait. According to Hassler (1988), the distribution of larvae in the estuary depends on river flow. In low-flow years, all eggs and larvae are found in the Delta, while in high-flow years, the majority of eggs and larvae are transported downstream into Suisun Bay.

Potential Changes to Striped Bass from Seasonal Operations

<u>CalSim 3 Flows</u>

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows at Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤ 4%) increases and/or decreases are April through June; this suggests habitat will remain similar to the No Action Alternative (Table O-267 through Table O-269).

<u>Water Temperature Analysis</u>

Full results of the analysis assessing the percent of months with water temperature outside the 59°F to 68°F optimal water temperature range for spawning, embryo incubation and initial rearing for striped bass during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 317 for Butte City.

Results for the analysis are summarized in Table O-130. Table O-130, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 59°F to 68°F optimal water temperature range, there was one month-water year type combinations (6.7 % of total combinations during the period) with favorable and unfavorable results at Butte City (Table O-130). These results suggest that there would be negligible water temperature-related effects of Alternative 4 on striped bass spawning and egg incubation in the Sacramento River.

Summary

Overall, under Alternative 4 compared to the No Action Alternative for CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will remain similar to the No Action Alternative. The optimal water temperature range analysis predicts 6.7% of month-water year type combinations would have favorable or unfavorable results. Overall, these results suggest there would be negligible flow impacts on spawning habitat and negligible water temperature-related impacts on striped bass spawning and egg incubation in the Sacramento River under Alternative 4 compared to the No Action Alternative.

Larval and Juvenile Rearing and Emigration

During this early period the embryos and larvae in the Sacramento River are carried into the Delta and Suisun Bay (Moyle 2002). YOY striped bass distribute themselves in accordance with the estuarine salinity gradient (Kimmerer 2002a; Feyrer et al. 2007), indicating that salinity is a major factor affecting their habitat use and geographic distributions. Kimmerer (2002a) found that distributions of fish species, including striped bass, substantially overlapped with the low-salinity zone. Older individuals are increasingly flexible about their distribution relative to salinity (Moyle 2002). Statistically significant correlations between indices of age-0 abundance or survival in the San Francisco Estuary and Delta have been found with Delta outflow (which can be approximated by X2, the distance in km from the Golden Gate Bridge at which bottom salinity is 2 psu) (e.g., Kimmerer et al. 2009; Mac Nally et al. 2010), with evidence for greater extent of habitat as the mechanism (Kimmerer et al. 2009). However, subsequent density-dependent survival after the first summer dampens the effects of flow on subsequent recruitment (Kimmerer et al. 2000).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows at Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤ 4%) increases and/or decreases are most months; this suggests habitat will remain similar to the No Action Alternative (Table O-267 through Table O-269).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F range of optimal temperatures for larvae, fry, and juvenile rearing and emigration year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 318 for Butte City.

Results for the analysis are summarized in Table O-131. Table O-131, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 61°F to 71°F optimal water temperature range for larvae, fry, and juvenile rearing and emigration, there were two month-water year type combination (3.3% of total combinations during the period) with favorable results at Butte City (Table O-131). There were zero combinations (0.0%) with unfavorable results at Butte City. These results suggest that there would be negligible positive water temperature-related impacts from Alternative 4 on striped bass larvae, fry, and juvenile rearing and emigration in the Sacramento River.

Summary

Overall, Alternative 4 compared to the No Action Alternative for CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will remain similar to the No Action Alternative. The optimal water temperature range analysis predicts that 3.3% month-water year type combinations would have favorable results at Butte City. Overall, these results suggest there would be negligible flow and water temperature-related impacts on striped bass juvenile rearing and emigration habitat in the Sacramento River under Alternative 4 compared to the No Action Alternative.

O.7.19.2 Lower American River

Adults

Striped bass are present in the lower American River throughout the year, with the greatest abundance in summer (Surface Water Resources 2001). Striped bass are distributed from the confluence with the Sacramento River to Nimbus Dam (Moyle 2002), and they provide a locally important sportfishing resource.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam and in the lower American River at H Street indicate that minor (≤ 7%) increase and/or decrease is estimated nearly all months in a given year (Table O-276 through Table O-278). These results suggest habitat will remain similar nearly all months of the year under Alternative 4 compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 77°F stress initiation value for adult striped bass year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 93 for Hazel Avenue and Table 94 for Watt Avenue.

Results for the analysis are summarized in Table O-132. Table O-132, as described in Section O.4.19.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 77°F stress initiation water temperature value for adult striped bass under Alternative 4, there were 0 month-water year type combinations (0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-132). There were also 0 month-water year type combinations (0%) with unfavorable results at Hazel Avenue and Watt Avenue.

These results suggest that under Alternative 4, there would be negligible water temperature-related effects to adult striped bass in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling flows suggests spawning habitat will remain similar to the No Action Alternative. The optimal water temperature range modeling estimates indicate there are no combinations with beneficial or adverse results at Butte City. Overall, these results suggest there would be generally negligible flow impacts on adult habitat and negligible water temperature-related impacts on adult striped bass in the lower American River at Hazel Avenue and Watt Avenue under Alternative 4 compared to the No Action Alternative.

Juvenile Rearing

Although the occurrence of spawning in the lower American River is uncertain, the river is believed to serve as a nursery area for YOY and subadult striped bass (Surface Water Resources 2001). Striped bass are distributed from the confluence with the Sacramento River to Nimbus Dam (Moyle 2002), and they provide a locally important sportfishing resource.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam and in the lower American River at H Street indicate that minor (≤ 7%) increase and/or decrease is estimated nearly all months in a given year (Table O-277 and Table O-278). These results suggest striped bass habitat will remain similar nearly all months of the year under Alternative 4 compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing year-round are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 95 for Hazel Avenue and Table 96 for Watt Avenue.

Results for the analysis are summarized in Table O-133. Table O-133, as described in Section O.4.19.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 61°F to 71°F optimal range for juvenile striped bass rearing under Alternative 4, there were one and four month-water year type combinations (1.7% and 6.7%, respectively) with

favorable results at both Hazel Avenue and Watt Avenue, respectively (Table O-133). There were three month-water year type combinations (5.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

These results suggest that under Alternative 4, there would be positive and negative water temperature-related impacts to juvenile striped bass rearing in the lower American River.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and water temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat will remain similar to the No Action Alternative. Overall, these results suggest there would be generally negligible flow impacts and adverse and beneficial water temperature-related impacts to juvenile striped bass rearing in the lower American River at Hazel Avenue and Watt Avenue.

O.7.19.3 Stanislaus River

Spawning and Egg Incubation

Striped bass have been observed at Lovers Leap and at Knights Ferry from May through the end of June. These adult fish were observed in all habitats (U.S. Fish and Wildlife Service 2002; Kennedy and Cannon 2005). The distribution of striped bass in the Stanislaus River is thought to be limited to downstream of the historic Knights Ferry Bridge due to a set of falls about 3 feet tall in the area (U.S. Fish and Wildlife Service 2002).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 4 compared to the No Action Alternative CalSim 3 flow results show minor (≤ 5%) and decreases in flow at Goodwin Dam and mouth of the Stanislaus River, except in April when flow is expected to decrease (8%) at Goodwin Dam (Table O-279 and Table O-280). These results suggest flows may have adverse impacts on striped bass in April.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature above the 59°F to 68°F optimal range of water temperature for spawning, embryo incubation, and initial rearing of striped bass for April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 70 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-134. Table O-134, as described in Section O.4.19.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 59°F to 68°F optimal range of water temperature for spawning, embryo incubation, and initial rearing of striped bass, there was one month-water year type combination (6.7%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-134).

These results suggest that Alternative 4 would have negligible water-temperature related effects on striped bass spawning, embryo incubation, and initial rearing at Orange Blossom Bridge in the Stanislaus River.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests flows may have adverse impacts in April. The optimal water temperature range modeling estimates indicate a 6.7% month-water year type combination with beneficial results and no combinations with adverse results at Orange Blossom Bridge. Overall, these results generally suggest adverse flow impacts in April and negligible water temperature-related impacts to striped bass spawning and egg incubation in the Stanislaus River at Goodwin Dam and the mouth under Alternative 4 compared to the No Action Alternative.

Larval and Juvenile Rearing and Emigration

Striped bass have been observed at Lovers Leap and at Knights Ferry from May through the end of June. The distribution of striped bass in the Stanislaus River is thought to be limited to downstream of the historic Knights Ferry Bridge due to a set of falls about 3 feet tall in the area (U.S. Fish and Wildlife Service 2002).

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows show minor (≤ 1%) to slight (≤ 10%) increases in flow and minor (≤1%) to slight (8%) decreases in flow at Goodwin Dam and mouth of the Stanislaus River (Table O-279 and Table O-280). At Goodwin Dam, slight (≤ 10%) increases are generally expected in February, July, August, and December and a slight (8%) decrease generally April. At the mouth, a slight (7%) increase is generally expected in August. These results suggest averaged flows may be generally beneficial on striped bass.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 71 for Orange Blossom Bridge and Table 72 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-135. Table O-135, as described in Section O.4.19.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 61°F to 71°F water temperature optimal range for striped bass juvenile rearing there were zero and two month-water year type combinations (0.0% and 3.3%) with favorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-135). There were zero and four month-water year type

combinations (0.0% and 6.7%, respectively) with unfavorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively.

These results suggest that Alternative 4 would have negligible water temperature-related effects on juvenile striped bass rearing in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests flows may have generally beneficial impacts. The optimal water temperature range modeling estimated 3.3% beneficial and 6.7% with adverse results month-water year type combinations above the confluence with the San Joaquin River. Overall, these results generally suggest beneficial flow impacts and adverse water temperature related impacts on juvenile striped bass rearing in the Stanislaus River.

O.7.19.4 San Joaquin River

Striped bass are regularly found in San Joaquin River tributaries, including in lower mainstem deep pools of the Stanislaus and Tuolumne Rivers (e.g., Anderson et al. 2007). Ainsley et al. (2013) reported that striped bass were collected at two locations between the Head of the Old River and the mouth of the Stanislaus River on the mainstem San Joaquin River in May. In the San Joaquin River outflow is balanced by tidal currents, so that embryos and larvae stay suspended in the same general area in which spawning took place. Essentially, larval bass from both rivers are most abundant where salt and fresh water meet. Thus, when they begin to feed they are concentrated in the most productive portions of the entire estuary. Larval growth and survival rates are also highest in areas of brackish water, presumably because of reduced energy costs for osmoregulation (Moyle 2002).

Potential Changes to Striped Bass from Seasonal Operations

Alternative 4 compared to the No Action Alternative CalSim 3 modeling results show minor (≤ 5%) increases and decreases in flow are estimated nearly all months at Vernalis; slight (≤ 8%) to moderate (≤ 22%) flow increases are anticipated generally in June through September of critically dry water years (Table O-281). The greatest increases are expected on average in July through August (21% and 22%, respectively) of critically dry water years. These results suggest averaged flows are generally similar, except during critically dry water years when flows would be higher under Alternative 4 compared to the No Action Alternative; this suggests a beneficial effect on striped bass.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on striped bass in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 4 compared to the No Action Alternative CalSim 3 results are generally similar, except in critically dry water years when flows would be higher under Alternative 4; this suggests beneficial impacts on striped bass during critically dry water years. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.7.19.5 Bay-Delta

Striped bass use the Delta as a migratory route and for rearing and seasonal foraging. Striped bass spend the majority of their lives in salt water, returning to freshwater to spawn. Adult striped bass spend about 6 to 9 months of the year in San Francisco and San Pablo Bays (Hassler 1988). Striped bass also use deeper areas of many of the larger channels in the Delta, in addition to large embayments such as Suisun Bay.

Spawning occurs in spring, primarily in the Sacramento River between Sacramento and Colusa and in the San Joaquin River between Antioch and Venice Island (Farley 1966). Eggs are free-floating and negatively buoyant and hatch as they drift downstream, with larvae occurring in shallow and open waters of the lower reaches of the Sacramento and San Joaquin Rivers, the Delta, Suisun Bay, Montezuma Slough, and Carquinez Strait. According to Hassler (1988), the distribution of larvae in the estuary depends on river flow. In low-flow years, all striped bass eggs and larvae are found in the Delta, while in high-flow years, the majority of eggs and larvae are transported downstream into Suisun Bay.

Potential Changes to Striped Bass from Seasonal Operations

CalSim 3 Flows

Alternative 4 compared to the No Action Alternative CalSim 3 modeling results show minor (≤ 5%) to substantial (≤ 54%) increases in flow and minor (5%) to slight (≤ 11%) decreases in flow in the Bay-Delta (Tables O.6-9, O.6-10, and O.6-11). At SWP and CVP exports, slight (8%, February) to moderate (25%, May) flow increases and slight (≤ 12%, December) are expected. At the confluence of Old and Middle River in the Delta, slight (16%, February) to substantial (≤ 54%, May) flow increases and slight (≤ 16%, December) are expected. For Delta outflow, a slight (6%) decrease in flow is generally expected in May. These differences suggest flows may have beneficial impacts on striped bass.

Delta Outflow vs. Bay-Delta Species Abundance

Predictions from the Delta Outflow model for striped bass indicated that the overall average abundance index for Alternative 4 although essentially similar to the No Action Alternative, would likely be the lowest when compared across all water year types (-3% to +2%).

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and Delta outflow modeling results had some differences. The differences determined by CalSim 3 modeling suggests flows may have generally beneficial impacts on striped bass. Predictions from the Delta Outflow species abundance modeling for striped bass indicated that the overall average abundance index for Alternative 4 would be similar to the No Action Alternative all water year types. Overall, these results suggest generally beneficial flow impacts on striped bass under Alternative 4.

Potential Changes to Entrainment of Striped Bass

Predictions from the salvage density model for striped bass include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of striped bass under Alternative 4 compared to the No Action Alternative at the SWP Banks Pumping Plant were generally similar or higher and CVP Jones Pumping Plant were generally similar or lower all water year types (Tables O-136 and O-137). At the SWP Banks Pumping Plant predicted average monthly loss was up to 5% higher on critically dry (Table O-136). At CVP Jones Pumping Plant predicted average monthly loss was up to 10% and 8% lower on dry and critically dry water years (Table O-137).

Summary

Overall, Alternative 4 compared to the No Action Alternative salvage density modeling results had some differences. The salvage density modeling predicted monthly loss under Alternative 4 are similar most water year types, except at SWP Banks Pumping Plant in critically dry water years when loss would have a minor (5%) increase and at CVP Jones Pumping Plant in dry and critically dry water year types when loss would have slight (≤ 10%) decreases. Overall, loss increases and decreases at SWP and CVP Delta facilities (respectively) from entrainment are anticipated under Alternative 4.

O.7.20 American Shad

O.7.20.1 Sacramento River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento River. Migrating adults generally take 2 to3 months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the February to April adult American shad migration into Delta, CalSim 3 estimates of mean monthly flows below Keswick Dam under Alternative 4 range from about 3,500 cfs for March in critically dry years to 24,000 cfs for February of wet water years (Table O-266). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. This increase in flows could result in more eggs and larval fish to be washed further downstream earlier than expected but Alternative 4 cannot be determined to have adverse effects. Therefore, Alternative 4 would likely have negligible flow impacts on American shad eggs and embryos relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 319 for Butte City.

Results for the analysis are summarized in Table O-138. Table O-138, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 62°F to 75°F optimal range, there were no month-water year type combinations (0% of total combinations during the period) with favorable or unfavorable results at Butte City (Table O-138). These results suggest that there would be negligible water temperature-related impacts from Alternative 4 on American shad spawning and larval rearing in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is largely expected to have negligible impacts on American shad spawning and larval rearing below Keswick Dam in the Sacramento River due to differences in flow. Flow for spawning is not a limiting factor for American shad. Water temperatures for spawning initiation under Alternative 4 compared to the No Action Alternative will have a negligible impact on American shad spawning and larval rearing in the Sacramento River. Therefore, the differences in flow and temperature under Alternative 4 compared to the No Action Alternative in the Sacramento River are expected to have negligible impacts on American shad spawning and larval rearing.

Juvenile Rearing and Emigration

In the Sacramento River, summer rearing habitat occurs in the main river from Colusa to the north Delta (Stevens et al. 1987). As the season progresses, juvenile American shad move downstream and enter salt water primarily during September through November (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the September to November juvenile American shad emigration back into Delta, CalSim 3 estimates of mean monthly flows below Keswick Dam under Alternative 4 range from about 4,000 cfs for October in critically dry years to 9,000 cfs for September of wet water years (Table O-266). Because American shad are anadromous fish that migrate great lengths to reach their spawning grounds, these flow levels are likely to be adequate for juvenile rearing and emigration, so no adverse effects are expected to result. Alternative 4 is higher (16%) in November of critically dry years (Table O-266). Alternative 4 would likely have negligible flow impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F range optimal range for juvenile rearing and emigration during July through November are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 320 for Butte City.

Results for the analysis are summarized in Table O-139. Table O-139, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 62°F to 75°F optimal range, there were four month-water year type combination (16.0% of total combinations during the period) with favorable results at Butte City (Table O-139). There were zero unfavorable results at Butte City. These results suggest that there would be positive water temperature-related effects of Alternative 4 on American shad juvenile rearing and emigration in the Sacramento River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have little impact on American shad juvenile rearing and emigration in the Sacramento River due to differences in flow. Flow for rearing and emigration is not a limiting factor for American shad. Water temperatures for larval rearing and emigration under Alternative 4 compared to the No Action Alternative would have beneficial impacts on American shad juvenile rearing and emigration in the lower American River.

O.7.20.2 Lower American River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento River. Migrating adults generally take two to three months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962).

Adult American shad migrate into the lower American River to spawn during the late spring, typically during April through early July (California Department of Fish and Wildlife 1986).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the February to April adult American shad migration into Delta, CalSim 3 estimates of mean monthly flows below Nimbus Dam and H street under Alternative 4 range from about 788 cfs for April at H St. in critically dry years to 12,307 cfs at H St. for February of wet water years (Table O-277 and Table O-278). Differences in flows between Alternative 4 and the No Action Alternative are generally minimal in these months below Nimbus Dam and at H St. with a reduction of flow (~24%) in March of critically dry years (Table O-277 and Table O-278). Because American shad spawn in depths from 1m to 10 m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. This decrease in flows could result in a reduction in adequate spawning habitat but Alternative 4 cannot be determined to have adverse effects. Therefore, Alternative 4 would likely have minimal flow effects on American shad spawning and larval rearing relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range for American shad spawning and larval rearing during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 97 for Hazel Avenue and Table 98 for Watt Avenue.

Results for the analysis are summarized in Table O-140. Table O-140, as described in Section O.4.20.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 62°F to 75°F optimal range for American shad spawning and larval rearing under Alternative 4, there were two and one month-water year type combinations (13.3% and 6.7%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively (Table O-140). There were zero and one month-water year type combinations (0.0% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 4, there would be positive and negative water temperature-related impacts to American shad spawning and larval rearing in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on American shad spawning and larval rearing below Nimbus Dam and at H Street due to differences in flow. Flow for spawning is not a limiting factor for American shad. Water temperatures for spawning initiation from Hazel Avenue and Watt Avenue under Alternative 4 compared to the No Action Alternative will have beneficial and adverse impacts on American shad spawning and larval rearing in the lower American River. Therefore, the differences in flow and water temperature under Alternative 4 compared to the No Action Alternative in the lower

American River are expected to have some beneficial and adverse impacts on American shad spawning and larval rearing.

Juvenile Rearing and Emigration

American shad rearing and emigration in the lower American River is dependent on water temperatures. August through September, but before November, are optimal months for juvenile American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the September to November juvenile American shad emigration back into Delta, CalSim 3 estimates of mean monthly flows below Nimbus Dam and H street under Alternative 4 range from about 583 cfs at H Street for October in critically dry years to 4,254 cfs below Nimbus Dam for November of wet water years (Table O-277 and Table O-278). Differences in flows between Alternative 4 and the No Action Alternative are slightly lower (~9%) for Alternative 4 below Nimbus Dam and at H Street in October and November during critically dry years (Table O-277 and Table O-278) Because American shad are anadromous fish that migrate great lengths to reach their spawning grounds, these flow levels are likely to be adequate for juvenile rearing and emigration, so no adverse effects are expected to result. Therefore, Alternative 4 would likely have negligible impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for American shad juvenile rearing and emigration during July through November are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 99 for Hazel Avenue and Table 100 for Watt Avenue.

Results for the analysis are summarized in Table O-141. Table O-141, as described in Section O.4.20.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 63°F to 77°F optimal range for American shad spawning and larval rearing under Alternative 4, there were two month-water year type combinations (8.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-141). There were three and zero month-water year type combinations (12.0% and 0.0%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively.

These results suggest that under Alternative 4, there would be positive and negative water temperature-related impacts to American shad juvenile rearing and emigration in the lower American River at Hazel Avenue and Watt Avenue.

Summary

Alternative 4 relative the No Action Alternative is largely expected to have negligible impacts on American shad juvenile rearing and emigration due to differences in flow. Flow for rearing and emigration is not a limiting factor for American shad. Water temperatures for larval rearing and emigration at Hazel Avenue and Watt Avenue under Alternative 4 compared to the No Action Alternative would have beneficial adverse impacts on American shad juvenile rearing and emigration in the lower American River. Therefore, the differences in flow and water temperatures under Alternative 4 compared to the No Action Alternative are expected to have beneficial and adverse impacts on American shad juvenile rearing and emigration.

O.7.20.3 Stanislaus River

Spawning and Larval Rearing

American shad migrate up the Stanislaus River to spawn in the late spring and support a sport fishery during that period. American shad have been observed on occasion from June through July at Lovers Leap (U.S. Fish and Wildlife Service 2002; Kennedy and Cannon 2005). American shad were found primarily in the faster habitats and were observed in schools of 20 or more (U.S. Fish and Wildlife Service 2002).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the February to April adult American shad migration into Delta, CalSim 3 estimates of mean monthly flows below Goodwin Dam and Stanislaus River mouth under Alternative 4 range from about 200 cfs for March in critically dry years to 2200 cfs for February below Goodwin Dam and at Stanislaus River Mouth of wet water years (Table O-279 and Table O-280). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. Differences in flows between Alternative 4 and the No Action Alternative are about 45% higher for Alternative 4 in February below Goodwin Dam in dry and critically dry years and 10% higher in February and March at the Stanislaus River Mouth for dry and critically dry water years (Table O-279 and Table O-280) Alternative 4 would likely have negligible flow impacts on American shad eggs and embryos relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 62°F to 75°F optimal range for American shad spawning and larval rearing during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 73 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-142. Table O-142, as described in Section O.4.20.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 59°F to 68°F 62°F to 75°F optimal range for American shad spawning and larval rearing, there was one month-water year type combinations (6.7%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-142).

These results suggest that Alternative 4 would have negligible water-temperature related effects on American shad spawning and larval rearing at Orange Blossom Bridge in the Stanislaus River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on American shad spawning and larval rearing due to differences in flow. Flow for spawning is not a limiting factor for American shad. Water temperatures for spawning initiation at Orange Bridge Dam and above the confluence under Alternative 4 compared to the No Action Alternative will have negligible water temperature-related impacts on American shad spawning and larval rearing at Orange Blossom Bridge in the Stanislaus River.

Juvenile Rearing and Emigration

American shad rearing and emigration in the Stanislaus River is dependent on water temperatures. From Orange Blossom Bridge to just above the confluence, juvenile rearing and emigration generally occur in July for American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

CalSim 3 Flows

During the September to November juvenile American shad emigration back into Delta, CalSim 3 estimates of mean monthly flows below Goodwin Dam and Stanislaus River Mouth under Alternative 4 range from about 200 cfs for September in critically dry years to 800 cfs in September and October below Goodwin Dam and Stanislaus River Mouth during wet water years (Table O-279 and Table O-280). Differences in flows between Alternative 4 and the No Action Alternative are unchanged for Alternative 4 below Goodwin Dam and 29% higher at Stanislaus River Mouth in September during critically dry years (Table O-279 and Table O-280). With no change below Goodwin Dam and an increase in flows at Stanislaus River Mouth, American shad could see no adverse effects from Alternative 4. Therefore, Alternative 4 would likely have negligible impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for American shad juvenile rearing and emigration during July through November are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 74 for Orange Blossom Bridge and Table 75 for above the confluence with the San Joaquin River.

Results for the analysis are summarized in Table O-143. Table O-143, as described in Section O.4.20.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 63°F to 77°F optimal range for American shad juvenile rearing and emigration there were zero and one month-water year type combinations (0.0% and 4.0%, respectively) with favorable results at Orange Blossom Bridge and above the confluence with the San Joaquin River, respectively (Table O-143). There were zero month-water year type combinations (0.0%) with unfavorable results at both Orange Blossom Bridge and above the confluence with the San Joaquin River.

These results suggest that Alternative 4 would have negligible negative water temperature related impacts on American shad juvenile rearing and emigration in the Stanislaus River at Orange Blossom Bridge and above the confluence with the San Joaquin River.

Summary

Alternative 4 relative to the No Action Alternative is expected to have negligible impacts on American shad juvenile rearing and emigration due to flow differences. Flow for rearing and emigration is not a limiting factor for American shad. Water temperatures for larval rearing and emigration at Orange Blossom Bridge and above the confluence under Alternative 4 compared to the No Action Alternative are suggested to have negligible water temperature-related impacts on American shad juvenile rearing and emigration in the Stanislaus River.

O.7.20.4 San Joaquin River

Spawning and Larval Rearing

American shad is an anadromous fish that spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas. Migrating adults generally take 2 to3 months to pass through the Delta starting as early as February (Painter et al. 1979). Most adults migrate into the Delta in March and early April (Skinner 1962).

Little is known about American shad populations inhabiting the San Joaquin River. American shad may spawn in the San Joaquin River system, but their abundance is unknown.

Potential Changes to American Shad from Seasonal Operations

During the February to April adult American shad migration into the Delta, CalSim 3 estimates of mean monthly flows in the San Joaquin River at Vernalis under Alternative 4 range from about 2,000 cfs for March critically dry years to 13,000 cfs for February (Table O-281). Because American shad spawn in depths from 1m to 10m, typically less than 3m (Moyle 2002), these flow levels are likely to be adequate for spawning and incubation. Differences in flows between Alternative 4 and the No Action Alternative are slightly higher (~1%) for Alternative 4 in February and March of critically dry water years (Table O-281) Alternative 4 would likely have negligible flow impacts on American shad eggs and embryos relative to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on American shad spawning and larval rearing in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the American shad spawning and larval rearing period (Figure O-15).

Summary

There may be negligible impacts from seasonal operations on American shad spawning and larval rearing based on analyses of simulated flows under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are unlikely to impact American shad juvenile rearing and non-spawning adult. Under Alternative 4, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the American shad spawning and larval rearing period.

Juvenile Rearing and Emigration

American shad rearing and emigration is dependent on water temperatures. Generally, juvenile rearing and emigration generally occur in July for American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

During the September to November juvenile American shad emigration back into the Delta, CalSim 3 estimates of mean monthly flows in the San Joaquin River at Vernalis under Alternative 4 range from about 800 cfs for September in critically dry years to 2,900 cfs for October and November in the San Joaquin River at Vernalis of wet water years (Table O-281) Differences in flows between Alternative 4 and the No Action Alternative are slightly higher (10%) for Alternative 4 in September in the San Joaquin River at Vernalis during critically dry years (Table O-281). With these flows, American Shad should not feel any adverse effects from Alternative 4. Therefore, Alternative 4 would likely have negligible impacts on American shad juvenile rearing and emigration relative to the No Action Alternative.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on American shad in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile rearing and emigration period (Figure O-15).

Summary

There may be negligible impacts from seasonal operations on American shad juvenile rearing and emigration based on analyses of simulated flows under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are unlikely to have impacts on American shad juvenile rearing and emigration. Under Alternative 4, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the juvenile rearing and emigration period.

O.7.20.5 Bay-Delta

American shad spend most of their adult life at sea and may make extensive migrations along the coast. American shad become sexually mature while in the ocean and migrate through the Delta to spawning areas in the Sacramento, Feather, American, and Yuba Rivers. Some spawning also takes place in the lower San Joaquin, Mokelumne, and Stanislaus Rivers (U.S. Fish and Wildlife Service 1995). The spawning migration may begin as early as February, but most adults migrate into the Delta in March and early April (Skinner 1962). Migrating adults generally take 2 to 3 months to pass through the Sacramento–San Joaquin estuary (Painter et al. 1979).

American shad rearing and emigration in the Bay-Delta is dependent on water temperatures. August through September, but before November, are optimal months for juvenile American shad to start emigrating into the Delta and out into the ocean (Moyle 2002).

Potential Changes to American Shad from Seasonal Operations

Delta Outflow vs. Bay-Delta Species Abundance

Predictions from the Delta Outflow model for American shad indicated that the overall abundance index for Alternative 4 would essentially be similar when compared to the No Action Alternative across all water year types (-2% to -1%, -1% overall).

Summary

There may be negligible impacts from seasonal operations on American shad abundance based on analyses of simulated flows under Alternative 4 in comparison to the No Action Alternative. American shad abundance index would be similar to the No Action Alternative across all water year types in the Bay-Delta based on the Delta Outflow model.

Potential Changes to Entrainment of American Shad

Differences in exports under Alternative 4 compared with the No Action Alternative may have effects on American shad entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for American shad include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of American shad under Alternative 4 compared to the No Action Alternative at the SWP Banks Pumping Plant was similar all water year types and CVP Jones Pumping Plant was similar most water year types (Tables O-144 and O-145). At CVP Jones Pumping Plant predicted average monthly loss decreased up to 5% on above normal water year types (Table O-145).

Summary

There may be beneficial and adverse changes to American shad entrainment based on analyses of simulated exports under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, entrainment was similar or increased at both Jones Pumping Plant and Banks Pumping Plant during February through May of all water year types and was similar or decreased in December, January, and June of all water year types when compared to the No Action Alternative.

O.7.21 Threadfin Shad

O.7.21.1 Sacramento River

Spawning for threadfin shad takes place in California April through August, peaking in June and July. The embryos hatch in 3 to 6 days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Threadfin shad are occasionally caught at the Red Bluff Diversion Dam RST in the Sacramento River, and occur year-round (Voss 2024).

Potential Changes to Threadfin Shad from Seasonal Operations

Flow Impacts

There is no strong evidence that flow influences threadfin shad abundance. While Feyrer et al. (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 4 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal spawning range during April through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 321 for Butte City.

Results for the analysis are summarized in Table O-146. Table O-146, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 63°F to 77°F optimal range, there were two month-water year type combinations (8.0% of total combinations during the period) with favorable results at Butte City (Table O-146). There were no month-water year type combinations (0%) with unfavorable results at Butte City. These results suggest that there would be positive water temperature-related effects of Alternative 4 on threadfin shad spawning in the Sacramento River.

Summary

There may be negligible impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are likely to have a negligible impact on threadfin shad. Temperature analysis predicts beneficial impacts of Alternative 4 on threadfin shad spawning in the Sacramento River.

O.7.21.2 Lower American River

Spawning for threadfin shad takes place in California April through August, peaking in June and July. The embryos hatch in 3 to 6 days and larvae immediately become planktonic. Threadfin shad are occasionally captured as part of the non-salmonid bi-catch in the RSTs in the lower American River (Pacific States Marine Fisheries Commission 2014).

Potential Changes to Threadfin Shad from Seasonal Operations

Flow Impacts

There is no strong evidence that flow influences threadfin shad abundance. While Feyrer et al. (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 4 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for threadfin shad adult spawning during April through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 101 for Hazel Avenue and Table 102 for Watt Avenue.

Results for the analysis are summarized in Table O-147. Table O-147, as described in Section O.4.21.2, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

For the 63°F to 77°F optimal range for threadfin shad spawning under Alternative 4, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-147). There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

These results suggest that under Alternative 4, there would be negligible water temperature-related effects to threadfin shad spawning in the lower American River at Hazel Avenue and Watt Avenue.

Summary

There may be negligible impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are likely to have a negligible impacts on threadfin shad. Temperature analysis also suggests negligible impacts from Alternative 4 on threadfin shad spawning in the lower American River.

O.7.21.3 Stanislaus River

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Threadfin shad are occasionally captured in the Caswell RST in the lower Stanislaus River (Bradbury and Hickey 2019).

Potential Changes to Threadfin Shad from Seasonal Operations

Flow Impacts

There is no strong evidence that flow influences threadfin shad abundance. While Feyrer et al. (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 4 are likely adequate for threadfin shad.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 63°F to 77°F optimal range for threadfin shad adult spawning during April through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 76 for Orange Blossom Bridge.

Results for the analysis are summarized in Table O-148. Table O-148, as described in Section O.4.21.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 63°F to 77°F optimal range for threadfin shad adult spawning, there were no month-water year type combinations (0.0%) with favorable or unfavorable results at Orange Blossom Bridge (Table O-148).

These results suggest that Alternative 4 would have negligible water-temperature related effects on threadfin shad spawning in the Stanislaus River at Orange Blossom Bridge.

Summary

There may be negligible impacts from seasonal operations on threadfin shad based on analyses of simulated flows and water temperature under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are expected to have a negligible impact on threadfin shad. The temperature analysis also suggests negligible impacts from Alternative 4 on threadfin shad spawning in the Stanislaus River.

O.7.21.4 San Joaquin River

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in 3 to 6 days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004). Juveniles can form dense schools and while they are typically abundant in freshwater, they may also be found in varying salinities throughout the estuary. Threadfin shad are fast-growing but short-lived, with an average lifespan of two years.

Potential Changes to Threadfin Shad from Seasonal Operations

There is no strong evidence that flow influences threadfin shad abundance. While Feyrer et al. (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 4 are likely adequate for threadfin shad.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impacts on threadfin shad in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

There may be negligible impacts from seasonal operations on threadfin shad juvenile rearing and non-spawning adults based on analyses of simulated flows under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, changes in flows are likely to have negligible impacts on threadfin shad spawning and larval rearing. Under Alternative 4, HEC-5Q simulated water temperatures are similar to the No Action Alternative throughout the year.

O.7.21.5 Bay-Delta

Threadfin shad spawning takes place in California April through August, peaking in June and July. The embryos hatch in three to six days and larvae immediately become planktonic. As noted by Baxter et al. (2010), threadfin shad are widely distributed but most encountered and abundant in the southeastern Delta, especially the San Joaquin River near and just downstream of Stockton. In these regions, suitable abiotic habitat coincides with high prey abundance (Feyrer et al. 2009). These regions also have a relatively high density of submerged aquatic vegetation, which provides important habitat for spawning and larval rearing (Grimaldo et al. 2004).

Potential Changes to Threadfin Shad from Seasonal Operations

There is no strong evidence that flow influences threadfin shad abundance. While Feyrer et al. (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 4 are likely adequate for threadfin shad.

Summary

There may be negligible impacts from seasonal operations on threadfin shad under Alternative 4 in comparison to the No Action Alternative.

Juvenile Rearing and Non-Spawning Adults

Threadfin shad have been established in the Sacramento–San Joaquin River system and the Delta. Threadfin shad live mainly in freshwater and become progressively less abundant as salinity increases. Juveniles can form dense schools and while they are typically abundant in freshwater, they may also be found in varying salinities throughout the estuary. Threadfin shad are fast-growing but short-lived, with an average lifespan of two years.

Potential Changes to Threadfin Shad from Seasonal Operations

There is no strong evidence that flow influences threadfin shad abundance. While Feyrer et al. (2004) found the abundance index for threadfin shad was highest during low outflow conditions it was likely due to warmer water temperatures earlier in the year during low outflow conditions which led to earlier spawning and larger populations of young-of-year fish. Other studies such as Stompe et al. (2023), showed threadfin shad abundance shifts in geographic space were non-linear with outflow in the San Francisco Estuary, likely due its ability to shift into different

regions. Analysis by Thomson et al. (2010) suggests threadfin shad are particularly vulnerable to exports because their entire lifecycle takes place in freshwater. Threadfin shad are most abundant in deep, clear, fresh water with high zooplankton abundance (Feyrer et al. 2009). Flows under Alternative 4 are likely adequate for threadfin shad.

Summary

There may be negligible impacts from seasonal operations on threadfin juvenile rearing and non-spawning adults based on analyses of simulated flows under Alternative 4 in comparison to the No Action Alternative.

Potential Changes to Entrainment of Threadfin Shad

Salvage Density

Predictions from the salvage density model for threadfin shad include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of threadfin shad under Alternative 4 compared to the No Action Alternative at the SWP Banks Pumping Plant was similar all water year types and CVP Jones Pumping Plant was similar most water year types (Table O-149 and O-150). At CVP Jones Pumping Plant predicted average monthly loss decreased up to 5% on dry water year types (Table O-150).

Summary

There may be beneficial and adverse changes to entrainment on threadfin shad juvenile rearing and non-spawning adults based on analyses of simulated exports under Alternative 4 in comparison to the No Action Alternative. Under Alternative 4, entrainment increased at Banks during the wet, above normal, and below normal water year types and decreased during the dry and critically dry water year type, while entrainment at Jones decreased during the wet year type, was negligible for the above normal and below normal water year types and decreased during the dry and critically dry water year types.

O.7.22 Black Basses

O.7.22.1 Three Micropterus spp.

Three *Micropterus* spp. constitute the group of black basses in California, and include largemouth bass (two species), smallmouth bass, and spotted bass (three sub-species). All three species are introduced but have recreational value in California.

Largemouth Bass

Largemouth bass first spawn during their second or third spring at about 7 inches in length. Spawning is limited to freshwater (Moyle 2002). The males begin building nests when the water temperature reaches about 60°F (15.6°C). Spawning takes place from April through June, at temperatures up to 75°F (23.9°C).

Smallmouth Bass

Smallmouth bass reach maturity in their third or fourth spring, at which point they move into shallower water. Spawning begins in May and can continue into June or July (Moyle 2002). Spawning has been observed at temperatures ranging from 13°C to 26°C (55.4°F to 78.8°F), with optimal water temperatures ranging from 16°C to 18°C (60.8°F to 64.4°F) (Wang 2010).

Spotted Bass

Maturity is reached in the second or third year and spawning occurs in freshwater when temperatures reach 15°C to 18°C (59°F to 64.4°F), continuing until temperatures reach 22°C to 23°C (71.6°F to 73.4°F) in early June. Males move to shallow water in March and early April, where they construct nests 40 to 80 cm (31.5 inches) in diameter, generally in shallow areas less than or equal to 6 m deep (University of California, Agriculture and Natural Resources 2019b; Wang 2010).

O.7.22.2 Sacramento River

Spawning

Spawning occurs in freshwater for all three taxa. This means all spawning occurs upstream of the brackish estuary. See details in Section O.4.22.1 above for spawning timing for each species.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 4 compared to the No Action Alternative CalSim 3 simulated mean monthly flows at Keswick Dam, Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤ 4%) increases and/or decreases are March through July; this suggest largemouth, smallmouth, and spotted bass spawning habitat will remain similar to the No Action Alternative (Table O-266, through Table O-269).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 323 for Butte City. Full results of the analysis assessing the percent of months with water temperature outside the 55°F to 70°F optimal range for smallmouth bass spawning during May through July are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 325 for Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April through June are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 331 for Butte City.

Results for the three analyses are summarized in Table O-151. Table O-151, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results at Butte City (Table O-151). For the 55°F to 70°F optimal range for smallmouth bass spawning, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Hamilton City. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Butte City. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on black bass spawning in the Sacramento River.

Summary

Overall, Alternative 4 compared to the No Action Alternative for CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will generally remain similar for largemouth, smallmouth, and spotted bass. The optimal water temperature range modeling estimates indicate neither beneficial nor adverse impacts for largemouth and spotted bass under Alternative 4 compared to the No Action Alternative in the Sacramento River. The optimal water temperature range modeling estimates also indicates no beneficial or adverse combinations at Hamilton City for smallmouth bass in the Sacramento River. Overall, these results suggest that there would be negligible flow impacts on largemouth, smallmouth, spotted bass spawning habitat; water temperature-related impacts on spawning and egg incubation of largemouth, smallmouth and spotted bass would be negligible in the Sacramento River under Alternative 4.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters and may be found from the tributaries of the Sacramento to the brackish estuary. As all three taxa require large quantities of food, they are likely to be more concentrated in areas with plentiful food and instream cover.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 4 compared to the No Action Alternative CalSim 3 simulated mean monthly flows at Keswick Dam, Red Bluff Diversion Dam, Wilkins Slough, and Hamilton City indicate that minor (≤ 4%) increases and/or decreases are most months; this suggest habitat will remain similar to the No Action Alternative (Table O-266, through Table O-269).

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for non-spawning adult largemouth bass growth year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 324 at Butte City. Full results of the analysis assessing the percent of months with water temperature above the 66°F lower end of observed summer-time range for non-spawning adult smallmouth bass during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 327 for the Sacramento River at Hamilton. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F

optimal range for non-spawning adult smallmouth bass growth year-round are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 320 for the Sacramento River at Hamilton City. Full results of the analysis assessing the percent of months with water temperature outside the 75°F to 87°F preferred summer-time range for non-spawning adult spotted bass during June through August are presented in Attachment L.1, *Sacramento River Water Temperature Analysis*, Table 332 for the Sacramento River at Butte City.

Results for the four analyses are summarized in Table O-152. Table O-152, as described in Section O.4.8.1, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 77°F to 86°F optimal range for non-spawning adult largemouth bass growth, there were no month-water year type combinations (0% of total combinations during the period) with either favorable or unfavorable results at Butte City (Table O-152). For the 66°F lower end of observed summer-time range for non-spawning adult smallmouth bass, there was one month-water year type combinations (6.7%) with favorable results and one combination (6.7%) with unfavorable results at Hamilton City. For the 77°F to 80°F optimal range for non-spawning adult smallmouth bass growth, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Hamilton City. For the 75°F to 87°F preferred summer-time range for non-spawning adult spotted bass, there were no month-water year type combinations (0%) with either favorable or unfavorable results at Butte City. These results suggest that there would be negligible water temperature-related effects of Alternative 4 on black bass non-spawning adults in the Sacramento River.

<u>Summary</u>

Overall, Alternative 4 compared to the No Action Alternative for CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will generally remain similar with some slight adverse impacts on largemouth, smallmouth, spotted bass. The optimal summer water temperature range modeling estimates indicate neither beneficial nor adverse conditions on black basses compared to the No Action Alternative at Butte and Hamilton cities in the Sacramento River. Overall, these results suggest that there would be minor to adverse and beneficial impacts from flow on largemouth, smallmouth, and spotted bass; no water temperature-related impacts on largemouth and spotted bass adults; and negligible water temperature-related impacts on smallmouth bass are expected in the Sacramento River under Alternative 4.

O.7.22.3 Lower American River

Spawning

Spawning for all three taxa occurs in cooler, shallow waters with flow. See details in Section O.4.22.1 above for spawning timing for each species.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam and in the lower American River at H Street indicate that minor (≤ 2%) increases or decreases are estimated March through July (Table O-277 and Table O-278). These results suggest largemouth, smallmouth, and spotted bass spawning habitat will remain similar under Alternative 4 compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 105 for Hazel Avenue and Table 106 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 55°F to 70°F optimal range for smallmouth bass spawning during May through July are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 109 for Hazel Avenue and Table 110 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 115 for Hazel Avenue and Table 116 for Watt Avenue.

Results for the three analyses are summarized in Table O-153. Table O-153, as described in Section O.4.22.2,reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue(Table O-153). There were zero month-water year type combinations with unfavorable results at both Hazel Avenue and Watt Avenue. For the 55°F to 70°F optimal range for smallmouth bass spawning, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were zero and two month-water year type combinations (0.0% and 13.3%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue, respectively. For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were two and zero month-water year type combinations (13.3% and 0.0%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

These results suggest that there would be positive and negative effects of Alternative 4 on black bass spawning in the lower American River.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests negligible impacts on largemouth, smallmouth, and spotting bass spawning habitat

extent. The water temperature modeling for black basses indicates beneficial and adverse impacts from Alternative 4.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters. However, they require large quantities of food; they are likely to remain in slower moving waters of the stream or move vertically within the lake to accommodate preferences.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows below Nimbus Dam and in the lower American River at H Street indicate that minor (≤ 7%) increase and/or decrease is estimated nearly all months in a given year (Table O-277 and Table O-278). These results suggest largemouth, smallmouth, and spotted bass habitat will remain similar nearly all months of the year under Alternative 4 compared to the No Action Alternative.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for growth for largemouth bass during April through June are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 107 for Hazel Avenue and Table 108 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 111 for Hazel Avenue and Table 112 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F optimal range for growth in smallmouth bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 113 for Hazel Avenue and 114 for Watt Avenue. Full results of the analysis assessing the percent of months with water temperature above the 75°F to 87°F preferred summer-time range for spotted bass during June through August are presented in Attachment M.2, *American River Water Temperature Analysis*, Table 117 for Hazel Avenue and Table 118 for Watt Avenue.

Results for the four analyses are summarized in Table O-154. Table O-154, as described in Section O.4.22.3,reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue (Table O-154). There were also zero month-water year type combinations (0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass, there was one month-water year type combinations (6.7%) with favorable results at both Hazel Avenue and Watt Avenue. There were two and one month-water year type combinations (13.3% and 6.7%, respectively) with unfavorable results at Hazel Avenue and Watt Avenue,

respectively. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were zero month-water year type combinations (0.0%) with favorable results at both Hazel Avenue and Watt Avenue. There were also zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue. For the 75°F to 87°F preferred summer-time range for spotted bass, there were zero and two month-water year type combinations (0.0% and 13.3%, respectively) with favorable results at Hazel Avenue and Watt Avenue, respectively. There were zero month-water year type combinations (0.0%) with unfavorable results at both Hazel Avenue and Watt Avenue.

These results suggest that there would be beneficial and negative effects of Alternative 4 on black bass non-spawning adults in the lower American River.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests spawning habitat extent will generally remain similar with some slight to moderate beneficial and adverse impacts. The water temperature modeling for black basses indicates beneficial and adverse impacts from Alternative 4.

O.7.22.4 Stanislaus River

Spawning

Spawning for all three taxa occurs in cooler, shallow waters with flow. See details in Section O.4.22.1 above for spawning timing for each species.

Potential Changes to Largemouth and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows show minor (≤ 1%) increases and minor (≤ 2%) to slight (8%) decreases in flow in March through April at Goodwin Dam and mouth of the Stanislaus River (Table O-279 and Table O-280). At Goodwin Dam, a slight (≤ 8%) decrease is expected April and a slight increase (≤ 10%) in July and August. At the mouth, a slight (7%) increase is generally expected in August. At the mouth of the Stanislaus River, all increases and decreases are expected to be minor (up to 3% decrease and up to 7% increase). These results suggest averaged flows may be anticipated to have generally negligible effects on largemouth, smallmouth, and spotted bass spawning habitat.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 52.7°F to 84°F observed range for largemouth bass spawning during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 78 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 58.1°F to 73.4°F observed range for spotted bass spawning during April through June are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 82 for Orange Blossom Bridge.

Results for the two analyses are summarized in Table O-155. Table O-155, as described in Section O.4.22.4, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 52.7°F to 84.2°F observed range for largemouth bass spawning, there was one month-water year type combinations (6.7%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge (Table O-155). For the 58.1°F to 73.4°F observed range for spotted bass spawning, there were two month-water year type combination (13.3%) with favorable results and zero month-water year type combinations (0.0%) with unfavorable results at Orange Blossom Bridge.

These results suggest that there would be positive effects of Alternative 4 on spawning black basses spawning in the Stanislaus River.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests flows may have generally negligible impacts on largemouth, smallmouth, and spotted bass spawning habitat. The optimal water temperature range modeling estimates indicate one (6.7%) month-water year type combinations with adverse conditions for largemouth bass. The optimal water temperature range modeling estimates indicate 1 (6.7%) month-water year type combinations with adverse and beneficial conditions for spotted bass. Overall, these results suggest generally negligible flow impacts on largemouth, smallmouth, and spotted bass spawning habitat; water temperature-related impacts on largemouth and spotted bass spawning are slightly adverse under Alternative 4.

Non-Spawning Adult

Non-spawning adults are generally more tolerant of various water quality parameters. However, they require large quantities of food; they are likely to remain in slower moving waters of the stream or move vertically within the reservoirs to accommodate preferences.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flow Analysis

Alternative 4 compared to the No Action Alternative CalSim 3 mean monthly flows show minor (≤ 1%) to slight (≤ 10%) increases in flow and minor (≤1%) to slight (8%) decreases in flow at Goodwin Dam and mouth of the Stanislaus River (Table O-279 and Table O-280). At Goodwin Dam, slight (≤ 10%) increases are generally expected in February, July, August, and December and a slight (8%) decrease generally April. At the mouth, a slight (7%) increase is generally expected in August. These results suggest averaged flows may be anticipated to have generally beneficial effects on largemouth, smallmouth, and spotted bass.

Water Temperature Analysis

Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 86°F optimal range for growth for largemouth bass during year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 79 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass during June through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 80 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature outside the 77°F to 80°F optimal range for growth in smallmouth bass during year-round are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 81 for Orange Blossom Bridge. Full results of the analysis assessing the percent of months with water temperature above the 75°F to 87°F preferred summer-time range for spotted bass during June through August are presented in Attachment N.1, *Stanislaus River Water Temperature Analysis*, Table 83 for Orange Blossom Bridge.

Results for the four analyses are summarized in Table O-156. Table O-156, as described in Section O.4.22.3, reports the percent of month-water year type combinations in which the percent difference between an alternative and the No Action Alternative in either exceedance above the index value or occurrence outside the index range was >10%.

Under Alternative 4 for the 77°F to 86°F optimal range for growth for largemouth bass, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Road (Table O-156). For the 66°F water temperature lower end of observed summer-time range of non-spawning adult smallmouth bass, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Road. For the 77°F to 80°F optimal range for growth in smallmouth bass, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Road For the 75°F to 87°F preferred summer-time range for spotted bass, there were zero month-water year type combinations (0.0%) with favorable and unfavorable results at Orange Blossom Road.

These results suggest that Alternative 4 would have negligible effects on black bass non-spawning adults in the Stanislaus River at Orange Blossom Bridge.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow and temperature modeling results had some differences. The differences determined by CalSim 3 modeling suggests flows may have generally beneficial impact on largemouth, smallmouth, and spotted bass. The optimal water temperature range modeling estimates were neither beneficial nor adverse for largemouth, smallmouth, and spotted bass. Overall, these results suggest generally minor beneficial and adverse flow and similar water temperature-related impacts on black bass species in the Stanislaus River under Alternative 4 compared to the No Action Alternative.

O.7.22.5 San Joaquin River

Spawning occurs in freshwater for all three taxa. This means all spawning occurs upstream of the brackish estuary. Non-spawning adults are generally more tolerant of various water quality

parameters and may be found from the tributaries of the San Joaquin to the brackish estuary. As all three taxa require large quantities of food, they are more likely to be concentrated in areas with plentiful food and instream cover.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

Alternative 4 compared to the No Action Alternative CalSim 3 modeling results show minor (≤ 5%) increases and decreases in flow are estimated nearly all months at Vernalis; slight (≤ 6%) to moderate (≤ 22%) flow increases are anticipated generally in June through September of critically dry water years (Table O-281). The greatest increases are expected on average in July through August (22%) of critically dry water years. These results suggest averaged flows are generally similar, except during critically dry water years when flows would be higher under Alternative 4 compared to the No Action Alternative; this suggests a beneficial effect on largemouth, smallmouth, and spotted bass.

Changes in water temperature from seasonal operations under Alternative 4 compared to the No Action Alternative are likely to have a negligible impact on black basses in the San Joaquin River. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year (Figure O-15).

Summary

Alternative 4, compared to the No Action Alternative CalSim 3 modeling results, are generally similar, except in critically dry water years when flows would be higher under Alternative 4; this suggests beneficial impacts on largemouth, smallmouth, and spotted bass during critically dry water years. Under Alternative 4, HEC-5Q simulated water temperatures in the San Joaquin River at Vernalis are similar to the No Action Alternative throughout the year.

O.7.22.6 Bay-Delta

Non- spawning adults are present year-round predominantly in the brackish water interface where food is abundant. Larvae and juveniles are likely to remain upstream of the brackish water interface, where plant beds and slower waters occur.

Potential Changes to Largemouth, Smallmouth, and Spotted Bass from Seasonal Operations

CalSim 3 Flows

Alternative 4 compared to the No Action Alternative CalSim 3 modeling results show minor (≤ 5%) to substantial (≤ 54%) increases in flow and minor (5%) to slight (≤ 16%) decreases in flow in the Bay-Delta (Tables O.6-9, O.6-10, and O.6-11). At SWP and CVP exports, slight (8%, February) to moderate (25%, May) flow increases and slight (≤ 12%, December) are expected. At the confluence of Old and Middle River in the Delta, slight (16%, February) to substantial (≤ 54%, May) flow increases and slight (≤ 16%, December) are expected. For Delta outflow, a slight (6%) decrease in flow is generally expected in May. These differences suggest flows may have generally beneficial effects on largemouth, smallmouth, and spotted bass.

Summary

Overall, Alternative 4 compared to the No Action Alternative CalSim 3 flow modeling results had some differences. The differences determined by CalSim 3 modeling suggests flows may generally have beneficial impacts on largemouth, smallmouth, and spotted bass, depending on location and month.

Potential Changes to Entrainment of Largemouth Bass

Differences in exports under Alternative 4 compared with the No Action Alternative may have effects on largemouth bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for largemouth bass include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of largemouth bass under Alternative 4 compared to the No Action Alternative at the SWP Banks Pumping Plant was similar or higher and CVP Jones Pumping Plant was similar or lower all water year types (Tables O-157 and O-158). At the SWP Banks Pumping Plant predicted average monthly loss was up to 18% higher on below normal water years; loss was similar all other water years (Table O-157). At CVP Jones Pumping Plant predicted average monthly loss was up to 9% lower on dry and critically dry water years; loss was similar all other water years (Table O-158).

Potential Changes to Entrainment of Smallmouth Bass

Differences in exports under Alternative 4 compared with the No Action Alternative may have effects on smallmouth bass entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for smallmouth bass include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of smallmouth bass of Alternative 4 compared to the No Action Alternative at SWP Banks Pumping Plant was similar all water year types, except in above normal water years when loss would increase and critically dry water year types when no fish are expected; at CVP Jones Pumping Plant loss would be similar on below normal water years and increase in critically dry water years, all other water year types have no anticipated loss (Table O-159 and Table O-160). At the SWP Banks Pumping Plant predicted average monthly loss increased up to 8% in December through February of below normal water years (Table O-159). At the CVP Jones Pumping Plant predicted average monthly loss increased up to 7% in February of critically dry water years (Table O-160). It should be noted that loss of smallmouth bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Potential Changes to Entrainment of Spotted Bass

Salvage Density

Predictions from the salvage density model for spotted bass include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative.

Predicted average monthly loss of spotted bass of Alternative 4 compared to the No Action Alternative at SWP Banks Pumping Plant was similar in below normal water years and no fish are expected all other water year types; at CVP Jones Pumping Plant loss was similar most water year types, except critically dry water years when loss would decrease (Table O-161 and Table O-162). At the CVP Jones Pumping Plant predicted average monthly loss decreased up to 8% in January and August of critically dry water years (Table O-162). Historical loss of spotted bass at both facilities is rare and infrequent; this is a driver of low values of predicted loss.

Summary

Overall, Alternative 4 compared to the No Action Alternative salvage density modeling results had some differences. The salvage density modeling predicted monthly loss under Alternative 4 are generally slightly to largely lower for largemouth bass for nearly all water year types; a few exceptions at SWP Banks Pumping Plant where slight loss increases are expected compared to the No Action Alternative. The salvage density modeling predicted monthly loss under Alternative 4 are generally slightly to substantially lower for smallmouth bass for nearly all water year types; a few exceptions at SWP Banks Pumping Plant where slight loss increases are expected compared to the No Action Alternative. Overall, loss decreases at CVP Jones Pumping Plant and slight loss increases at SWP Banks Pumping Plant from entrainment of largemouth and smallmouth bass, while spotted bass would have both loss increases and decreases at both facilities under Alternative 4.

O.7.23 Starry Flounder

O.7.23.1 Bay-Delta

Adult starry flounder primarily inhabit coastal marine waters (Orcutt 1950; Haertel and Osterberg 1967; Bottom et al. 1984; Hieb and Baxter 1993). Distribution of age-0 juveniles within the San Francisco Estuary and Delta is primarily in Suisun Bay and San Pablo Bay, with lower abundance in the west Delta (Baxter et al. 1999). Starry flounder older than age 1 (age-1+ fish) occur principally in San Pablo Bay, Suisun Bay, and Central Bay (Baxter et al. 1999).

Starry flounder can tolerate a wide range of salinities. In the Sacramento and San Joaquin Rivers, starry flounder have been observed in salinities as low as 0.02–0.06 ppt (i.e., essentially fresh water) (Orcutt 1950). Age-0 and age-1+ starry flounder are a common species in estuarine habitats along the West Coast (see Orcutt 1950; Pearson 1989; Emmett et al. 1991; Baxter et al. 1999; Kimmerer 2002b).

Spawning occurs primarily during the winter months of December and January (Orcutt 1950). By age-two, many starry flounder are nearing reproductive maturity and have migrated to ocean habitats adjacent to their natal estuaries. Adults may move seasonally into shallow coastal waters

to spawn, perhaps in proximity to estuaries to take advantage of estuarine circulation which would advect fertilized eggs near the bottom into nursery areas.

Potential Changes to Starry Flounder from Seasonal Operations

Differences in Delta outflow between March and June due to seasonal operations under Alternative 4 compared with the No Action Alternative may have effects on starry flounder annual abundance in the Bay-Delta region. These possible differences were evaluated using modeled Delta outflow values from CalSim 3 that were then used as input to the relationship between outflow and abundance for the starry flounder.

Delta Outflow vs. Bay-Delta Species Abundance

Predictions from the Delta Outflow model for starry flounder indicated that the overall average abundance index for Alternative 4 would essentially be similar to mean abundance under the No Action Alternative across all water years (-3% to 0%), with considerable overlap in confidence intervals around median values. This would indicate substantial variability between years (Attachment J.6, *Bay-Delta Species Abundance- Delta Outflow Relationships*).

Summary

The Delta Outflow model indicated minimal adverse impacts on mean abundance for the starry flounder across all water year types when comparing Alternative 4 and the No Action Alternative, with a considerable overlap in confidence intervals. This suggests substantial variability between years.

Potential Changes to Entrainment of Starry Flounder

Differences in exports under Alternative 4 compared with the No Action Alternative may have effects on starry flounder entrainment at the Delta Fish Collection Facilities. These possible differences were evaluated using the Salvage Density Model (Attachment I.2, *Salvage Density Model Loss Simulation*).

Salvage Density

Predictions from the salvage density model for starry flounder include mean monthly total exports. Table O-271 shows modeled mean monthly total exports at SWP and CVP. Refer to the table for differences between Alternative 4 and the No Action Alternative. Predicted average monthly loss of starry flounder under Alternative 4 compared to the No Action Alternative at the SWP Banks Pumping Plant increased most water year types, except critically dry water years when loss was similar; at CVP Jones Pumping Plant loss was similar all water year types (Table O-163 and Table O-164). At the SWP Banks Pumping Plant predicted average monthly loss increase ranged from 12% in February through August of below normal water years to 51% in March, April, May, July, August, and November of dry water years (Table O-163). Historical loss of starry flounder at both facilities is infrequent; this is a driver of low values of predicted loss.

Summary

Alternative 4 relative to the No Action Alternative is expected to have a minimal adverse impact on entrainment of starry flounder due to difference in exports. The predicted average monthly loss of starry flounder due to operations at SWP Banks were projected to increase in most water

year types and be similar to the No Action Alternative in critically dry years. At the CVP Jones, loss was similar to the No Action Alternative across all water year types.

O.7.24 Coastal Pelagic Species

O.7.24.1 Potential Changes to Northern Anchovy and Pacific Herring from Seasonal Operations

Northern anchovy and Pacific herring could be subject to operational effects of the Proposed Action as it pertains to Delta outflow and its effect on the salinity field. However, the effects on salinity would be small relative to the salinity tolerance of Coastal Pelagic Species EFH such as Northern Anchovy (Baxter et al. 1999). Kimmerer et al. (2009) showed for Northern Anchovy that neither indices of habitat extent nor indices of abundance were related to X2, an index of Delta outflow and its effects.

Kimmerer (2009) found Pacific herring abundance indices were not associated with flow. However, Pacific herring do utilize the San Francisco Bay Estuary as spawning and rearing habitat (Pak et al. 2023, Grimaldo et al. 2020, Watters et al. 2004). Grimaldo et al. (2020) found Pacific herring larvae presence and abundance was lower in landward regions (e.g. Suisun Bay) during a high outflow year, likely due to either increased advection from high flows or reduced net landward movement via gravitational circulation. Juvenile herring abundance in Suisun Bay in the spring is associated with saltier conditions that allow their range to expand landward (Pak et al. 2023).

O.7.24.2 Potential Changes to Entrainment of Northern Anchovy and Pacific Herring

There are no expected impacts to entrainment of Northern anchovy due to operations since the distribution in the San Francisco Estuary has shifted towards higher salinities (> 20) since the introduction of the invasive clam, *Potamocorbula amurensis* (Kimmerer 2006). Impacts to entrainment of Pacific herring are potentially adverse in drier water year types depending on severity but are likely to be extremely rare. Historical salvage of Pacific herring has only occurred a few times since 2000, primarily in 2014, a critically dry year (during the months of March and April), fish were also salvaged in 2019 and 2020 in much lower numbers (CDFW 2024c).

O.7.25 Southern Oregon/Northern California Coast Coho salmon ESU

O.7.25.1 Trinity River

Spawning and Egg/Alevin Incubation

Most coho salmon spawning in the mainstem Trinity River occurs in November and December between Lewiston Dam and the North Fork Trinity River (Section O.1.2.5.1, *Coho salmon, Southern Oregon/Northern California Coast ESU*). Coho salmon eggs and alevins in the Trinity and Klamath River basins may be present in the gravel from November to mid-May (Leidy and Leidy 1984), so effects of flow and water temperature on coho salmon eggs and alevins may occur during this period.

Potential Changes to Coho Salmon from Seasonal Operations

Under Alternative 4, modeled monthly average flows in the Trinity River below Lewiston Dam in December of wet water years, January of wet water years, and February of above normal water years would be at least 5% greater than the No Action Alternative (Table O-264). These changes would have variable effects on the availability and suitability of spawning and egg/alevin incubation habitat for coho salmon.

In December and January when coho salmon are spawning and eggs/alevins may be incubating in the Trinity River, modeled monthly average flow would increase in December of wet water years from 1,133 cfs under the No Action Alternative to 1,193 cfs under Alternative 4 and in January in wet water years from 1,872 cfs under the No Action Alternative to 1,985 cfs under Alternative 4 (Table O-264). In February when coho salmon eggs/alevins are incubating, modeled monthly average flow in above normal water years would increase in February from 1,194 cfs under the No Action Alternative to 1,393 cfs under Alternative 4.

The increased modeled monthly average flow in December of wet water years may provide variable changes to spawning coho salmon by slightly increasing WUA for spawning adults in the most heavily used spawning reach from Lewiston to Dutch Creek and slightly decreasing WUA for spawning adults in the lesser used downstream reaches (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999; Rupert et al. 2017a, b). In January, the increased monthly average flow in wet water years may increase spawning WUA for coho salmon in lesser-used downstream portions of the Trinity River but is predicted to have little to no change in spawning WUA in the more heavily used reach from Dutch Creek to North Fork Trinity River (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

The effect of the modeled December and January flow increases on spawning suitability in the reach from Lewiston Dam to Dutch Creek is uncertain because WUA for adult salmon in this reach has not been quantified for flows above 800 cfs (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In this reach as in other reaches, WUA is likely to vary spatially with channel confinement and incision (Goodman et al. 2018).

Compared with the No Action Alternative, the December and January flow increases would not result in changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-20 and Figure O-21) and average water temperatures under Alternative 4 would likely remain well below the upper water temperature objective of 56°F to protect spawning coho salmon in the reach from Lewiston Dam to the North Fork Trinity River (Table O-11). In all but the driest water years, average December and January water temperatures from Lewiston Dam to the North Fork Trinity River would likely remain below the 50°F upper suitability limit recommended by Washington State Department of Ecology (WDOE) (2002, as cited in Carter 2005) to support coho salmon incubation and emergence (Asarian et al. 2023).

Compared with the No Action Alternative, the increased monthly average flows in December and January under Alternative 4 would likely have variable effects on the availability and suitability of coho salmon spawning and incubation habitat in the Trinity River, potentially including an increase in the amount of usable habitat in the reaches most heavily used by coho salmon. The potential increase would occur in December in wet water years, which have occurred 28% of the

time over the 100-year simulation period. In the lesser used downstream reaches, there would be a modeled increase in WUA in January of wet water years.

Although WUA for egg/alevin incubation is not available for the Trinity River, the changes in modeled monthly average flows in above normal water years in February under Alternative 4 would be unlikely to change redd hydraulics or redd substrate conditions relative to the No Action Alternative, and no effects on egg/alevin incubation suitability are expected. The modeled February flow increases would result in no change in modeled monthly average water temperature relative to the No Action Alternative (Figure O-17) and water temperature in February under Alternative 4 would remain well below the 50°F upper suitability limit recommended by Washington State Department of Ecology (WDOE) (2002, as cited in Carter 2005) to support coho salmon incubation and emergence (Asarian et al. 2023). Compared with the No Action Alternative, the flow increases in February under Alternative 4 would be unlikely to have substantial impacts on the availability or suitability of coho salmon spawning and egg/alevin incubation habitat.

Compared with the No Action Alternative, the changes in seasonal operations in December, January, and February under Alternative 4 are expected to have minor adverse impacts to benefits on the availability or suitability of coho salmon spawning and egg/alevin incubation habitat.

Juvenile Rearing and Emigration

Naturally spawned juvenile coho salmon in the Trinity River emerge from the gravel and begin rearing in winter and early spring, with the first captures of young-of-year (age-0) coho salmon typically occurring in early March (U.S. Fish and Wildlife Service 2023, unpublished; Yurok Tribe 2023, unpublished). Fry, juvenile, and subyearling coho salmon rearing in the Trinity River strongly prefer areas of slow water velocity and habitat with cover from woody material, overhanging vegetation, and clusters of aquatic vegetation (Hampton 1988, 1997; Chase et al. 2009; Pinnix et al. 2019). During high flows, young coho salmon use floodplains and other off-channel habitats (Chase et al. 2009). Rearing occurs year-round, typically over a period of 12–15 months, and the effects of flow and water temperature on rearing coho salmon therefore occur throughout the year. Most Trinity River coho salmon outmigrate to the ocean as yearling smolts between January and July (Harris et al. 2016; Petros et al. 2015; Petros et al. 2017).

Potential Changes to Coho Salmon from Seasonal Operations

Seasonal operations under Alternative 4 would have spatially and temporally variable effects on the availability and suitability of juvenile rearing and emigration habitat for coho salmon. Compared with the No Action Alternative, substantial differences (greater than 5%) in modeled monthly average flows would occur in some water year types in December, January, and February and are described in detail in the preceding sections and shown in Table O-264. In all other months and water year types there would be little or no difference in modeled monthly average flow between Alternative 4 and the No Action Alternative and no effects on coho salmon would be expected.

Compared with the No Action Alternative, the increased modeled monthly average flow in December of wet water years would have little to no change in WUA for fry and juvenile coho salmon across all reaches of the Trinity River from Lewiston Dam to Weitchpec (U.S. Fish and

Wildlife Service & Hoopa Valley Tribe 1999). In December of wet water years, increased monthly average flow under Alternative 4 would result in a slight increase in fry WUA and a slight decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, little to no change in fry and juvenile WUA in the reach from Dutch Creek to North Fork Trinity River, little to no change in fry WUA and a slight decrease in juvenile WUA in the reach from North Fork Trinity River to South Fork Trinity River, and a slight increase in fry WUA and little to no change in juvenile WUA in the reach from South Fork Trinity River to Weitchpec.

The increased monthly average flows in January in wet water years would result in increases in WUA for fry and juvenile coho salmon from Lewiston Dam to Dutch Creek, no change in fry and juvenile WUA from Dutch Creek to North Fork Trinity River, a slight increase in fry WUA and a slight decrease in juvenile WUA from North Fork Trinity River to South Fork Trinity River, and little to no change in fry and juvenile WUA from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

The effect of flow differences on rearing suitability is likely to vary spatially with channel confinement and incision (Cooper-Hertel et al. 2022). In locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships. These changes in WUA for coho salmon fry and juveniles may have minor, short-term effects on the ability of these life stages to access cover and preferred habitat that would occur only in a few months of the 12–15 month rearing period and in some reaches of the Trinity River.

In December of wet water years, January of wet water years, and February of above normal water years, differences in modeled monthly average flows between Alternative 4 and the No Action Alternative would not result in differences in modeled monthly average water temperature in the Trinity River below Lewiston (Figure O-20 and Figure O-21, respectively).. December, January, and February of the aforementioned water year types, modeled monthly average water temperatures at Trinity River below Lewiston Dam under Alternative 4 would remain well below the 59°F water temperature objective for emigrating juvenile coho salmon (smolts) recommended for normal and wetter water year types and the 62.6°F objective in dry and critically dry water years (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999).

Although the water temperature objectives are intended to be measured at Weitchpec and applicable prior to June 4, historical data and model results suggest that water temperatures in December, January, and February would remain below both objectives under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating coho salmon under Alternative 4 relative to the No Action Alternative. The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 4 through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives in portions of the coho salmon juvenile rearing and emigration period at downstream locations in some water year types under Alternative 4, water temperatures and the potential effects on coho salmon would not differ from the No Action Alternative.

Compared with the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 4 would cause only negligible changes in factors affecting the availability or suitability of coho salmon rearing and emigration habitat and substantial impacts on coho salmon would be unlikely.

Adult Upstream Migration and Holding

From August to January, coho salmon return from the ocean through the Klamath River Estuary to the Trinity River, moving upstream toward spawning habitat. Based on recent weir counts, the date of peak abundance of upstream-migrating coho salmon in the Trinity River ranges from late September to mid-November (Kier et al. 2018, 2019, 2020, 2021, 2022). After completing their upstream migration, mature coho salmon may hold for days, weeks, or sometimes months before spawning. Because most spawning occurs in November and December, the effects of flow and water temperature on migrating and holding coho salmon would primarily occur from August through December.

Potential Changes to Coho Salmon from Seasonal Operations

During the coho salmon upstream migration and holding period there would be no differences in modeled monthly average flow between Alternative 4 and the No Action Alternative in August, September, October, or November and substantial (greater than 5%) differences in December and January. Differences would vary by month and water year type, and are described in detail in the preceding sections and shown in Table O-264. These differences may result in minor, short-term changes in habitat conditions but modeled monthly average flows from August through December when adult coho salmon are migrating and holding would be equal to or greater than 300 cfs in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and holding habitat to support pre-spawning coho salmon.

Modeled monthly average flows in August and September, when adult coho salmon begin migrating upstream from the ocean and water temperatures are typically at or near seasonal highs (Asarian et al. 2023), would be the same under Alternative 4 as under the No Action Alternative (Table O-264). Under both alternatives, modeled August and September flows of 760 cfs in wet water years and 863 cfs in all other water year types would maintain suitable water temperatures for adult upstream migration (60°F in August and early September and 56°F in late September; Table O-11) based on modeled monthly average water temperatures in the Trinity River at Lewiston Dam (Figure O-17). Although downstream warming during August and September could result in unsuitable water temperatures for migrating coho salmon at some locations, the likelihood of this occurring would be the same under Alternative 4 as under the No Action Alternative due to the identical flows.

During the late September to mid-November peak adult migration period, the modeled monthly average flows under Alternative 4 would be the same as the No Action Alternative except for a reduction of 5 cfs in November in above normal water years (Table O-264), which is essentially the same. In December and January, a substantial flow difference (greater than 5%) between the two alternatives would be a modeled increase of 60 cfs in December in wet water years from 1,133 cfs under the No Action Alternative to 1,193 cfs under Alternative 4 and in January in wet water years would be a modeled increase of 114 cfs under the No Action Alternative from 1,872 cfs to 1,985 cfs under Alternative 4. The December flow difference would not have measurable

impacts on modeled monthly average water temperature at Lewiston Dam in the respective water year types (Figure O-20 and Figure O-21) and there would be no impacts on water temperature suitability for coho salmon migration and holding relative to the No Action Alternative. Compared with the No Action Alternative, the differences in modeled monthly average flows and associated differences in modeled monthly average water temperature under Alternative 4 would cause only negligible changes in factors affecting the availability or suitability of coho salmon upstream migration and holding habitat and substantial impacts on coho salmon would be unlikely.

O.7.26 Upper Klamath-Trinity River Spring-run Chinook Salmon ESU

O.7.26.1 Trinity River

Spawning and Egg/Alevin Incubation

Most spring-run Chinook salmon in the Trinity River spawn from late September to mid-November, with a peak in October (Gough et al. 2021a,b). At optimal intragravel temperatures (41–55°F) the incubation period lasts 40–60 days and alevins may remain in the gravel for another four to six weeks (Healey 1991, Moyle 2002). In the Trinity River, spring-run Chinook salmon incubation and emergence typically occurs through February (Leidy and Leidy 1984). The effects of flow and water temperature on spring-run Chinook salmon spawning and egg/alevin incubation may therefore occur from approximately mid-September through February.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Under Alternative 4, modeled monthly average flows in the Trinity River below Lewiston Dam in December of wet water years, January of wet water years, and February of above normal water years would be at least 5% greater than the No Action Alternative (Table O-264). The monthly flow differences would have minor effects on the availability or suitability of spawning and egg/alevin incubation habitat for spring-run Chinook salmon relative to the No Action Alternative. Under Alternative 4, like the No Action Alternative, the variable flow regime is expected to maintain spawning habitat quality through periodic scour and redeposition of spawning gravel, which is intended to improve incubation conditions and egg-to-emergence survival by reducing fine sediment.

Modeled monthly average flow in December of wet water years would increase from 1,133 cfs under the No Action Alternative to 1,193 cfs under Alternative 4. Some adult spring-run Chinook salmon may still be spawning and eggs/alevins may be incubating during December. The December flow increase may benefit spawning spring-run Chinook salmon by increasing WUA for spawning adults in the downstream portion of the primary spawning reach from Dutch Creek to North Fork Trinity River compared with the No Action Alternative (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999; Rupert et al. 2017a, b). The WUA results for spawning spring-run Chinook salmon in the upstream portion of the primary spawning reach from Lewiston Dam to Dutch Creek do not include flows greater than 800 cfs so no WUA evaluation is possible for this segment of the river. Comparative effects on spawning suitability would vary in reaches downstream of North Fork Trinity River, with a decrease in spawning WUA from North Fork Trinity River to South Fork Trinity River and no change in spawning WUA from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe

1999). The effects of flow changes on spawning suitability are likely to vary spatially with channel confinement and incision (Goodman et al. 2018), with the modeled average flow increase in December of wet water years potentially resulting in greater spawning WUA in unconfined channels than in confined channels. Although WUA for egg/alevin incubation is not available for the Trinity River, the modeled flow increase under Alternative 4 in December of wet water years is unlikely to cause changes in redd hydraulics, sediment, or other conditions relative to the No Action Alternative, and no effects on egg/alevin incubation suitability are expected.

In January of wet water years, modeled monthly average flow would increase from 1,872 cfs under the No Action Alternative to 1,985 cfs under Alternative 4 (Table O-264). In February of above normal water years, modeled monthly average flow would increase from 1,194 cfs under the No Action Alternative to 1,393 cfs under Alternative 4. Although WUA for egg/alevin incubation is not available for the Trinity River, the January and February flow increases are not expected to change redd hydraulics, sediment, or other conditions that may affect incubation suitability.

The modeled December flow increase would not result in measurable changes in modeled average water temperature in the Trinity River below Lewiston Dam (Figure O-17) and average water temperatures under Alternative 4 would likely remain well below the upper water temperature objective of 56°F to protect spawning spring-run Chinook salmon in the reach from Lewiston Dam to the North Fork Trinity River (Table O-11). Similarly, the January and February flow increases would not result in measurable changes in modeled average water temperature in the Trinity River below Lewiston Dam (Figure O.3-1) and average water temperatures under Alternative 4 would remain below the 50°F (10°C) upper optimum limit recommended by USEPA (2001, as cited in Carter 2005) from Lewiston Dam to North Fork Trinity River in all water year types to support spring-run Chinook salmon incubation and emergence (Asarian et al. 2023).

Overall, the impacts in the reaches most heavily used by spawning and incubating spring-run Chinook salmon would likely be negligible or slightly beneficial under Alternative 4 relative to the No Action Alternative, with spatial variability related to the effects of channel geometry on habitat suitability.

Juvenile Rearing and Emigration

In the Trinity River, spring-run Chinook salmon fry emerge from the gravel beginning in December and most emergence is complete by the end of February (Leidy and Leidy 1984). Fry and juvenile Chinook salmon rearing in the Trinity River preferentially use areas of relatively slow water velocity and habitat with woody material, undercut banks, and other complex cover (Hampton 1988, Pinnix et al. 2019). Naturally spawned juvenile spring-run Chinook salmon typically outmigrate as sub-yearlings from the Trinity River and occasionally as yearlings. Hatchery releases of spring-run Chinook salmon also include mostly sub-yearlings and some yearling releases in spring and fall, respectively. Peak outmigration of natural and hatchery origin juveniles occurs in May, June, and July based on monitoring in the lower Trinity River near the town of Willow Creek (Harris et al. 2016; Petros et al. 2017). The effects of flow and water temperature on rearing and emigrating spring-run Chinook salmon may therefore occur from December through July.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Under Alternative 4, modeled monthly average flows in the Trinity River below Lewiston Dam in December of wet water years, January of wet water years, and February of above normal water years would be at least 5% greater than the No Action Alternative (Table O-264). The December, January, and February differences may have spatially variable effects on the availability and suitability of juvenile rearing and emigration habitat for spring-run Chinook salmon.

The increase in modeled monthly average flow in December in wet water years from 1,133 cfs under the No Action Alternative to 1,193 cfs under Alternative 4 would result in an increase in fry WUA and a decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, a decrease in both fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and an increase in fry WUA and a decrease in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The modeled monthly average flow increase in January of wet water years from 1,872 cfs under the No Action Alternative to 1,985 cfs under Alternative 4 would result in an increase in fry and juvenile WUA in the reach from Lewiston Dam to Dutch Creek, a decrease in fry and juvenile WUA in the reach from Dutch Creek to North Fork Trinity River, an increase in fry WUA and a decrease in juvenile WUA in the reach from North Fork Trinity River to South Fork Trinity River, and an increase in fry WUA and no change in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In February of above normal water years, the modeled monthly average flow increase from 1,194 cfs under the No Action Alternative to 1,393 cfs under Alternative 4 would result in an increase in fry WUA and a decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, a decrease in both fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and a decrease in fry WUA and no change in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Where the channel is naturally unconfined and not overly incised and in locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships and rearing WUA in some restored areas may exhibit a stronger positive relationship to flow up to approximately 3,500 cfs (Cooper-Hertel et al. 2022). Consequently, spring-run Chinook salmon WUA in all reaches is likely to vary spatially with channel confinement and incision and WUA in restored areas may be greater than described in U.S. Fish and Wildlife Service and Hoopa Valley Tribe (1999). See Section O.4.24.1.1 for additional details. The potential changes in WUA for spring-run Chinook salmon fry and juveniles may have minor, short-term effects on the ability of these life stages to access cover and preferred habitat that would occur only in a few months of the eight-month rearing and emigration period and in some reaches of the Trinity River and in certain water years.

In December and January of wet water years and February of above normal water years, differences in modeled monthly average flows between Alternative 4 and the No Action Alternative would not result in measurable changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figures O-19 and O-17). In these months and water year types, modeled monthly average water temperatures at Trinity River below Lewiston Dam under Alternative 4 would remain well below the 62.6°F water temperature

objective for emigrating juvenile spring-run Chinook salmon recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the objectives are intended to be measured at Weitchpec and applicable prior to July 9, historical data and model results suggest that water temperatures in December, January, and February would remain below the objective under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating spring-run Chinook salmon under Alternative 4 relative to the No Action Alternative.

Compared with the No Action Alternative, seasonal operations under Alternative 4 would likely have negligible impacts on the availability and suitability of spring-run Chinook salmon juvenile rearing and emigration habitat in the Trinity River. The impacts would vary spatially due to the effects of channel geometry on habitat suitability.

Adult Upstream Migration and Holding

Adult spring-run Chinook salmon typically enter the Trinity River from April through September. By the end of July, most fish have arrived at the primary spawning reach, which extends from Lewiston Dam downstream to the confluence with the North Fork Trinity River. After entering freshwater, spring-run Chinook salmon remain in deep pools until the onset of the spawning season, which typically begins in late September (Leidy and Leidy 1984; Gough et al. 2019, 2021a,b). The effects of flow and water temperature on migrating and holding spring-run Chinook salmon adults may therefore occur from April through September.

Potential Changes to Spring-run Chinook Salmon from Seasonal Operations

Under Alternative 4, seasonal operations in the Trinity River are expected to provide similar habitat conditions for spring-run Chinook salmon upstream migration and holding to the No Action Alternative. Like the No Action Alternative, Trinity River flow and water temperature below Lewiston Dam would be managed to maintain suitable habitat conditions for anadromous fish including Chinook salmon. During the April–September spring-run Chinook salmon upstream migration and holding period there would be minor (less than 5%) differences in modeled monthly average flow between the two alternatives in April and no differences in May through September (Table O-264). The minor differences in April are not expected to result in changes in habitat suitability for migrating and holding spring-run Chinook salmon. During the entirety of the adult upstream migration and holding period, monthly average flows would be approximately 500 cfs or greater in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and holding habitat to support pre-spawning spring-run Chinook salmon.

Modeled monthly average flows in July, August and September, when adult spring-run Chinook salmon may be holding and water temperatures are typically at or near seasonal highs (Asarian et al. 2023), would be the same under Alternative 4 as under the No Action Alternative (Table O-264). Under both alternatives, July–September flows would maintain suitable water temperatures for adult upstream migration (60°F from July 1 to September 14 and 56°F from September 15 to September 30 at Douglas City [RM 93.7]; Table O-11) (Asarian et al. 2023). Although downstream warming during the warmest months and driest water year types could result in unsuitable water temperatures for migrating spring-run Chinook salmon at some locations (Buxton 2023), the likelihood of this occurring would be the same under Alternative 4 as under the No Action Alternative because May–September flows would be the same under both

alternatives. Under Alternative 4, suitability for adult spring-run Chinook salmon upstream migration and holding would be the same as under the No Action Alternative.

O.7.27 Upper Klamath-Trinity River Fall-run Chinook Salmon ESU

O.7.27.1 Trinity River

Spawning and Egg/Alevin Incubation

Most fall-run Chinook salmon in the Trinity River spawn from late October to December, with a peak in spawning occurring in November (Myers et al. 1998, Leidy and Leidy 1984). Optimal spawning temperatures are reported to be less than 55.4°F (Moyle 2002). At optimal intragravel temperatures (43–54°F) the incubation period lasts 40–60 days and alevins may remain in the gravel for another 4–6 weeks (Moyle 2002). In the Trinity River, fall-run Chinook salmon incubation and emergence typically occurs from December through late February (Leidy and Leidy 1984). The effects of flow and water temperature on fall-run Chinook salmon spawning and egg/alevin incubation may therefore occur from approximately mid-October through February.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Under Alternative 4, modeled monthly average flows in the Trinity River below Lewiston Dam in December of wet water years, January of wet water years, and February of above normal water years would be at least 5% greater than the No Action Alternative (Table O-264). The December, January, and February flow increases would occur during the egg/alevin incubation period. The monthly flow differences would have minor effects on the suitability of egg/alevin incubation habitat for fall-run Chinook salmon relative to the No Action Alternative. Under Alternative 4, like the No Action Alternative, the variable flow regime is expected to periodically scour and redeposit spawning gravel, which is expected to improve incubation conditions and egg-to-emergence survival by reducing fine sediment.

Modeled monthly average flow in the Trinity River below Lewiston Dam would increase in December of wet water years from 1,133 cfs under the No Action Alternative to 1,193 cfs under Alternative 4 and in January of wet water years from 1,872 cfs under the No Action Alternative to 1,985 cfs under Alternative 4 (Table O-264). In February of above normal water years, modeled monthly average flow would increase from 1,194 cfs under the No Action Alternative to 1,393 cfs under Alternative 4. Although WUA for egg/alevin incubation is not available for the Trinity River, these modeled flow increases are unlikely to cause changes in redd hydraulics, sediment, or other conditions relative to the No Action Alternative, and no changes in egg/alevin incubation suitability are expected.

The modeled December, January, and February flow increases would not result in measurable changes in modeled average water temperature in the Trinity River below Lewiston Dam (Figure O.-17) and average water temperatures under Alternative 4 would remain below the 50°F (10°C) upper optimum limit recommended by USEPA (2001, as cited in Carter 2005) from Lewiston Dam to North Fork Trinity River in all water year types to support fall-run Chinook salmon incubation and emergence (Asarian et al. 2023).

Overall, the impacts in the reaches most heavily used for spawning and incubation by fall-run Chinook salmon would likely be negligible under Alternative 4 relative to the No Action Alternative.

Juvenile Rearing and Emigration

In the Trinity River, fall-run Chinook salmon fry emerge from the gravel beginning in December and most emergence is complete by mid-April. Natural juvenile fall-run Chinook salmon primarily outmigrate as sub-yearlings from the Trinity River. Hatchery releases of fall-run Chinook salmon also include mostly smolts released primarily in late spring and fall. Peak outmigration occurs in March, April, and May but can extend to July based on monitoring in the lower Trinity River near the town of Willow Creek (Moyle 2002, Chesney and Yokel 2003). The effects of flow and water temperature on rearing and emigrating fall-run Chinook salmon may therefore occur primarily from December through July.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Under Alternative 4, modeled monthly average flows in the Trinity River below Lewiston Dam would be at least 5% greater than the No Action Alternative in December of wet water years, January of wet water years, and February of above normal water years (Table O-264). The modeled December, January, and February flow increases may have spatially variable effects on the availability and suitability of juvenile rearing and emigration habitat for fall-run Chinook salmon. The increase in modeled monthly average flow in December of wet water years from 1,133 cfs under the No Action Alternative to 1,193 cfs under Alternative 4 would result in an increase in fry WUA and a decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, a decrease in both fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and an increase in fry WUA and a decrease in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The modeled monthly average flow increase in January of wet water years from 1,872 cfs under the No Action Alternative to 1,985 cfs under Alternative 4 would result in an increase in fry and juvenile WUA in the reach from Lewiston Dam to Dutch Creek, a decrease in fry and juvenile WUA in the reach from Dutch Creek to North Fork Trinity River, an increase in fry WUA and a decrease in juvenile WUA in the reach from North Fork Trinity River to South Fork Trinity River, and an increase in fry WUA and no change in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In February of above normal water years, the modeled monthly average flow increase from 1,194 cfs under the No Action Alternative to 1,393 cfs under Alternative 4 would result in an increase in fry WUA and a decrease in juvenile WUA in the reach from Lewiston Dam to Dutch Creek, a decrease in both fry and juvenile WUA in the reaches from Dutch Creek to North Fork Trinity River and North Fork Trinity River to South Fork Trinity River, and a decrease in fry WUA and no change in juvenile WUA in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Where the channel is naturally unconfined and not overly incised and in locations where channel restoration has reduced anthropogenic confinement and incision, the 1999 WUA estimates may not accurately represent contemporary flow-habitat relationships and rearing WUA in some restored areas may exhibit a stronger positive relationship to flow up to approximately 3,500 cfs (Cooper-Hertel et al. 2022). Consequently, fall-run Chinook salmon WUA in all reaches is likely to vary spatially with channel confinement and incision and in

WUA in restored areas may be greater than described in U.S. Fish and Wildlife Service and Hoopa Valley Tribe (1999) at all but the lowest flows. See Section O.4.24.1.1 for additional details. The potential changes in WUA for fall-run Chinook salmon fry and juveniles may have minor, short-term effects on the ability of these life stages to access cover and preferred habitat that would occur only in a few months during the rearing and emigration period and in some reaches of the Trinity River and certain water years.

In December and January of wet water years and February of above normal water years, differences in modeled monthly average flows between Alternative 4 and the No Action Alternative would not result in measurable changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figures O-19 and O-17). In these months and water year types, modeled monthly average water temperatures at Trinity River below Lewiston Dam under Alternative 4 would remain well below the 62.6°F water temperature objective for emigrating juvenile fall-run Chinook salmon recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the objectives are intended to be measured at Weitchpec and applicable prior to July 9, historical data and model results suggest that water temperatures in December, January, and February would remain below the objective under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating fall-run Chinook salmon under Alternative 4 relative to the No Action Alternative.

Compared with the No Action Alternative, seasonal operations under Alternative 4 would likely have negligible impacts on the availability and suitability of fall-run Chinook salmon juvenile rearing and emigration habitat in the Trinity River. The impacts would vary spatially due to the impacts of channel geometry on habitat suitability.

Adult Upstream Migration and Holding

Adult fall-run Chinook salmon typically enter the Trinity River from September through October (Moyle et al. 2015). Two to four weeks after river entry, adults have made it to the primary spawning reach which extends from Lewiston Dam downstream to the confluence of the North Fork Trinity River. After entering freshwater, fall-run Chinook salmon remain in deep pools until the onset of the spawning season, which typically ranges from the third week of September through November, peaking in October (Chesney and Knechtle 2012). The effects of flow and water temperature on migrating and pre-spawning fall-run Chinook salmon adults may therefore occur from August through November.

Potential Changes to Fall-run Chinook Salmon from Seasonal Operations

Under Alternative 4, seasonal operations in the Trinity River are expected to provide similar habitat conditions for fall-run Chinook salmon upstream migration and holding to the No Action Alternative. Like the No Action Alternative, Trinity River flow and water temperature below Lewiston Dam would be managed to maintain suitable habitat conditions for anadromous fish including Chinook salmon. During the August through November fall-run Chinook salmon upstream migration and pre-spawning period there would be no differences in modeled monthly average flow from August through October, and less than 5% reduction in flow in November of above normal water years (Table O-264). The modeled average flow difference in November would be negligible (5 cfs) and is not expected to result in changes in habitat suitability for migrating and holding fall-run Chinook salmon. During the entirety of the adult upstream

migration and holding period, modeled monthly average flows would be approximately 300 cfs or greater in all water year types, and substantially greater in some months and water years, to provide suitable depth for upstream passage as well as access to cover and holding habitat to support pre-spawning fall-run Chinook salmon.

Modeled monthly average flows in August, September, and October during the adult fall-run Chinook salmon migration and pre-spawning period would be the same under Alternative 4 as under the No Action Alternative (Table O-264). Under both alternatives, modeled average August and September flows would be approximately 760 cfs or greater in all water year types and substantially greater in wetter years. Modeled average flows in October would be 373 cfs in all water year types. Under both alternatives, September through October flows would maintain suitable water temperatures for adult upstream migration (60°F to 56°F in September, and <56°F from August through October at Douglas City [RM 93.7]; Table O-11) (Asarian et al. 2023). Under Alternative 4, suitability for adult fall-run Chinook salmon upstream migration and pre-spawning would be the same as the No Action Alternative.

O.7.28 Klamath Mountains Province Steelhead DPS

O.7.28.1 Trinity River

Monthly average flows in the Trinity River below Lewiston Dam would generally be similar under Alternative 4 to flows under the No Action Alternative. Differences in modeled monthly average flows between Alternative 4 and the No Action Alternative would occur in November through April of some water year types, with most differences less than 5%. Like the No Action Alternative, seasonal flow releases under Alternative 4 are expected to maintain a low risk of disease outbreaks for steelhead by maintaining minimum flows and relatively cool water temperatures.

Spawning and Egg/Alevin Incubation

Spawning across run types in the Trinity River may occur anytime from December through May so effects of flow and water temperature on spawning may occur during this period.

Steelhead eggs and alevins across run types in the Trinity River may be present in the gravel from December through June, so effects of flow and water temperature on steelhead eggs and alevins may occur during this period.

Potential Changes to Steelhead from Seasonal Operations

Under Alternative 4, modeled monthly average flows in the Trinity River below Lewiston Dam in December of wet water years, January of wet water years, and February of above normal water years would be at least 5% greater than the No Action Alternative (Table O-264). These changes would have variable effects on the availability and suitability of spawning and egg/alevin incubation habitat for steelhead. In March and April, modeled monthly average flows under Alternative 4 would be largely the same as the No Action Alternative, with minor (less than 5%) differences in March in a few water year types and negligible differences in April in a few water year types. Modeled monthly average flows in May under Alternative 4 would be the same as the No Action Alternative.

Modeled monthly average flow in the Trinity River below Lewiston Dam would increase in December of wet water years from 1,133 cfs under the No Action Alternative to 1,193 cfs under Alternative 4 and in January of wet water years from 1,872 cfs under the No Action Alternative to 1,985 cfs under Alternative 4 (Table O-264). In February of above normal water years, modeled monthly average flow would increase from 1,194 cfs under the No Action Alternative to 1,393 cfs under Alternative 4.

The increased modeled monthly average flow in December of wet water years would result in slightly increased WUA for spawning adults from Dutch Creek to North Fork Trinity River and little to no change from North Fork Trinity River to South Fork Trinity River and South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). The effect of the modeled December flow increase on spawning suitability in the reach from Lewiston Dam to Dutch Creek is uncertain because WUA in this reach has not been quantified for flows above 800 cfs (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In this reach as in other reaches, WUA for spawning is likely to vary spatially with channel confinement and incision (Goodman et al. 2018). Compared with the No Action Alternative, the December flow increase would not result in measurable changes in modeled monthly average water temperature in the Trinity River below Lewiston Dam (Figure O-20 and Figure O-21) and average water temperatures under Alternative 4 would likely remain well below the upper water temperature objective of 56°F to protect spawning salmonids in the reach from Lewiston Dam to the North Fork Trinity River (Table O-11). Compared with the No Action Alternative, the increased monthly average flows in December under Alternative 4 would likely have a negligible or slightly beneficial effect on the availability and suitability of steelhead spawning and incubation habitat in the Trinity River.

The modeled flow increases in January of wet water years would result in little to no change in WUA for steelhead spawning in the reaches from Dutch Creek to South Fork Trinity River and a small increase in the reach from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). In February of above normal water years, the modeled flow increase would result in a negligible decrease in WUA for steelhead spawning from Dutch Creek to North Fork Trinity River, a decrease from North Fork Trinity River to South Fork Trinity River, and an increase from South Fork Trinity River to Weitchpec. The modeled December, January, and February flow increases would not result in measurable changes in modeled monthly average water temperatures relative to the No Action Alternative (Figure O-17) and water temperatures would remain well below the 56°F upper water temperature objective for spawning salmonids. Compared with the No Action Alternative, the flow increases in December, January, and February under Alternative 4 would be unlikely to have substantial effects on the availability or suitability of steelhead spawning and egg/alevin incubation habitat.

Compared with the No Action Alternative, the change in seasonal operations in December, January, and February under Alternative 4 is expected to have few substantial impacts on the availability or suitability of steelhead spawning and egg/alevin incubation habitat.

Juvenile Rearing and Emigration

Rearing or moving (migrating or redistributing) fry and/or juveniles can occur downstream of Lewiston Dam any time of year, with peak emigration times in March, May/June, and October/November.

Potential Changes to Steelhead from Seasonal Operations

Seasonal operations under Alternative 4 would have spatially and temporally variable effects on the availability and suitability of rearing and emigration habitat for steelhead fry and juveniles. Compared with the No Action Alternative, substantial increases (greater than 5%) in modeled monthly average flows would occur in some water year types in December, January, and February and are described in detail in the preceding section and shown in Table O-264. In all other months and water year types there would be little or no difference in modeled monthly average flow between Alternative 4 and the No Action Alternative and no effects on steelhead would be expected in those months.

Compared with the No Action Alternative, the increased modeled monthly average flow in December of wet water years would increase WUA for steelhead fry and would decrease or result in no change in WUA for steelhead juveniles in the Trinity River from Lewiston Dam to Dutch Creek (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). From Dutch Creek to North Fork Trinity River and from North Fork Trinity River to South Fork Trinity River, WUA for steelhead fry and juveniles would decrease relative to the No Action Alternative. From South Fork Trinity River to Weitchpec, there would be an increase in WUA for steelhead fry and a decrease in WUA for steelhead juveniles.

In January of wet water years, the increased modeled monthly average flow relative to the No Action Alternative would result in an increase in steelhead fry WUA and a decrease in steelhead juvenile WUA from Lewiston Dam to Dutch Creek, a decrease in steelhead fry and juvenile WUA from Dutch Creek to North Fork Trinity River, and an increase in steelhead fry WUA and a decrease in steelhead juvenile WUA from North Fork Trinity River to South Fork Trinity River and South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). WUA for overwintering juvenile steelhead is predicted to respond somewhat differently, with a slight decrease in the reach from Dutch Creek to North Fork Trinity River and no change from North Fork Trinity River to South Fork Trinity River and from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). WUA for overwintering juvenile steelhead has not been quantified from Lewiston Dam to Dutch Creek at the range of monthly average flows that would occur in January of wet water years.

Compared with the No Action Alternative, the increased modeled monthly average flow in February of above normal water years would increase WUA for steelhead fry and would decrease or result in no change in WUA for steelhead juveniles in the Trinity River from Lewiston Dam to Dutch Creek (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). From Dutch Creek to North Fork Trinity River and from North Fork Trinity River to South Fork Trinity River, WUA for fry and juvenile steelhead would decrease relative to the No Action Alternative. From South Fork Trinity River to Weitchpec, the increased modeled monthly average flow under Alternative 4 would result in negligible decreases in steelhead fry and juvenile WUA relative to the No Action Alternative. WUA for overwintering juvenile steelhead would decrease slightly from Dutch Creek to Weitchpec relative to the No Action Alternative.

The modeled monthly average flow increases in December and January of wet water years and February of above normal water years under Alternative 4 would not result in measurable changes in modeled monthly average water temperatures compared with the No Action Alternative (Figure O-17). In these months and water year types, modeled monthly average water temperatures at Trinity River below Lewiston Dam under Alternative 4 would remain well below the 59°F water temperature objective for emigrating juvenile salmonids recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the 59°F objective is intended to be measured at Weitchpec and applicable prior to June 4, historical data and model results suggest that water temperatures in December, January, and February would remain below the 59°F objective under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for rearing or emigrating steelhead under Alternative 4 relative to the No Action Alternative. The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton 2023) would likely be met under Alternative 4 through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023). Despite the potential for exceedance of some water temperature objectives during this period at downstream locations in some water year types under Alternative 4, water temperatures and the potential effects on steelhead would not differ from the No Action Alternative.

Compared with the No Action Alternative, the change in seasonal operations under Alternative 4 would increase WUA for steelhead fry in the reach immediately downstream of Lewiston Dam and decrease steelhead fry WUA in most downstream reaches. There would be a slight decrease or no change in WUA for juvenile steelhead in most reaches of the Trinity River compared with the No Action Alternative. Substantial adverse impacts on steelhead would be unlikely under Alternative 4 .

Adult Upstream Migration and Holding

Consistent adult monitoring data are limited by environmental conditions and challenges in overlapping populations with different run timing, kelting or “runbacks,” and half pounders but summer/fall steelhead (stream-maturing steelhead) are thought to return from the ocean from approximately April through November and hold for varying lengths of time in the Klamath-Trinity watershed (Moyle et al. 2017, Moyle et al. 2015, Pinnix et al 2007). Winter steelhead (ocean-maturing steelhead) can return from the ocean about November through March (Moyle et al. 2017, Moyle et al. 2015, Pinnix et al 2007). Given the overlapping run timings and varying life history strategies, adults at various stages of maturation can enter the Klamath-Trinity watershed, hold in the Trinity River, and/or migrate up or down Trinity River and into tributaries in any month of the year.

Potential Changes to Steelhead from Seasonal Operations

In the Trinity River below Lewiston Dam, differences in modeled monthly average flow between Alternative 4 and the No Action Alternative would occur in some months and water year types and are described in detail in the preceding sections and shown in Table O-264. Compared with the No Action Alternative, minor reductions (less than 5%) in modeled monthly average flow under Alternative 4 would occur in November, December, February, and April of some water year types, and a minor increase (less than 5%) would occur in December, January, and March of some water year types. Substantial increases (greater than 5%) in modeled monthly average flow would occur in December and January of wet water years and in February of above normal water years. Monthly average flows would be equal to or greater than 300 cfs in all months and all water year types, and substantially greater in some months and water years, to provide suitable depth for adult steelhead passage. Flow increases in December and January of wet water years and in February of above normal water years may result in short-term changes in holding habitat for pre-spawning steelhead.

Compared with the No Action Alternative, the modeled monthly average flow increase in December of wet water years and February of above normal water years under Alternative 4 would result in a decrease in WUA for holding adult steelhead in the Trinity River from Dutch Creek to North Fork Trinity River, a slight increase from North Fork Trinity River to South Fork Trinity River, and a decrease from South Fork Trinity River to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). WUA for holding adult steelhead has not been quantified in the reach from Lewiston Dam to Dutch Creek for the range of flows that that would occur in December of wet water years. Wet and above normal water years make up 28% and 14% of the 100-year record, respectively. Overall, the availability and suitability of holding habitat for steelhead in these months and water year types may decrease under Alternative 4 compared with the No Action Alternative, potentially resulting in greater competition, predation risk, disease risk, and/or lower fitness of adult steelhead.

In January of wet water years, increased monthly average flow under Alternative 4 would result in a decrease in adult WUA overall across all reaches of the Trinity River from Dutch Creek to Weitchpec (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999) (WUA has not been quantified for flows greater than 800 cfs in the reach between Lewiston Dam and Dutch Creek). This may result in greater competition, predation risk, disease risk, and/or lower fitness of adult steelhead under Alternative 4 compared with the No Action Alternative.

The changes in modeled monthly flows in November through April of some water year types under Alternative 4 would have little or no effect on water temperatures in the Trinity River at Lewiston Dam (Figure O-10) and modeled monthly average water temperatures in these months and water year types would remain well below the 59°F water temperature objective for emigrating juvenile salmonids recommended for normal and wetter water year types (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Although the 59°F objective is intended to be measured at Weitchpec, historical data and model results suggest that water temperatures in November through April of normal and wetter water years would remain below the 59°F objective under a wide range of flow scenarios (Asarian et al. 2023) and there would be no change in the temperature suitability for adult steelhead under Alternative 4 relative to the No Action Alternative. The 61.7°F water temperature objective recommended by TRRP scientists to support juvenile salmonids upstream of the North Fork Trinity River in April–July (Buxton

2023) would likely be met under Alternative 4 through July at Douglas City but would not be met at the North Fork Trinity River confluence in June in drier water year types or in July in all water year types (Asarian et al. 2023) and should also be suitable for adults. Despite the potential for exceedance of some water temperature objectives during this period at downstream locations in some water year types under Alternative 4, water temperatures and the potential effects on steelhead adults would not differ from the No Action Alternative.

Compared with the No Action Alternative, the change in seasonal operations under Alternative 4 may reduce availability and suitability of holding habitat in December and January of wet water years and February of above normal water years. Wet and above normal water years together make up approximately 42% of the 100-year record. Therefore, the changes in flow under Alternative 4 may result in short-term adverse effects on holding adult steelhead in these months and water year types.

O.7.29 Northern DPS Green Sturgeon

O.7.29.1 Trinity River

Spawning and Egg Incubation

Northern DPS green sturgeon adults spawn primarily from March through July, though most spawning takes place from April to June (Section O.1.2.5.1, *Green Sturgeon, Northern* DPS). Northern DPS green sturgeon eggs hatch approximately a week after fertilization, and optimal temperatures for incubation range from 51.8–62.6°F (Van Eenennaam et al. 2005). The effects analysis period for incubating eggs is considered to be the same as the spawning period due to the short incubation period and includes March through July.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally be similar to flows under the No Action Alternative during spawning and egg incubation periods for green sturgeon. Compared with the No Action Alternative, modeled monthly average flows under Alternative 4 would increase slightly (less than 5%) in March of below normal and wetter water year types and decrease slightly (less than 5%) in April of above normal and wet water year types (Table O-264). The minor flow changes under Alternative 4 are not expected to affect suitability for green sturgeon spawning or egg incubation compared with the No Action Alternative.

Green sturgeon are only known to occur within the lower 43 miles of the Trinity River, ranging as far upstream as Grays Falls near Burnt Ranch, approximately 70 miles downstream of Lewiston Dam (Benson et al. 2007). Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several tributaries that enter the Trinity River (e.g., Canyon Creek, North Fork Trinity River, New River, South Fork Trinity River, and small tributaries). Results of previous water temperature modeling for the Trinity River predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43, and smaller temperature differences are expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al.

2023). As a result, minor changes in seasonal operations are not likely to have a detectable influence on the water temperature suitability for green sturgeon spawning and egg incubation.

Larval and Juvenile Rearing and Emigration

The northern DPS green sturgeon spawning period is from March through July, and the larval period is considered to be March through September. The juvenile stage of green sturgeon begins when metamorphosis of the larva is complete, typically at about 45 days after hatching. Juveniles (up to 150 cm TL) typically migrate downstream slowly and rear in the Lower Klamath River for up to a year or until approximately their first summer, and optimal growth temperatures range from 59–66.2°F (Moyle 2002; Mayfield and Cech, Jr. 2004). During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near Burnt Ranch to the Klamath River Estuary (Section O.1.2.5.1, *Green Sturgeon, Northern DPS*). The effects analysis period for larval and juvenile life stages in the Trinity River is considered to be April to September.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam would be nearly identical under Alternative 4 to flows under the No Action Alternative during larval and juvenile rearing and emigration periods for juvenile green sturgeon (Table O-264). Under Alternative 4, modeled monthly average flows would be the same as the No Action Alternative from April through September except for negligible differences (less than 5%) in April of above normal and wet water year types. Flows during the green sturgeon rearing and emigration period would correspond to the No Action Alternative flows that currently are managed to improve habitat conditions for anadromous fish. Under Alternative 4, modeled monthly average flows would have no effects on larval and juvenile rearing and emigration of green sturgeon when compared with the No Action Alternative.

Green sturgeon larvae and juveniles are only known to occur within the lower 43 miles of the Trinity River, and after hatching, they begin to migrate downstream. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several tributaries that enter the Trinity River and results of previous water temperature modeling for the Trinity River predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43, and smaller temperature differences are expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations are not likely to have a detectable influence on the water temperature suitability for green sturgeon larval and juvenile rearing and emigration.

Adult Upstream Migration and Holding

Green sturgeon adults enter the Trinity River from the Klamath River Estuary as early as February and make their way upstream to spawn in deep pools in the lower section of the mainstem Trinity River, from its confluence with the Klamath River approximately 43 miles to Gray's Falls near Burnt Ranch. After spawning, the adults remain in mainstem river pools for varying amounts of time, representing distinct migration patterns. Directly after spawning, approximately 25% of adults emigrate back to the Klamath River estuary and ocean, but some may remain in fresh water for up to 199 days (Moyle 2002; Section O.1.3.2.5, *Green Sturgeon, Northern DPS*). With the extended adult holding period, the effects analysis period for adult upstream migration, holding, and emigration is considered to be February through December.

Potential Changes to Northern DPS Green Sturgeon from Seasonal Operations

Flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally be similar to flows under the No Action Alternative. Compared with the No Action Alternative, modeled monthly average flows under Alternative 4 would increase substantially (greater than 5%) in December and January of wet water years and in February of above normal water years (Table O-264). Minor changes (less than 5%) in modeled monthly average flow would occur in November, March, and April of some water year types. Throughout the February–December adult upstream migration, holding, and emigration period, flows under Alternative 4 would provide adequate passage and pool holding habitats and there would be no effects relative to the No Action Alternative.

Green sturgeon adults are only known to occur within the lower 43 miles of the Trinity River, and they have variable freshwater residence time (Benson et al. 2007). Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43, and smaller temperature differences are expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations are not likely to have a detectable influence on the water temperature suitability for adult green sturgeon during the migration, holding, and emigration period.

O.7.30 Eulachon

O.7.30.1 Lower Klamath River from Confluence With Trinity River to Pacific Ocean

Spawning and Egg Incubation

Eulachon adults spawn from December through May, with peak spawning occurring in March and April (Section O.1.2.6 *Eulachon*). Eulachon eggs hatch in 20 to 40 days depending on water temperature, with cooler temperatures leading to longer incubation times. Spawning is reported to occur at temperatures from 39 to 50°F; colder temperatures may stop migration (National Marine Fisheries Service 2017). Eulachon are broadcast spawners most commonly over sand, though spawning substrates can range from silt, sand or gravel to cobble and detritus (California

Department of Fish and Wildlife 2010; National Marine Fisheries Service 2017). Eulachon usually die after spawning. The effects analysis period for eulachon spawning and egg incubation is December through June.

Potential Changes to Eulachon from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally be similar to or greater than flows under the No Action Alternative during the eulachon spawning and egg incubation periods, with greater than 5% increases in December and January of wet water years and in February of above normal water years (Table O-264). The increase in flows would likely have negligible effects on eulachon spawning habitat and egg incubation. Under Alternative 4, modeled monthly average flows of 1,193 cfs in December of wet water years, 1,985 cfs in January of wet water years, and 1,393 cfs in February of above normal water years would maintain suitable spawning and egg incubation conditions for eulachon. Compared with the No Action Alternative, the flow increases under Alternative 4 are not expected to affect the availability or quality of spawning substrates and would have little or no effect on water temperature in the lower Klamath River.

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Water temperature within this section of the Klamath River below the confluence with the Trinity River is influenced by both the upper Klamath River and several tributaries that enter the Trinity River (e.g., Canyon Creek, North Fork Trinity River, New River, South Fork Trinity River, and small tributaries). Previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 4 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for eulachon spawning and egg incubation.

Larval Emigration

Eulachon spawning occurs from December through May and eggs hatch in 20 to 40 days, so the larval period is considered to be January through June. After hatching, larval eulachon are quickly carried out to the ocean by river currents (Scott and Crossman 1973). Larval eulachon only remain in the Klamath River for about 5 days until they are washed out to sea. Larvae live on their yolk sac reserves after hatching—they do not feed while in fresh water (Gustafson et al. 2022). Effects of flow and water temperature on eulachon larvae in the Klamath River may occur from January through June.

Potential Changes to Eulachon from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally be similar to or greater than flows under the No Action Alternative during the eulachon larval emigration period, with greater than 5% increases in January of wet water years and February of above normal water years (Table O-264). The increase in flows

would likely have negligible effects on eulachon larval emigration. Under Alternative 4, modeled monthly average flows of 1,985 cfs in January of wet water years and 1,393 cfs in February of above normal water years would maintain suitable emigration conditions for eulachon. Compared with the No Action Alternative, the flow increases under Alternative 4 are not expected to affect larval transport or downstream passage and would have little or no effect on water temperature in the lower Klamath River.

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Water temperature within this section of the Klamath River below the confluence with the Trinity River is influenced by both the upper Klamath River and several tributaries that enter the Trinity River (e.g., Canyon Creek, North Fork Trinity River, New River, South Fork Trinity River, and small tributaries). Previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 4 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for eulachon larval emigration.

Adult Upstream Migration

The spawning migration period for adult eulachon in the Klamath River begins in December and continues until May, with peak migration occurring in March and April (Yurok Tribal Fisheries Program 1998; Larson and Belchik 1998, Section O.1.2.6). Eulachon distribution in the Trinity River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Spawning occurs most commonly in sand-bedded areas but spawning substrates can range from silt, sand or gravel to cobble and detritus (California Department of Fish and Wildlife 2010; National Marine Fisheries Service 2017). The effects analysis period for eulachon adult upstream migration is December through May.

Potential Changes to Eulachon from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally be similar to or greater than flows under the No Action Alternative during the eulachon adult upstream migration period, with greater than 5% increases in December and January of wet water years and in February of above normal water years (Table O-264). The increase in flows would likely have negligible effects on eulachon adult upstream migration. Under Alternative 4, modeled monthly average flows of 1,193 cfs in December of wet water years, 1,985 cfs in January of wet water years, and 1,393 cfs in February of above normal water years would maintain suitable conditions for adult eulachon upstream migration. Compared with the No Action Alternative, the flow increases under Alternative 4 are not expected to affect the ability of adult eulachon to move upstream to spawning areas and would have little or no effect on water temperature in the lower Klamath River

Eulachon distribution in the Klamath River is limited to the lower approximately 24 river miles except during rare years when they are sometimes observed as far upstream as Pecwan Creek and even Weitchpec (Yurok Tribal Fisheries Program 1998). Water temperature within this section of the Klamath River below the confluence with the Trinity River is influenced by both the upper Klamath River and several tributaries that enter the Trinity River (e.g., Canyon Creek, North Fork Trinity River, New River, South Fork Trinity River, and small tributaries). Previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). As a result, minor changes in seasonal operations between Alternative 4 and the No Action Alternative are not likely to have a detectable influence on the water temperature suitability for eulachon adult upstream migration.

O.7.31 Coastal Cutthroat Trout

O.7.31.1 Lower Klamath River from Confluence With Trinity River to Pacific Ocean

Spawning and Egg Incubation

Generally, spawning of anadromous and resident coastal cutthroat trout may occur from September to April (Moyle 2002). Coastal cutthroat trout are associated with shaded streams and instream cover with water temperatures below 64°F, while preferred temperatures range from 48–54°F, with spawning temperatures of 43–63°F. (Moyle 2002). Spawning habitat is typically found in headwater streams with 1–3 feet/sec flow velocities and unembedded small- to medium-sized gravel (0.08–4 inches) (Moyle 2002). Embryos hatch about 6–7 weeks following incubation and alevins emerge 1–2 weeks thereafter (Moyle 2002).

The effects analysis period for coastal cutthroat trout spawning and egg incubation is September through June.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally be similar to or greater than flows under the No Action Alternative, with greater than 5% increases in December and January of wet water years and in February of above normal water years (Table O-264). The increase in Trinity River flows would be unlikely to affect the availability or suitability of coastal cutthroat trout spawning and egg incubation habitat, as most spawning is expected to occur in tributaries of the Trinity River and lower Klamath River. Compared with the No Action Alternative, there would be no changes in the availability or suitability of coastal cutthroat trout spawning and egg incubation habitat under Alternative 4 since Trinity River flows do not impact tributaries where coastal cutthroat trout typically spawn.

Juvenile Rearing and Emigration

Juvenile coastal cutthroat trout may spend anywhere from one to five years rearing in freshwater or a combination of freshwater and estuarine/ocean environments. Cutthroat fry are associated with slow water velocities (less than 1 foot/sec, with <0.3 feet/sec preferred), and are typically found in shaded streams with instream cover and water temperatures below 64°F. Preferred temperatures range from 48–54°F (Moyle 2002).

Most coastal cutthroat trout exhibiting an amphidromous life history leave their natal streams during summer, rear in estuaries, lagoons and nearshore ocean areas, and return to overwinter in freshwater (Moyle 2002). Anadromous forms may emigrate to estuaries or the ocean as juveniles in their first year or remain in freshwater for up to five years before entering ocean or estuarine environments. In Blue Creek, a Klamath River tributary, yearling and older cutthroat emigration occurred mainly between April and June (Moyle 2002). For individuals that emigrated to an estuary, Wallace (2004) found that the residence time within the estuary ranged from 5 to 89 days, with a mean of 27 days. Some populations, especially in California, migrate between large and small streams or between rivers and estuaries. Resident coastal cutthroat trout will remain in freshwater their entire lives, rather than emigrating to a lagoon or estuary or the ocean. Most coastal cutthroat trout in California, including those the Trinity River and lower Klamath River, are weakly anadromous, spawning in tributaries and moving primarily between tributaries and the larger rivers and estuary (Moyle 2002).

The effects analysis period for coastal cutthroat trout juvenile rearing and emigration is April through June for amphidromous coastal cutthroat trout and January through December (year-round) for resident coastal cutthroat trout.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally be similar to or greater than flows under the No Action Alternative, with greater than 5% increases in December and January of wet water years and February of above normal water years (Table O-264). The increase in flows would likely have negligible effects on coastal cutthroat trout juvenile rearing and emigration habitat. Under Alternative 4, modeled monthly average Trinity River flows of 1,193 cfs in December of wet water years, 1,985 cfs in January of wet water years, and 1,393 cfs in February of above normal water years would maintain suitable rearing and emigration conditions for coastal cutthroat trout in the Trinity River and lower Klamath River. Compared with the No Action Alternative, the flow increases under Alternative 4 are not expected to affect conditions for rearing or downstream passage, especially since most rearing occurs in natal tributaries and in estuaries, lagoons, and nearshore ocean environments. Modeled monthly average flow increases in the Trinity River may slightly improve emigration conditions in the Trinity River but the effects on flow and water temperature in the lower Klamath River would be negligible and unlikely to influence emigration conditions for coastal cutthroat moving downstream toward the ocean or estuary.

Water temperature and habitat conditions within the Klamath River below the confluence with the Trinity River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023).Compared with the No Action Alternative, the maximum increases in modeled monthly average flow under Alternative 4 range from 60 cfs to 199 cfs depending on month and water year type. As a result, minor changes in seasonal operations between Alternative 4 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for coastal cutthroat trout juvenile rearing and emigration.

Seasonal operations under Alternative 4 are expected to maintain suitable habitat conditions for coastal cutthroat trout juvenile rearing and emigration in the Trinity River, lower Klamath River, and the Klamath River estuary. Compared with the No Action Alternative, changes in the availability or suitability of coastal cutthroat trout juvenile rearing and emigration habitat would be negligible.

Adult Holding and Migration

Migration of coastal cutthroat trout to freshwater typically occurs between August and October between the ages of one and five (Moyle 2002). While most anadromous salmonids die after completing spawning, coastal cutthroat may survive spawning, re-enter the ocean, and return the following year(s) to spawn up to five times (Moyle 2002). Overwintering coastal cutthroat trout prefer pools with cover (e.g., logs, undercut banks, boulders) (Moyle 2002).

The effects analysis period for coastal cutthroat trout adult holding and migration is August through October for amphidromous coastal cutthroat trout and January through December for resident coastal cutthroat trout.

Potential Changes to Coastal Cutthroat Trout from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally be similar to or greater than flows under the No Action Alternative, with greater than 5% increases in December and January of wet water years and February of above normal water years (Table O-264). The increase in flows would likely have negligible effects on coastal cutthroat trout adult holding and migration habitat. Under Alternative 4, modeled monthly average Trinity River flows of 1,193 cfs in December of wet water years, 1,985 cfs in January of wet water years, and 1,393 cfs in February of above normal water years would maintain suitable rearing and emigration conditions for coastal cutthroat trout in the Trinity River and lower Klamath River. Compared with the No Action Alternative, the flow increases under Alternative 4 would have negligible effects on conditions for adult upstream passage and no effect on holding which would occur in tributaries unaffected by mainstem river flows.

Water temperature and habitat conditions within the Klamath River below the confluence with the Trinity River are influenced by both the upper Klamath River and several tributaries that enter the Trinity River. Results of previous water temperature modeling for the Trinity River predicted a difference of less than 1°F in April water temperature for flows of 300 cfs and 450 cfs near the confluence of the Trinity and Klamath Rivers (U.S. Fish and Wildlife Service & Hoopa Valley Tribe 1999). Recent synthesis of Trinity River temperature data described a cooling effect of up to 3.4°F per 1,000 cfs at the Klamath/Trinity River confluence from Lewiston Dam releases (Asarian et al. 2023). Compared with the No Action Alternative, the maximum increases in modeled monthly average flow under Alternative 4 range from 60 cfs to 199 cfs depending on month and water year type. As a result, minor changes in seasonal operations between Alternative 4 and the No Action Alternative are unlikely to have a detectable influence on the water temperature suitability for coastal cutthroat trout adult migration.

Seasonal operations under Alternative 4 are expected to maintain suitable habitat conditions for coastal cutthroat trout adult migration in the Trinity River and lower Klamath River. No effects on adult holding are expected. Compared with the No Action Alternative, changes in the availability or suitability of coastal cutthroat trout adult migration habitat would be negligible.

O.7.32 Brown Trout

O.7.32.1 Trinity River

Spawning and Egg Incubation

Brown trout spawn in fall and winter, most commonly in November and December in California (Moyle 2002). Trout typically mature and spawn in their second or third year, but they may wait longer (7 or 8 years) (Moyle 2002). Adults begin selecting spawning locations when water temperatures are between 42.8–50ºF (Moyle 2002). Spawning habitat comprises pea- to walnut-sized gravel in less turbulent waters, which are typically found at pool tailouts (Moyle 2002). Embryos hatch in seven to eight weeks (ranging from 4–21 weeks), with alveins emerging three to six weeks later, depending on water temperature.

The effects analysis period for brown trout spawning and egg incubation is November through April.

Potential Changes to Brown Trout from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally similar to or greater than flows under the No Action Alternative during the brown trout spawning and egg incubation period, with greater than 5% increases in December and January of wet water years and in February of above normal water years (Table O-264). Under Alternative 4, modeled monthly average flows of 1,193 cfs in December of wet water years, 1,985 cfs in January of wet water years, and 1,393 cfs in February of above normal water years would maintain suitable spawning and egg incubation conditions for brown trout. Compared with the No Action Alternative, the flow increases under Alternative 4 are not expected to affect the availability or quality of spawning substrates and would have little or no effect on water temperature in the lower Klamath River Compared to the No Action Alternative, changes in the availability or suitability of brown trout spawning and egg incubation habitat would be minimal and unlikely to have adverse impacts on brown trout.

Juvenile Rearing and Emigration

The ideal temperature range for brown trout is between 53.6–68°F, with optimal growth between 62.6–64.4°F; they can survive for only short period at higher temperatures up to 84.2°F (Moyle 2002). Cold temperatures reduce brown trout's ability to effectively capture prey: when temperatures reduced from 58.5°F to 42.3°F the foraging effectiveness reduced from 96% to 53% (Watz and Piccolo 2010).

In California, brown trout reach 2–3 inches in length their first year, 5–6 inches in their second year, 8–11 inches in their third, and 14–16 inches in their fourth year (Moyle 2002). Fry rear in edge-water habitat that is slow and shallow (<12 inches deep), with juveniles selecting riffles and pools with deeper water (20–30 inches), higher velocities (0.3–1.3 feet/second), and cover from overhead, rocks, and logs (Moyle 2002). It is uncertain the degree to which brown trout exhibit an anadromous life history in the Trinity River, with juveniles emigrating to the ocean, or are riverine (potamodromous) with juveniles emigrating further downstream while continuing to remain in freshwater. In Ireland, where they are native, brown trout juveniles emigrated to brackish or marine habitats throughout the year, with distinct seasonal peeks in spring (March through June) and fall (September through December) (Wynne et al. 2023).

The effects analysis period for brown trout juvenile rearing and emigration is January through December.

Potential Changes to Brown Trout from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally similar to or greater than flows under the No Action Alternative during the brown trout spawning and egg incubation period, with greater than 5% increases in December and January of wet water years and in February of above normal water years (Table O-264). Under Alternative 4, modeled monthly average flows of 1,193 cfs in December of wet water years, 1,985 cfs in January of wet water years, and 1,393 cfs in February of above normal water years would maintain suitable juvenile rearing and emigration conditions for brown trout. Compared with the No Action Alternative, the flow increases under Alternative 4 are not expected to affect the availability of rearing habitat or emigration conditions and would have little or no effect on water temperature in the lower Klamath River. Seasonal operations under Alternative 4 are expected to maintain suitable habitat conditions for brown trout juvenile rearing and emigration in the Trinity River. Compared to the No Action Alternative, changes in the availability or suitability of brown juvenile rearing and emigration habitat would be minimal and unlikely to have adverse impacts on brown trout.

Adult Holding and Migration

Upstream migration occurs in fall and winter, prior to spawning, which most commonly occurs in November and December. Sullivan and Hilemean (2018) noted a shift in migration timing on the Trinity River to later in the season following the implementation of the Record of Decision (ROD) flows (2005-2011, 2017), as compared to Pre-ROD flows (1982–2002). In rivers, adults will hold in a wide range of habitats, but are often associated with low velocity pools ranging from 2.3–11.5 feet deep that have cover (Moyle 2002).

The effects analysis period for brown trout adult holding and migration is January through December with migration primarily in November and December.

Potential Changes to Brown Trout from Seasonal Operations

Modeled monthly average flows in the Trinity River downstream of Lewiston Dam under Alternative 4 would generally similar to or greater than flows under the No Action Alternative during the brown trout adult holding and migration period, with greater than 5% increases in December (Table O-264). Under Alternative 4, modeled monthly average flows of 1,193 cfs in December of wet water years would maintain suitable adult holding and migration conditions for brown trout. Compared with the No Action Alternative, the flow increases under Alternative 4 are not expected to affect the availability of adult holding or migration conditions and would have little or no effect on water temperature in the lower Klamath River. Seasonal operations under Alternative 4 are expected to maintain suitable habitat conditions for brown trout adult holding and migration in the Trinity River. Compared to the No Action Alternative, changes in the availability or suitability of brown trout adult holding and migration habitat would be minimal and unlikely to have adverse impacts on brown trout.

O.7.33 Trinity Reservoir Species

O.7.33.1 Trinity Reservoir

Spawning and Egg Incubation

Coldwater fish species (rainbow trout, brown trout, Kokanee, and landlocked Chinook salmon) in the lake generally migrate into tributaries to spawn either from December through March (rainbow trout), November–December (brown trout), or August through April (kokanee). Populations of rainbow trout, brown trout, and Kokanee are sustained through a combination of natural reproduction and fish hatchery stocking practices. Landlocked Chinook salmon do not typically reproduce (Perales et al. 2015) and are supported by annual stocking practices.

Warmwater fish species (smallmouth bass, largemouth bass, white catfish, and brown bullhead) typically rely on habitat in the lake during all life stages. In general, smallmouth and largemouth bass spawn from April through July in shallow water (1.5 feet to 6.0 feet deep) along the lake margins at water temperatures ranging from 55°F to 75°F (Moyle 2002). These nests are vulnerable to fluctuations in water levels. Rapid drops in water levels may cause guarding males to abandon the nests, increase predation, and limit water circulation and dissolved oxygen levels around the eggs (Edwards et al. 1983). White catfish spawning typically occurs during June and July when water temperatures exceed 68°F, but spawning can sometimes extend into September; spawning occurs in sandy substrate adjacent to cover (e.g., rocks, wood, or aquatic vegetation) and eggs hatch in about a week (Moyle 2002). Brown bullhead spawn from May through mid-July and will build their nests in sand or gravel near cover (Moyle 2002). Warmwater fish species in Trinity Lake are currently self-sustaining through natural reproduction.

The effects analysis period for coldwater fish species spawning and egg incubation is August through April. The effects analysis period for warmwater fish species spawning and egg incubation is April through September.

Potential Changes to Trinity Reservoir Fish Species from Seasonal Operations

Trinity Reservoir storage under Alternative 4 would generally be higher than storage under the No Action Alternative (Table O-265) but all inor differences would be negligible (<5%) and unlikely to reduce the availability or suitability of spawning and egg incubation habitat for Trinity Reservoir fish species.

Larval and Juvenile Rearing and Emigration

Rainbow trout fry emerge 3–4 weeks after fertilization and will remain in the gravel for about 2–3 weeks (Moyle 2002, USFWS 1984, Habitat Suitability Information: Rainbow Trout, FWS/OBS-82/10.60). Juvenile rainbow trout may spend two summers in their natal stream and two summers in a reservoir or lake before maturing. Brown trout fry typically hatch in 2 months, though it can range from 1–5 months depending on water temperature, and larvae will emerge from the gravel around 1 month later. Juveniles will spend several years in tributaries before emigrating to the reservoir where they will become sexually mature (Moyle 2002, Belica 2007).

Smallmouth and largemouth bass fry prefer shallow water and are vulnerable to fluctuations in water levels. These fry hatch in 2–7 days and then spend another week in the nest. Larval bass stay in shallow water on the edge of vegetation (Moyle 2002). Rapid drops in water levels may cause stranding. Juvenile bass tend to live in deeper water habitats with submerged shelter (e.g., logs or boulders). White catfish will move throughout the reservoir and don't have a regular seasonal migration, thought they tend to concentrate at depts of 10–30 ft but will move deeper in the summer as temperatures increase (Moyle 2002). Brown bullhead typically live in deeper water (6–30 ft deep) in areas with aquatic plants and muddy substrate (Moyle 2002).

The effects analysis period for both coldwater and warmwater fish species larval and juvenile rearing and emigration is January through December.

Potential Changes to Trinity Reservoir Fish Species from Seasonal Operations

Trinity Reservoir storage under Alternative 4 would generally be higher than storage under the No Action Alternative (Table O-265) but all changes would be minor (<5%) and None of these changes are likely to have a detectable influence on the water temperature and habitat suitability for larval and juvenile rearing and emigration of Trinity Reservoir coldwater or warmwater fish species.

Adult Holding

The life expectancy of rainbow trout can be 4–8 years in northern California lake populations. After maturing, resident rainbow trout will migrate upstream to spawn in tributaries. They can spawn annually and will quickly move back downstream to the reservoir or lake (Moyle 2002), moving to cooler, deeper waters during the summer months (Belica 2007). Brown trout typically become sexually mature at age two or three and have been found as old as can live for up to nine years in California, spawning several times during their life (Moyle 2002, Belica 2007). Brown trout will use varying habitats within the reservoir and will also move to cooler waters in the summer habitats (Belica 2007).

Warmwater species will remain in the reservoir their entire lives. Smallmouth bass prefer narrow bays and upstream ends of reservoirs or along the shore where rocky shelves are present at a depth of 1–10m (Moyle 2002). They become sexually mature at age 3–4 and typically live less than 7 years (Edwards et al. 1983). Age of largemouth bass in California reservoirs is four and five years and they typically spawn during their second season (Moyle 2002). Adult bass tend to prefer deeper, colder waters in lakes and reservoirs in areas with vegetation and other forms of cover (Edwards et al. 1983). White catfish will move throughout the reservoir and don't have a regular seasonal migration, thought they tend to concentrate at depts of 10–30 ft but will move deeper in the summer as temperatures increase (Moyle 2002). Brown bullhead typically live in deeper water (6–30 ft deep) in areas with aquatic plants and muddy substrate (Moyle 2002). They become sexually mature at age 3 and will spawn multiple times during their lifetime of up to eight to ten years (Moyle 2002).

The effects analysis period for both coldwater and warmwater fish species adult holding is January through December.

Potential Changes to Trinity Reservoir Fish Species from Seasonal Operations

Trinity Reservoir storage under Alternative 4 would generally higher than storage under the No Action Alternative (Table O-265) but all modeled changes would be minor (<5%) and none of these changes are likely to have a detectable influence on the water temperature and habitat suitability for adult holding of Trinity Reservoir coldwater or warmwater fish species.

O.7.34 Central Valley Reservoir Species

O.7.34.1 Potential Changes to Central Valley Reservoir Species from Seasonal Operations

Shasta Reservoir

Warmwater Species

Reductions in Shasta Reservoir WSE month-over-month reductions of six feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Shasta_2.

For Alternative 4, there would be between two more to eight fewer WSE reductions of six feet or more compared to the No Action Alternative. These results indicate that Alternative 4 would have a beneficial effect on warmwater species in Shasta Reservoir.

Coldwater Species

Shasta Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Shasta_1.

For Alternative 4, end-of-month storage would be similar to storage under the No Action Alternative in wet, above normal, below normal, and dry water years and 5.0 to 12.8% higher than the No Action Alternative in critical water years. These results indicate that there would be negligible and beneficial effects of Alternative 4 on coldwater species in Shasta Reservoir.

Whiskeytown Reservoir

Coldwater and Warmwater species

Reductions in Whiskeytown Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Whiskey_2.

For Alternative 4, there would be no or negligible difference in WSE month-over-month reductions of six feet or more relative to the No Action Alternative. Therefore, there would be no effect or negligible effects of Alternative 4 on warmwater species in Whiskeytown Reservoir.

Coldwater Species

Whiskeytown Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Whiskey_1.

End-of-month storage volume under Alternative 4 would be similar to that of the No Action Alternative. These results indicate that Alternative 4 would have negligible effects on coldwater species in Whiskeytown Reservoir.

Folsom Reservoir

Coldwater and Warmwater Species

Reductions in Folsom Reservoir WSE month-over-month reductions of six feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Folsom_2.

There would be zero to four more reductions of six feet or more under Alternative 2 than under the No Action Alternative depending on month. These results indicate that there would be a negligible negative effect of Alternative 4 on warmwater species in Folsom Reservoir.

Coldwater Species

Folsom Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Folsom_1.

For Alternative 4, end-of-month storage would be similar to storage under the No Action Alternative in wet, above normal, below normal, and dry water years and 14.4 to 20.4% higher than the No Action Alternative in critical water years. These results indicate that there would be negligible and beneficial effects of Alternative 4 on coldwater species in Folsom Reservoir.

New Melones Reservoir

Warmwater Species

Reductions in New Melones Reservoir WSE month-over-month reductions of six feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects of seasonal operations on warmwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Melones 2.

For Alternative 4, here would be zero to two fewer WSE month-over-month reductions of six feet or more than the No Action Alternative depending on month. These results indicate that there would be negligible effects of Alternative 3 on warmwater species in New Melones Reservoir.

Coldwater Species

New Melones Reservoir end-of-month storage volume during April through October for each alternative was compared to the No Action Alternative to assess potential effects of seasonal operations on coldwater reservoir species. Please see Section O.4.33.2, *Methods*, for a description of the methods used for this analysis. Results are presented in Table Melones_1.

For Alternative 4, there would be negligible differences in storage volume throughout the period analyzed compared to the No Action Alternative. This indicates that Alternative 4 would have negligible effects on coldwater species in New Melones Reservoir.

O.7.35 Delta-Mendota Canal / California Aqueduct Species

O.7.35.1 Potential Changes to Delta-Mendota Canal/California Aqueduct Species from Seasonal Operations

Water from the Delta is diverted through the California Aqueduct and Delta-Mendota Canal and held for off-stream storage (e.g., in San Luis Reservoir) and there is no coldwater habitat in the Delta-Mendota Canal. Therefore, no analysis of coldwater habitat was conducted. Warmwater species such as black basses and striped bass support recreational fishing in the California Aqueduct. Water velocity in the canal is not specifically managed to support or enhance recreational fisheries. Increases in water velocity may decrease water temperatures and flowing water for species, improving conditions; while decreases in water velocity may increase water temperatures and lead to stagnant water for species, diminishing conditions.

Differences in flows and velocity under Alternative 4, compared to the No Action Alternative, are expected to be minimal thus, impacts to species present are not expected to change.

O.7.36 San Luis Reservoir Species

O.7.36.1 Potential Changes to San Luis Reservoir Species from Seasonal Operations

Warmwater Species

Reductions in San Luis Reservoir WSE month-over-month reductions of 6 feet or more during March through June under each alternative were compared to reductions under the No Action Alternative to assess potential effects. Please see Section O.4.33.2, *Methods,* for details on the methods used in this analysis. Results are presented in Table SLR_1.

For Alternative 4, there would be 20 fewer to 2 more WSE month-over-month reductions of 6 feet or more than under the No Action Alternative depending on month. These results indicate that there would be predominantly beneficial effects of Alternative 4 on warmwater species in San Luis Reservoir.

O.7.37 Southern Resident Killer Whale

O.7.37.1 Nearshore Pacific Ocean on the California Coast

Changes in water operations under the alternatives could have the potential to affect Chinook salmon prey for Southern Resident Killer Whale (Southern Resident) relative to the No Action Alternative. Outlined below are expected changes in Southern Resident prey. Four lines of evidence were used (Salmort, XT, CVPIA SIT LCM, and DPM), and Attachment F.7, *Change in Abundance Estimate of Central Vally Chinook Salmon Available to Southern Resident Killer Whales*, provides detailed results of all models and analyses.

Based on the lines of evidence, Alternative 4 is predicted to have an annual median abundance of about 232,812 Chinook salmon that survive to adulthood or about 3,495,669 pounds of Chinook salmon biomass in the ocean available as potential prey to Southern Residents. This is about 61 more Chinook salmon or 923 pounds more than the No Action Alternative. This is likely a negligible difference in Chinook salmon and biomass available to Southern Residents for prey between the No Action Alternative and Alternative 4.

O.8 Summary of Impacts

Table O-282, Summary of Aquatic Resources Impacts, includes a summary of impacts. Avoidance and minimization measures and potential mitigation measures can be found in more detail in Section O-9, *Mitigation Measures*, and Appendix D, *Mitigation Measures*. In general, given the complexity and length of the Fish and Aquatic Resources analyses, the table focuses on the direction of changes under each alternative. The magnitude of the changes is discussed within Appendix O and Chapter 12, *Fish and Aquatic Resources*.

Table O-282. Summary of Aquatic Resources Impacts

Impact	Alternative	Direction of Impacts
SACRAMENTO RIVER WINTER-RUN CHINOOK SALMON ESU		
Sacramento River		
Potential changes to winter-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations. The No Action Alternative results in impacts and benefits to winter-run Chinook salmon including coldwater pool management. • **Adverse Components:** Fall Operations and Rice Decomposition Smoothing, Fall and Winter Refill and Redd Maintenance. • **Potential Beneficial Components:** Ramping Rates, Spring Pulse Flows, Water Temperature Management, Winter-run Chinook Salmon Supplementation
	Alternative 1	• **Spawning and Egg/Alevin Incubation:** Possible adverse to beneficial impacts from *flow* on spawning habitat and redd dewatering potential, adverse impacts on spawner abundance and female escapement. Adverse impacts from *water temperatures* on incubating eggs from TDM, beneficial impacts from *water temperatures* on spawning adults and egg/alevin incubation. • **Juvenile Rearing and Emigration:** Potential adverse and beneficial impacts from *flow* on fry and juvenile rearing habitat adverse impacts on fry survival during critically dry years. Beneficial impacts on survival and travel time. Beneficial impacts from *water temperatures*. • **Adult Migration and Holding:** Beneficial impacts from *flow*, flows high enough to allow upstream passage. Negligible adverse impacts from *water temperatures*.
	Alternative 2 [1]	• **Spawning and Egg/Alevin Incubation:** Possible adverse to beneficial impacts from *flow* on spawning habitat and redd dewatering potential, possible adverse and beneficial impacts on spawner abundance. Possible beneficial impacts from *water temperatures* from TDM, beneficial impacts on spawning and egg/alevin incubation, negligible adverse impacts specific to egg incubation and fry emergence.

[1] Language for Alternative 2 refers to across all four phases of Alternative 2, unless otherwise stated.

Impact	Alternative	Direction of Impacts
		• **Juvenile Rearing and Emigration:** Potential adverse to beneficial impacts from *flow* on fry and juvenile rearing habitat, beneficial impacts on fry stranding, adverse to beneficial impacts on juvenile production index (depending on the phase). Adverse to beneficial impacts on fry survival and juvenile survival and travel time. Adverse to beneficial impacts from *water temperatures* on juvenile rearing and emigration. • **Adult Migration and Holding:** Potential adverse to beneficial impacts from *flow*, generally beneficial impacts early in the season (December: January) and adverse impacts later in the season (May and June), flows high enough to allow upstream passage. Negligible adverse impacts from *water temperatures* on upstream migrating and holding adults.
	Alternative 3	• **Spawning and Egg/Alevin Incubation:** Potential adverse to beneficial impacts from *flow* on spawning habitat and redd dewatering potential, potential adverse or beneficial impacts on spawner abundance depending on water year type, potential beneficial impacts on female escapement. Potential beneficial impacts from *water temperatures*, while potential adverse impacts on egg to fry survival, potential beneficial impacts on spawning and egg/alevin, adverse impacts on spawning initiation and egg incubation and fry emergence from water temperatures analysis. • **Juvenile Rearing and Emigration:** Potential adverse to beneficial impacts from *flow* on fry and juvenile rearing habitat, beneficial impacts on fry survival particularly in critically dry years. Potential adverse to beneficial impacts on travel time and beneficial impacts on survival. Potential beneficial impacts from *water temperatures*. • **Adult Migration and Holding:** Potential adverse to beneficial impacts from *flow*, flows high enough to allow upstream passage. Adverse impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg/Alevin Incubation:** Potential adverse impacts from *flow* on spawning habitat, beneficial impacts in a critically dry water year type, adverse to beneficial impacts on spawner abundance; beneficial impacts on female escapement. Potential beneficial impacts from *water temperatures*, adverse to beneficial impacts on spawning and egg/alevin incubation from water temperatures analysis. • **Juvenile Rearing and Emigration:** Potential adverse to beneficial impacts from *flow* on fry and juvenile rearing habitat, potential beneficial impacts on fry stranding, adverse impacts on juvenile production index, beneficial impacts on fry survival particularly in critically dry years. Potential adverse to beneficial impacts in all water year types on survival and travel time in the upper Sacramento River. Potential adverse and beneficial impacts from *water temperatures*. • **Adult Migration and Holding:** Potential beneficial impacts from *flow*, except June of a critically dry years; flows high enough to allow upstream passage. Negligible adverse impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
Bay-Delta		
Potential changes to winter-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Spring Delta Outflow. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	Possibly less flow into CVP under OMR -2,000 and -5,000, Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 2	Negligible impacts on flow into HOR. Alternatives without VA may have minimal less flow into CVP under OMR -2,000; alternatives with VA may have negligible impacts on flow into CVP. Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 3	Potential little to less flow into CVP under OMR -3,500, Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 4	Potential little to less flow into CVP under OMR -2,000, impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
Potential changes to entrainment of winter-run Chinook salmon	No Action	No measurable change from current conditions, continuation of current trends. • **Beneficial:** Seasonal and Real-time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** DCC Gates Operations, RRDS Fall Flood-up, Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	Adverse impacts from *flow* on entrainment of genetically and LAD identified juveniles.
	Alternative 2	2 phases of Alternative 2 with VA expected to have overall beneficial impacts from *flow* on entrainment of juveniles, except during a wet water year type. 2 phases of Alternative 2 without VA could have adverse to beneficial impacts, depending on water year type and quantitative model.
	Alternative 3	Potential beneficial impacts from *flow* on entrainment of juveniles, particularly in WYTs with better conditions (wet, above normal, below normal). Potential adverse impacts on entrainment, particularly in dry and critically dry years.
	Alternative 4	Potential adverse impacts from *flow* on entrainment of juveniles, except at CVP in critically dry and dry WYT where there may be beneficial impact.

Impact	Alternative	Direction of Impacts
Potential changes to routing of winter-run Chinook salmon	No Action	No change from current conditions, included under seasonal operations.
	Alternative 1	Potential adverse and beneficial impacts from *flow* on routing into the Interior Delta.
	Alternative 2	Potential adverse and beneficial impacts from *flow* on routing into the Interior Delta.
	Alternative 3	Potential adverse and beneficial impacts from *flow* on routing into the Interior Delta.
	Alternative 4	Potential adverse and beneficial impacts from *flow* on routing into the Interior Delta.
Potential changes to through Delta survival of winter-run Chinook salmon	No Action	No measurable change from current operations and trends, included under seasonal operations.
	Alternative 1	Potential adverse impacts from *flow* on survival of outmigrating juveniles.
	Alternative 2	Potential adverse or beneficial impacts from *flow*..
	Alternative 3	Potential adverse or beneficial impacts from *flow*.
	Alternative 4	Potential adverse or beneficial impacts from *flow*.
CENTRAL VALLEY SPRING-RUN CHINOOK SALMON ESU		
Sacramento River		
Potential changes to spring-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations and trends. • **Adverse Components:** Fall Operations and Rice Decomposition Smoothing, Fall and Winter Refill and Redd Maintenance. • **Beneficial Components:** Ramping Rates, Water Temperature Management, and Spring Pulse Flows.
	Alternative 1	• **Spawning and Egg/Alevin Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat. Potential adverse impacts on redd dewatering during wet and above normal water years. Beneficial impact from *water temperatures* on spawning below Keswick Dam and pathogen virulence at Red Bluff Diversion Dam. Adverse impacts on egg/alevin incubation below Keswick Dam. • **Juvenile–Yearling Rearing and Emigration:** Adverse impacts from *flow* on fry and juvenile rearing habitat depending on water year type. Beneficial impacts on fry and juvenile rearing during critically dry years. Adverse impacts on fry stranding in most water years and beneficial impacts in critically dry years. Adverse and beneficial impacts from *water temperatures* on growth, smoltification, and predation vulnerability. • **Adult Migration and Holding:** Flows high enough to allow upstream passage. Negligible impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
	Alternative 2	• **Spawning and Egg/Alevin Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat. . Potential adverse to beneficial impacts from *flow* on redd dewatering potential (depending on water year type). Adverse and beneficial impacts from *water temperatures* on spawning and egg/alevin incubation. • **Juvenile–Yearling Rearing and Emigration:** Adverse impacts from *flow* on fry rearing habitat and beneficial and adverse impacts on juvenile rearing habitat. For juvenile stranding, all phases show beneficial impacts in wet and above normal water years and a mix of beneficial and adverse impacts for drier years. Beneficial impacts on juvenile survival due to a decrease in travel time. Potential adverse or beneficial impacts from *water temperatures* on juvenile and yearling growth, smoltification, and predation vulnerability. • **Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on upstream migration and holding adults. Flows high enough to allow upstream passage. Negligible adverse impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg/Alevin Incubation:** Possible beneficial impacts from *flow* on spawning habitat, redd dewatering potential. Beneficial impacts from *water temperatures* on spawning, egg/alevin incubation and pathogen virulence. • **Juvenile–Yearling Rearing and Emigration:** Possible adverse and beneficial impacts from *flow* on juvenile and yearling rearing habitat. Negligible adverse impacts on stranding except for adverse impacts during critically dry years. Potential adverse to beneficial impacts on travel time and beneficial impacts on juvenile survival (depending on water year type). Adverse and beneficial impacts from *water temperatures*, except at Keswick Dam where there would be an adverse impact on fry and yearling juvenile life stages. Negligible adverse impacts on lethal water temperatures. • **Adult Migration and Holding:** Potential adverse to beneficial impacts from *flow*, flows high enough to allow upstream passage. Negligible adverse impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg/Alevin Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat, spawner abundance, and egg/alevin incubation. Adverse to beneficial impacts on redd dewatering potential (depending on water year type). Potential adverse to beneficial impacts from *water temperatures* on spawning and egg/alevin incubation. • **Juvenile–Yearling Rearing and Emigration:** Potential adverse to beneficial impacts from *flow* on fry and juvenile rearing habitat. Adverse and beneficial impacts on stranding (depending on water year type). Beneficial impacts from *flow* on juvenile survival and travel time. Adverse and beneficial impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
		• **Adult Migration and Holding:** Negligible adverse impacts from *flow*. Flows are high enough to allow upstream passage. Negligible impacts from *water temperatures*.
Clear Creek		
Potential changes to spring-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations. • **Adverse and/or Beneficial:** Summer and Fall Operations. • **Beneficial:** Ramping Rates, Segregation Weir, Minimum Instream Flows, Pulse Flows, Water Temperature Management, and Spawning and Rearing Habitat.
	Alternative 1	• **Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat area. Negligible impacts from *water temperatures*. • **Juvenile–Yearling Rearing and Emigration:** Adverse impacts from *flow* on fry rearing habitat and adverse impacts on juvenile rearing habitat. Negligible adverse impacts from *water temperatures*. • **Adult Migration and Holding:** Adverse impacts from *flow* on adult migration and holding. Negligible impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat area. No anticipated impacts from *water temperatures*. • **Juvenile–Yearling Rearing and Emigration:** Beneficial impacts from *flow* on fry rearing habitat and adverse impacts on juvenile rearing habitat. Negligible impacts from *water temperatures*. • **Adult Migration and Holding:** Adverse impacts from *flow* and no anticipated impact from *water temperatures*.
	Alternative 3	• **Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat area. No anticipated impacts from *water temperatures* on spawning, pathogen virulence, or egg incubation and fry emergence. • **Juvenile–Yearling Rearing and Emigration:** Beneficial impacts from *flow* on fry rearing habitat and adverse impacts on juvenile rearing habitat. Negligible impacts from *water temperatures* on juvenile and yearling rearing and lethal water temperatures. • **Adult Migration and Holding:** Adverse impacts from *flow* on adult migration and holding. No anticipated impacts from *water temperatures* on adult migration and holding.
	Alternative 4	• **Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat area. No anticipated impacts from *water temperatures* on spawning, pathogen virulence, and egg incubation and fry emergence. • **Juvenile–Yearling Rearing and Emigration:** Beneficial impacts from *flow* on fry rearing habitat and adverse impacts on juvenile rearing habitat. Negligible adverse impacts from *water temperatures* on juvenile and yearling rearing and lethal temperature threshold (UILT).

Impact	Alternative	Direction of Impacts
		• **Adult Migration and Holding:** Adverse impacts from *flow*. No anticipated impacts from *water temperatures* on adult migration and holding.
Bay-Delta		
Potential changes to spring-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations. • **Adverse:** Agricultural Barriers. • **Beneficial:** Spring Delta Outflow • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	**Juvenile–Yearling Rearing and Emigration:** Possibly less flow into CVP under OMR -2,000 and -5,000 Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 2	**Juvenile–Yearling Rearing and Emigration:** Negligible impacts on *flow* into HOR. Alternatives without VA may have minimal less flow into CVP under OMR -2,000; alternatives with VA may have negligible impacts on flow into CVP. Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 3	**Juvenile–Yearling Rearing and Emigration:** Potential less flow into CVP under OMR -3,500. Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 4	**Juvenile–Yearling Rearing and Emigration:** Potential less *flow* into CVP under OMR -2,000. Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
Potential changes to entrainment of spring-run Chinook salmon	No Action	No measurable change from current conditions, continuation of current trends. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** Suisun Marsh RRDS Fall Flood-up, DCC Gates, and Tracy Fish Collection Facility and John E. Skinner Delta Fish Protective Facility.
	Alternative 1	**Juvenile–Yearling and Emigration:** Adverse impacts from *flow* on entrainment at both fish facilities.
	Alternative 2	**Juvenile–Yearling and Emigration:** Adverse impacts from *flow* on monthly loss at SWP and salvage. Beneficial impacts at CVP for loss.
	Alternative 3	**Juvenile–Yearling and Emigration:** Beneficial impacts from *flow* on entrainment and salvage at both fish facilities
	Alternative 4	**Juvenile–Yearling and Emigration:** Adverse impacts from *flow* on entrainment and salvage at both facilities.
Potential changes to routing of	No Action	No measurable change from current conditions, included under seasonal operations. Current trends will continue.
	Alternative 1	**Juvenile–Yearling and Emigration:** Beneficial impacts from *flow* on routing.

Impact	Alternative	Direction of Impacts
spring-run Chinook salmon	Alternative 2	**Juvenile–Yearling and Emigration:** Adverse or beneficial impacts from *flow* in the winter and spring, dependent on OMR grouping.
	Alternative 3	**Juvenile–Yearling and Emigration:** Adverse or beneficial impacts from *flow*, particularly under OMR -5,000.
	Alternative 4	**Juvenile–Yearling and Emigration:** Adverse or beneficial impacts from *flow* dependent on OMR grouping.
Potential changes to through Delta survival of spring-run Chinook salmon	No Action	No measurable change from current conditions, included under seasonal operations. Current trends are expected to continue.
	Alternative 1	**Juvenile–Yearling and Emigration:** Beneficial impacts from *flow* on routing. Negligible impacts on survival.
	Alternative 2	**Juvenile–Yearling and Emigration:** Adverse or beneficial impacts from *flow* on survival.
	Alternative 3	**Juvenile–Yearling and Emigration:** Adverse or beneficial impacts from *flow* on survival under certain OMR groupings.
	Alternative 4	**Juvenile–Yearling and Emigration:** Adverse or beneficial impacts from *flow* on survival.
CALIFORNIA CENTRAL VALLEY STEELHEAD DPS		
Sacramento River		
Potential changes to steelhead from seasonal operations	No Action	No measurable change from current operations expected. • **Beneficial Components:** Ramping Rates. • **Adverse and/or Beneficial Components:** Seasonal Operations and Rice Decomposition Smoothing, Water Temperature Management, Fall and Winter Refill and Redd Maintenance, and Spring Pulse Flows.
	Alternative 1	• **Spawning and Egg Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat area, and moderate beneficial impacts in critically dry water year types on redd dewatering potential. Beneficial impacts and some adverse impacts from *water temperatures* on spawning and egg incubation. Potential beneficial impacts to spawning behavior from removal of Spring Pulse Flows component. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on fry and juvenile rearing habitat area, adverse impacts on fry stranding during wetter water year types, and beneficial impacts on fry stranding during drier water year types. Beneficial impacts from *water temperatures* on juvenile rearing and emigration. Potential adverse impacts on juvenile outmigration and beneficial impacts on fry stranding from removal of Spring Pulse Flows component. • **Adult Upstream Migration and Holding:** Negligible adverse impacts from *flow* in the upper river but may have adverse impacts during peak migration of critically dry years. in the lower river. Adverse impacts from *water temperatures* on adult migration and holding. Potential adverse impact on adult migration from removal of Spring Pulse Flows component.

Impact	Alternative	Direction of Impacts
		• **Kelt Emigration:** Potential negligible adverse impacts from *flow*, as *flows* are expected to be above the minimum *flow* to avoid crowding and passage delays. Beneficial impacts from *water temperatures* on kelt emigration. Potential adverse impact on kelt emigration from removal of Spring Pulse Flows component.
	Alternative 2	• **Spawning and Egg Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat area, and generally beneficial impacts on redd dewatering potential. Potential adverse and beneficial impacts from *water temperatures* on spawning and egg incubation. Potential adverse impacts to spawning behavior from Spring Pulse Flows. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on fry and juvenile rearing habitat area. General beneficial impacts from *flow* on fry stranding, however, two phases of Alternative 2 (Without TUCP Delta VA and Without TUCP Systemwide VA) are expected to have adverse impacts in critically dry water year types. Beneficial and negligible adverse impacts from *water temperatures*. Spring Pulse Flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding. • **Adult Upstream Migration and Holding:** Negligible impacts from *flow* from impacts in the upper river but may have adverse and beneficial impacts during critically dry water year types in the lower river. Beneficial and negligible adverse impacts from *water temperatures*. Spring Pulse Flows may have a beneficial impact on adult migration. • **Kelt Emigration:** Potential negligible adverse impacts from *flow* change, as *flow*s are expected to be above the minimum *flow* to avoid crowding and passage delays. Beneficial impacts from *water temperatures*. Spring Pulse Flows may have a beneficial impact on kelt emigration.
	Alternative 3	• **Spawning and Egg Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat area, and adverse and beneficial impacts on redd dewatering potential. Frequent beneficial impacts and some adverse impacts from *water temperatures* on spawning and egg incubation. Potential adverse impacts to spawning behavior from Spring Pulse Flows. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flows* on fry and juvenile rearing habitat area, adverse impacts on fry stranding during above normal/below normal years and beneficial impacts in fry stranding during dry years. Frequent beneficial impacts and negligible adverse impacts from *water temperatures*. Spring Pulse Flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding.

Impact	Alternative	Direction of Impacts
		• **Adult Upstream Migration and Holding:** Negligible impacts from *flow* in the upper river but may have adverse and beneficial impacts during critically dry years in the lower river. Potential beneficial impacts and negligible adverse impacts from *water temperatures* on adult migration and holding. Spring Pulse Flows may have a beneficial impact on adult migration. • **Kelt Emigration:** Potential negligible adverse impacts from *flow* changes, as *flows* are expected to be above the minimum *flow* to avoid crowding and passage delays. Beneficial impacts and negligible adverse impacts from *water temperatures*. Spring Pulse Flows may have a beneficial impact on kelt emigration.
	Alternative 4	• **Spawning and Egg Incubation:** Negligible adverse impacts from *flow* on spawning habitat area, and beneficial impacts on redd dewatering potential during some water years. Beneficial impacts and adverse impacts from *water temperatures*. Potential adverse impacts to spawning behavior from Spring Pulse Flows. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow*s on fry and juvenile rearing habitat area, beneficial impacts on fry stranding with decreases during dry years. Beneficial impacts and negligible adverse impacts from *water temperatures*. Spring Pulse Flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding. • **Adult Upstream Migration and Holding:** Negligible adverse impacts from *flow* in the upper river but may have beneficial impacts during critically dry years in the lower river. Beneficial impacts and negligible adverse impacts from *water temperatures*. Spring Pulse Flows may have a beneficial impact on adult migration. • **Kelt Emigration:** Potential negligible impacts from *flow* change, as *flows* are expected to be above the minimum *flow* to avoid crowding and passage delays. Adverse and beneficial impacts from *water temperatures*. Spring Pulse Flows may have a beneficial impact on kelt emigration.
Clear Creek		
Potential changes to steelhead from seasonal operations	No Action	No measurable change from current operations and trends. • **Adverse:** Segregation Weir. • **Adverse and/or Beneficial:** Seasonal Operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Pulse Flows, Water Temperature Management, and Spawning and Rearing Habitat.

Impact	Alternative	Direction of Impacts
	Alternative 1	• **Spawning and Egg Incubation:** Adverse impacts from *flow* on spawning habitat across all water year types. Beneficial impacts from *water temperatures* on spawning and egg incubation. • **Juvenile Rearing and Emigration:** Adverse impacts from *flow*s on fry and juvenile rearing habitat area. Negligible adverse impacts from *water temperatures*. • **Adult Upstream Migration and Holding:** Adverse impacts from reductions in *flow* throughout the year. Negligible impacts from *water temperatures*. • **Kelt Emigration:** Adverse impacts from reductions in *flow* throughout the year. Negligible impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Beneficial impacts from *flow* on spawning habitat across all water year types. Potential negligible impacts from *water temperatures.* • **Juvenile Rearing and Emigration:** Negligible impacts from *flow* on fry rearing habitat and adverse impacts on juvenile rearing habitat. No anticipated impacts from *water temperatures*. • **Adult Upstream Migration and Holding:** Negligible impacts from *flow*. No anticipated impacts from *water temperatures*. • **Kelt Emigration:** Negligible impacts from *flow* and no anticipated impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial impacts from *flow* on spawning habitat. Negligible impacts from *water temperatures* on spawning and egg incubation. • **Juvenile Rearing and Emigration:** Negligible impacts from *flow* on fry rearing habitat and adverse impacts on juvenile rearing habitat. • **Adult Upstream Migration and Holding:** Negligible impacts from *flow*. • **Kelt Emigration:** Negligible impacts from *flow* and no anticipated impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Beneficial impacts from *flow* on spawning habitat. Similar adverse and beneficial impacts from *water temperatures* on spawning and egg incubation. • **Juvenile Rearing and Emigration:** Negligible impacts from *flow* on fry rearing habitat and adverse impacts on juvenile rearing habitat. No anticipated impacts from *water temperatures*. • **Adult Upstream Migration and Holding:** Negligible impacts from *flow*. No anticipated impacts from *water temperatures*. • **Kelt Emigration:** Negligible impacts from *flow* and no anticipated impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
Lower American River		
Potential changes to steelhead from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Pulse Flows, Redd Dewatering Adjustments, and Spawning and Rearing Habitat Restoration. • **Adverse and/or Beneficial:** Seasonal Operations and Water Temperature Management.
	Alternative 1	• **Spawning and Egg Incubation:** Adverse impacts from *flow* on spawning habitat area and adverse impacts on redd dewatering potential in drier water year types. Adverse impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse impacts from *flow* in critically dry water year types on rearing habitat area. Adverse and beneficial impacts from *water temperatures* on juvenile rearing and emigration. • **Adult Upstream Migration and Holding:** Negligible impacts from *flow* during peak adult migration and holding but there may be adverse impacts in September of drier water year types. Adverse and beneficial impacts from *water temperatures*. • **Kelt Emigration:** Negligible impacts from *flow* and *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Adverse impacts from *flow* on spawning habitat area and redd dewatering potential. Adverse and beneficial impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* in critically dry water year types on rearing habitat area depending on the month. Negligible adverse and beneficial impacts from *water temperatures*. • **Adult Upstream Migration and Holding:** Negligible impacts from *flow* during peak adult migration and holding but there may be adverse impacts in October and November of drier water year types. Adverse and beneficial impacts from *water temperatures* depending on the location (Hazel Ave or Watt Ave). • **Kelt Emigration:** Negligible impacts from *flow*. Adverse and beneficial impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Adverse or beneficial impacts from *flow* on spawning habitat area and are expected decrease redd dewatering potential. Adverse impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* in critically dry years on rearing habitat. Adverse impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
		• **Adult Upstream Migration and Holding:** Negligible impacts from *flow* during peak adult migration and holding. Adverse and beneficial impacts from *water temperatures* depending on the location (Hazel or Watt Ave). • **Kelt Emigration:** Negligible impacts from *flow*. Adverse and beneficial impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Adverse impacts from *flow* on spawning habitat area and adverse impacts on redd dewatering potential. Adverse impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse impacts from *flow* in critically dry waters on rearing habitat area. Beneficial and adverse impacts from *water temperatures*. • **Adult Upstream Migration and Holding:** Negligible impacts from *flow*. Beneficial and adverse impacts from *water temperatures* on adult migration and holding. • **Kelt Emigration:** Negligible impacts from *flow*. Adverse impacts from *water temperatures*.
Bay-Delta		
Potential changes to steelhead from seasonal operations	No Action	No measurable change from current operations. • **Adverse:** Agricultural Barriers. **Beneficial:** Spring Delta Outflow. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	**Juvenile Rearing and Emigration:** Possibly less *flow* into CVP under OMR -2,000 and -5,000; possibly less flow into HOR.
	Alternative 2	**Juvenile Rearing and Emigration:** Negligible impacts on *flow* into HOR. Phases without VA may have minimal less flow into CVP under OMR -2,000; phases with VA may have negligible impacts on flow into CVP. Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 3	**Juvenile Rearing and Emigration:** Possibly little to less *flow* into CVP under OMR -3,500. Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 4	**Juvenile Rearing and Emigration:** Possibly little to less *flow* into CVP under OMR -2,000. Impacts from pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
Potential changes to entrainment of steelhead	No Action	No measurable change from current conditions, continuation of current trends under the No Action Alternative. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, and Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	**Juvenile Rearing and Emigration:** Increases in entrainment.
	Alternative 2	**Juvenile Rearing and Emigration:** Increases and decreases in entrainment.

Impact	Alternative	Direction of Impacts
	Alternative 3	**Juvenile Rearing and Emigration:** Decreases in entrainment.
	Alternative 4	**Juvenile Rearing and Emigration:** Increases and decreases in entrainment.
Potential changes to routing and through Delta survival of steelhead	No Action	No measurable change from current conditions, included under seasonal operations.
	Alternative 1	**Juvenile Rearing and Emigration:** Beneficial impacts with a smaller proportion routed to Interior Delta between December and March, particularly in OMR bins more negative than -5,500.
	Alternative 2	**Juvenile Rearing and Emigration:** Adverse or beneficial impacts for outmigrating juvenile steelhead in the winter and spring, dependent on OMR grouping. Adverse or beneficial impacts on survival of outmigrating juvenile steelhead depending on OMR grouping.
	Alternative 3	**Juvenile Rearing and Emigration:** Adverse or beneficial impacts with a smaller proportion routed to Interior Delta between December and March, particularly under OMR -5,000. Potential adverse or beneficial impacts on survival of outmigrating juvenile steelhead, under certain OMR conditions.
	Alternative 4	**Juvenile Rearing and Emigration:** Adverse or beneficial impacts from *flow* dependent on OMR grouping.
San Joaquin River		
Potential changes to steelhead from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	• **Juvenile Rearing and Emigration:** Negligible impacts from *flow* and *water temperatures* on juvenile emigration. • **Adult Upstream Migration and Holding:** Negligible to minor beneficial impacts from *flow* and *water temperatures*.
	Alternative 2	• **Juvenile Rearing and Emigration:** Negligible impacts from *flow* and *water temperatures* on juvenile emigration. • **Adult Upstream Migration and Holding:** Beneficial impacts from *flow* and *water temperatures*.
	Alternative 3	• **Juvenile Rearing and Emigration:** Negligible impacts from *flow* and *water temperatures* on juvenile emigration. • **Adult Upstream Migration and Holding:** Adverse impacts from *flow* and *water temperatures*.
	Alternative 4	• **Juvenile Rearing and Emigration:** Negligible impacts from *flow* and *water temperatures* on juvenile emigration. • **Adult Upstream Migration and Holding:** Potential beneficial impacts from *flow* and *water temperatures*.

Impact	Alternative	Direction of Impacts
Stanislaus River		
Potential changes to steelhead from seasonal operations	No Action	No measurable change from current conditions, continuation of current trends under the No Action Alternative. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Winter Instability Flows, Spring Pulse Flows, Fall Pulse Flows, Spawning, and Rearing Habitat Restoration. • **Adverse/and or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Adverse impacts from *flow* on spawning habitat area. Potential beneficial impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse or beneficial impacts from *flow* on juvenile and fry rearing habitat area depending on the water year type and may decrease depending on the month. Potential beneficial impacts from *water temperatures* on juvenile emigration. • **Adult Upstream Migration and Holding:** Potential adverse and beneficial impacts from *flow* during critically dry water year types. Potential negligible impacts from *water temperatures*. • **Kelt Emigration:** Potential beneficial impacts from *flow* during critically dry years. Potential beneficial impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat area, depending on the water year type. Potential negligible adverse impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on juvenile and fry rearing habitat area depending on the water year type. Potential negligible adverse impacts from *water temperatures* on juvenile emigration. • **Adult Upstream Migration and Holding:** Potential beneficial impacts from *flow* in the fall of drier years. Potential negligible impacts from *water temperatures*. • **Kelt Emigration:** Potential beneficial impacts from *flow* in February of drier years. Potential adverse impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Adverse impacts from *flow* on spawning habitat area in wet, below normal, and dry water year types. Potential beneficial impacts from *water temperatures* on spawning and egg incubation. • **Juvenile Rearing and Emigration:** Adverse or beneficial impacts from *flow* on juvenile and fry rearing habitat area depending on the water year type. Potential beneficial impacts from *water temperatures* on juvenile emigration. • **Adult Upstream Migration and Holding:** Potential adverse impacts from *flow* in September, November, December of drier water year types. Potential negligible impacts from *water temperatures* on adult migration and holding.

Impact	Alternative	Direction of Impacts
		• **Kelt Emigration:** Potential beneficial impacts from *flow* in February of drier years. Potential beneficial impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Adverse or beneficial impacts from *flow* on spawning habitat area depending on water year type. Potential negligible impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse or beneficial impacts from *flow* on juvenile and fry rearing habitat area depending on the water years. Potential negligible impacts from *water temperatures* on juvenile emigration. • **Adult Upstream Migration and Holding:** Potential beneficial impacts from *flow* in the fall of drier years. Potential negligible impacts from *water temperatures* on adult migration and holding. • **Kelt Emigration:** Potential beneficial impacts from changes in *flow* in February of drier years. Potential adverse impacts from *water temperatures*.
SOUTHERN DPS GREEN STURGEON		
Sacramento River		
Potential changes to green sturgeon from seasonal operations	No Action	No measurable change from current operations. • **Adverse and/or Beneficial Components:** Seasonal Operations and Fall and Winter Refill and Redd Maintenance. • **Adverse Components:** Rice Decomposition Smoothing. • **Beneficial Components:** Ramping Rates, Spring Pulse Flows, Water Temperature Management.
	Alternative 1	• **Spawning and Egg Incubation:** Potential adverse impacts from *flow* on spawning and incubation habitat. Beneficial impacts from *water temperatures* on spawning and egg incubation. • **Larval and Juvenile Rearing and Emigration:** Potential adverse impacts from *flow* on rearing and emigration. Adverse and beneficial impacts from *water temperatures*. • **Adult Upstream Migration and Holding:** Possible adverse impacts from *flow* on upstream migration and holding habitats. Adverse and beneficial impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** No impacts to possible beneficial impacts from *flow* on spawning habitat depending on phase, location, month, and water year type. Beneficial impacts and minor adverse impacts from *water temperatures* on spawning and egg incubation depending on location, month, and water year type. • **Larval and Juvenile Rearing and Emigration:** Minor adverse impacts from *flow* are expected on rearing and emigration depending on phase, location, month, and water year type. Adverse and beneficial impacts from *water temperatures* are expected depending on phase, location, month, and water year type.

Impact	Alternative	Direction of Impacts
		• **Adult Upstream Migration and Holding:** Adverse and beneficial impacts from *flow* on upstream migration and holding habitats depending on phase, location, month, and water year type. Adverse impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat. Beneficial and adverse impacts from *water temperatures*. • **Larval and Juvenile Rearing and Emigration:** Adverse impacts from *flow* are expected on rearing and emigration. Adverse and beneficial impacts from *water temperatures*. • **Adult Upstream Migration and Holding:** Adverse and beneficial impacts from *flow* on upstream migration and holding habitats. Negligible adverse and beneficial impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Adverse and beneficial impacts from *water temperatures*. • **Larval and Juvenile Rearing and Emigration:** Beneficial impacts from *flow*. Adverse and beneficial impacts from *water temperatures*. • **Adult Upstream Migration and Holding:** No impacts to beneficial impacts from *flow*. Adverse impacts from *water temperatures* on upstream migration and holding depending on location, month, and water year type.
San Joaquin River		
Potential changes to green sturgeon from seasonal operations	No Action	No measurable change from current operations and trends.
	Alternative 1	**Adults:** Beneficial impacts from *flow*
	Alternative 2	**Adults:** Beneficial impacts from *flow*
	Alternative 3	**Adults:** No impacts from *flow*.
	Alternative 4	**Adults:** Beneficial impacts from *flow*.
Bay-Delta		
Potential changes to green sturgeon from seasonal operations	No Action	No change from current operations. • **Adverse:** Seasonal Operations and Agricultural Barriers.
	Alternative 1	• **Juvenile Rearing and Emigration:** No impacts from *flow* on year class strength. • **Adult Upstream Migration and Holding:** No impacts from *flow*
	Alternative 2	• **Juvenile Rearing and Emigration:** No impacts from *flow* on year class strength. • **Adult Upstream Migration and Holding:** No impacts from *flow* on adult migration.
	Alternative 3	• **Juvenile Rearing and Emigration:** Beneficial impacts from *flows* on year class strength. • **Adult Upstream Migration and Holding:** Beneficial impacts from *flow* on adult migration.

Impact	Alternative	Direction of Impacts
	Alternative 4	• **Juvenile Rearing and Emigration:** No impacts from *flow* on year class strength. • **Adult Upstream Migration and Holding:** No impacts from *flow* on adult migration.
Potential changes to entrainment of green sturgeon	No Action	No measurable change from current conditions, continuation of current trends under the No Action Alternative. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	**Juvenile Rearing and Emigration:** Potential adverse impacts but since salvaged so rarely, numbers may not be representative.
	Alternative 2	**Juvenile Rearing and Emigration:** Potential beneficial impacts but since salvaged so rarely, numbers may not be representative.
	Alternative 3	**Juvenile Rearing and Emigration:** Potential beneficial impacts but since salvaged so rarely, numbers may not be representative.
	Alternative 4	**Juvenile Rearing and Emigration:** Potential beneficial and adverse impacts but since salvaged so rarely, numbers may not be representative.
DELTA SMELT		
Bay-Delta		
Potential changes to Delta smelt from seasonal operations	No Action	No measurable change from current operations. • **Adverse Components:** Seasonal Operations. • **Beneficial Components:** Spring Delta Outflow, Delta Smelt Supplementation, and Delta Smelt SFH.
	Alternative 1	• **Adults:** Adverse impacts from *flow* on prey abundance (CPUE) and population growth rates. Negligible impacts on low salinity habitat (i.e., X2 position). • **Eggs and Larvae:** Adverse impacts from *flow* on prey abundance (CPUE) and population growth rates. Negligible impacts on low salinity habitat (i.e., X2 position). • **Juveniles:** Potential adverse impacts from *flow* on prey abundance (CPUE), and population growth rates. Potential impacts on low salinity habitat. Potential adverse impacts on suitable summer and fall habitat.
	Alternative 2	• **Adults:** Adverse impacts from *flow* on prey abundance (CPUE), and population growth rates. Negligible impacts on low salinity habitat (i.e., X2 position). • **Eggs and Larvae:** Adverse to beneficial impacts from *flow* on prey abundance (CPUE), and population growth rates. Negligible impacts on low salinity habitat (i.e., X2 position).

Impact	Alternative	Direction of Impacts
		• **Juveniles:** Adverse impacts from *flow* on prey abundance (CPUE), and population growth rates. Negligible impacts on low salinity habitat (i.e., X2 position). Negligible to minor beneficial and minor adverse impacts on suitable summer and fall habitat depending on water year type and application of temperature threshold.
	Alternative 3	• **Adults:** Beneficial impacts from *flow* on prey abundance (CPUE), and population growth rates. Negligible to beneficial impacts on low salinity habitat (i.e., X2 position). • **Eggs and Larvae:** Beneficial impacts from *flow* on prey abundance (CPUE), and population growth rates. Negligible to beneficial impacts on low salinity habitat (i.e., X2 position). • **Juveniles:** Beneficial impacts from *flow* on prey abundance (CPUE), and population growth rates. Negligible on low salinity habitat (i.e., X2 position). Beneficial and adverse impacts on suitable summer and fall habitat
	Alternative 4	• **Adults:** Adverse impacts from *flow* on prey abundance (CPUE), and population growth rates. Negligible impacts on low salinity habitat (i.e., X2 position). • **Eggs and Larvae:** Adverse impacts from *flow* on prey abundance (CPUE), and population growth rates. Negligible impacts on low salinity habitat (i.e., X2 position). • **Juveniles:** Adverse impacts from *flow* on prey abundance (CPUE), and population growth rates. Adverse impacts on low salinity habitat (i.e., X2 position). Adverse impacts on suitable summer and fall habitat.
Potential changes to entrainment of Delta smelt	No Action	No measurable change from current conditions, continuation of current trends. • **Adverse:** RRDS Fall Flood-up. • **Beneficial:** BSPP, Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** Tracy Fish Collection Facility and John E. Skinner Fish Protective Facility.
	Alternative 1	• **Adults:** Adverse impacts from *flow*, OMR values were more negative from January to June. • **Eggs and Larvae:** Possible adverse to beneficial impacts from *flow* on larvae depending on particle origin, inflow grouping, and OMR grouping. • **Juveniles:** Adverse to beneficial impacts from *flow*, in general, OMR values were more negative in June, September and October and less negative in November.
	Alternative 2	• **Adults:** Adverse to beneficial impacts from *flow*, OMR values were more negative during April and May for phases without VAs and May for phases with VAs. OMR values were less negative during June for phases without VAs, March and June for the Delta VA phase and March, April and June for the phase with systemwide VAs.

Impact	Alternative	Direction of Impacts
		• **Eggs and Larvae:** Beneficial to adverse impacts from *flow* based on inflow grouping and OMR grouping. • **Juveniles:** Negligible to beneficial impacts from *flow*, OMR was less negative across all phases in June.
	Alternative 3	• **Adults:** Beneficial impacts from *flow*, OMR values were less negative from January to June • **Eggs and Larvae:** Beneficial impacts from *flow* for all inflow grouping. Negligible impacts from *flow* based on OMR groupings. • **Juveniles:** Beneficial impacts from *flow*, OMR values were less negative from June to November.
	Alternative 4	• **Adults:** Adverse to beneficial impacts from *flow*, OMR values were less negative from January and June but more negative from February to May. • **Eggs and Larvae:** Potential adverse tonegligible impacts from *flow* based on inflow grouping and OMR grouping. • **Juveniles:** Negligible to beneficial impacts from *flow*, OMR values were less negative in June.
LONGFIN SMELT		
Bay-Delta		
Potential changes to Longfin smelt from seasonal operations	No Action	No measurable change from current operations. • **Adverse Components:** Seasonal Operations. • **Beneficial Components:** Spring Delta Outflow, and Delta Smelt SFH.
	Alternative 1	• **Adults:** Adverse impacts from *flow* on prey abundance (CPUE). Negligible impacts on low salinity habitat (i.e., X2 position) in winter and spring, adverse impacts during wet and above normal years in fall (September and October). • **Eggs and Larvae:** Adverse and beneficial impacts from *flow* on prey abundance (CPUE), depending on water year type and season. Negligible impacts on low salinity habitat (i.e., X2 position). • **Juveniles:** Adverse impacts from *flow* on prey abundance (CPUE), and juvenile abundance. Negligible impacts on low salinity habitat (i.e., X2 position).
	Alternative 2	• **Adults:** Beneficial and adverse impacts from *flow* on prey abundance (CPUE). Negligible impacts on low salinity habitat (i.e., X2 position). • **Eggs and Larvae:** Adverse and beneficial impacts from *flow* on prey abundance (CPUE). Negligible impacts on low salinity habitat (i.e., X2 position). • **Juveniles:** Beneficial and adverse impacts from *flow* on juvenile abundance and prey abundance (CPUE). Negligible impacts on low salinity habitat (i.e., X2 position).

Impact	Alternative	Direction of Impacts
	Alternative 3	• **Adults:** Beneficial impacts from *flow* on prey abundance (CPUE) and negligible to beneficial impacts on low salinity habitat (i.e., X2 position). • **Eggs and Larvae:** Beneficial impacts from *flow* on prey abundance (CPUE) and negligible to beneficial impacts on low salinity habitat (i.e., X2 position). • **Juveniles:** Beneficial impacts from *flow* on juvenile abundance and prey abundance (CPUE) and negligible to beneficial impacts on low salinity habitat (i.e., X2 position).
	Alternative 4	• **Adults:** Negligible to beneficial and adverse impacts from *flow* on prey abundance (CPUE) depending on water year type. Negligible impacts on low salinity habitat (i.e., X2 position). • **Eggs and Larvae:** Negligible to beneficial and adverse impacts from *flow* on prey abundance (CPUE) depending on water year type. Negligible impacts on low salinity habitat (i.e., X2 position). • **Juveniles:** Negligible impacts from *flow* on juvenile abundance and negligible to adverse impacts on prey abundance (CPUE). Negligible impacts on low salinity habitat (i.e., X2 position).
Potential changes to entrainment of Longfin smelt	No Action	No measurable change from current conditions, continuation of current trends. • **Adverse:** RRDS Fall Flood-up. • **Beneficial:** BSPP, and Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** Tracy Fish Collection Facility and John E. Skinner Delta Fish Protective Facility.
	Alternative 1	• **Adults:** Negligible impacts from *flow* on X2 position in winter and spring, adverse impacts during wet and above normal years in fall (September and October). Adverse impacts from increased exports and more negative OMR values that were greater than -5000 cfs during the winter. • **Eggs and Larvae:** Potential negligible to adverse impacts from *flow* for inflow groupings and OMR groupings. • **Juveniles:** Adverse impacts from *flow*, particularly in above normal water year type.
	Alternative 2	• **Adults:** Negligible impacts from *flow* on X2 position. Adverse impacts from higher exports and more negative OMR values for phases without VAs and beneficial impacts from lower exports and less negative OMR values for phases with VAs. • **Eggs and Larvae:** Negligible to beneficial impacts from *flow* depending on particle origin, inflow grouping, and OMR grouping. • **Juveniles:** Adverse impacts from *flow* under all phases of Alternative 2 in all water year types except a dry water year type under Alternative 2 without TUCP Systemwide VA, which is expected to have beneficial impacts.

Impact	Alternative	Direction of Impacts
	Alternative 3	• **Adults:** Negligible to beneficial impacts from *flow* on X2 position, moving X2 further seaward for most months and water year types. Beneficial impacts from decreased exports and less negative OMR values. • **Eggs and Larvae:** Beneficial impacts from *flow* based on inflow grouping. Possible negligible to beneficial impacts from *flow* depending on OMR grouping. • **Juveniles:** Beneficial impacts from *flow*.
	Alternative 4	• **Adults:** Negligible impacts from *flow* on X2 position. Adverse and beneficial impacts from exports and OMR values depending on month. • **Eggs and Larvae:** Possible negligible impacts from *flow* depending on inflow grouping and OMR grouping. • **Juveniles:** Adverse impacts from *flow*.
FALL-RUN AND LATE FALL-RUN CHINOOK SALMON ESU		
Sacramento River		
Potential changes to fall-run and late fall-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations. • **Beneficial Components:** Ramping Rates and Water Temperature Management. • **Adverse and/or Beneficial Components:** Seasonal Operations and Rice Decomposition Smoothing, Fall and Winter Refill and Redd Maintenance, and Spring Pulse Flows.
	Alternative 1	• **Fall-run Spawning and Egg/Alevin Incubation:** Beneficial impacts from *flow* on spawning habitat area and redd dewatering potential. Adverse impacts from *water temperatures* on spawning initiation. • **Fall-run Juvenile Rearing and Emigration:** Adverse impacts from *flow* on rearing habitat. Adverse and beneficial impacts from *flow* on fry stranding, depending on water year type. Adverse impacts from *water temperatures* on growth and smoltification and beneficial impacts on pathogen virulence. Potential adverse impacts on juvenile outmigration and beneficial impacts on fry stranding from removal of Spring Pulse Flows component. • **Fall-run Adult Migration and Holding:** Adverse impacts from *water temperatures* on adult migration and pathogen virulence. • **Late Fall-run Spawning and Egg/ Alevin Incubation:** Adverse impacts from *flow* on spawning habitat. Adverse impacts from *water temperatures* on spawning and incubation and the frequency of pathogen virulence. Potential beneficial impacts to spawning behavior from removal of Spring Pulse Flows component. • **Late Fall-run Juvenile Rearing and Emigration:** Adverse impacts from *flow* on fry and juvenile rearing habitat. Adverse and beneficial impacts from *water temperatures* on conditions for growth, smoltification, vulnerability to predators and virulent pathogens. Potential adverse impacts on juvenile outmigration and beneficial impacts on fry stranding from removal of Spring Pulse Flows component.

Impact	Alternative	Direction of Impacts
	Alternative 2	• **Fall-run Spawning and Egg/Alevin Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat and redd dewatering potential. Adverse impacts from *water temperatures* on spawning initiation below Keswick Dam. • **Fall-run Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on fry and juvenile rearing habitat, and adverse and beneficial impacts on fry stranding, however the beneficial impacts are greater and more frequent. Adverse and beneficial impacts from *water temperatures* on juvenile rearing and emigration. Spring pulse flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding. • **Fall-run Adult Migration and Holding:** Beneficial impacts from *water temperatures* on adult migration and holding. • **Late Fall-run Spawning and Egg/Alevin Incubation:** Negligible adverse impacts from *flow* on spawning habitat area and impact redd dewatering potential. Beneficial impacts from *water temperatures* on incubation and fry emergence. Potential adverse impacts to spawning behavior from spring pulse flows. • **Late Fall-run Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on fry and juvenile rearing habitat area and fry stranding. Adverse and beneficial impacts from *water temperatures* on conditions for growth, smoltification, and vulnerability to predators, and beneficial impacts for juveniles with regards to pathogen virulence. Spring pulse flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding. • **Late Fall-run Adult Migration and Holding:** Beneficial impacts on juveniles with regards to pathogen virulence.
	Alternative 3	• **Fall-run Spawning and Egg/Alevin Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat and redd dewatering potential. • **Fall-run Juvenile Rearing and Emigration:** Adverse impacts from *flow* on fry rearing habitat, adverse and beneficial impacts on juvenile rearing habitat. Some adverse impacts on fry stranding in above normal years. Adverse impacts from *water temperatures* on growth, smoltification and predation, but beneficial impacts on juveniles in regards to pathogen virulence. Spring pulse flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding. • **Fall-run Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on adult migration and holding. Beneficial impacts from *water temperatures* on adult migration and pathogen virulence.

Impact	Alternative	Direction of Impacts
		• **Late Fall-run Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat area in above normal water years. Minor adverse impacts from on redd dewatering potential. Beneficial impacts from *water temperatures* on spawning initiation, egg incubation and fry emergence. Potential adverse impacts to spawning behavior from spring pulse flows. • **Late Fall-run Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on fry and juvenile rearing habitat, and adverse impacts on fry stranding. Adverse impacts from *water temperatures* on growth, smoltification, predation except at Hamilton City, where beneficial impacts are predicted. Beneficial impacts on juveniles in regard to pathogen virulence, except at Hamilton City where adverse impacts are predicted. Spring pulse flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding. • **Late Fall-run Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on adult migration and holding conditions. Beneficial impacts from *water temperatures* on migration and pathogen virulence.
	Alternative 4	• **Fall-run Spawning and Egg/Alevin Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat area. Adverse impacts from *flow* on redd dewatering potential in critically dry water years. • **Fall-run Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on fry and juvenile rearing habitat, and beneficial impacts on fry stranding. Adverse and beneficial impacts from *water temperatures*. Spring pulse flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding. • **Fall-run Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on adult migration and holding. Beneficial impacts from *water temperatures* on migration and pathogen virulence. • **Late Fall-run Spawning and Egg/ Alevin Incubation:** Adverse and beneficial impacts from *flow* on spawning habitat. Potential adverse impacts to spawning behavior from spring pulse flows. • **Late Fall-run Juvenile Rearing and Emigration:** Adverse impacts from *flow* on fry and juvenile rearing habitat and fry stranding. Adverse and beneficial impacts from *water temperatures*.. Spring pulse flows may have beneficial impacts on juvenile outmigration and adverse impacts on fry stranding. • **Late Fall-run Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on adult migration and holding conditions. Beneficial impacts from *water temperatures* on migration and pathogen virulence.

Impact	Alternative	Direction of Impacts
Clear Creek		

Potential changes to fall-run and late fall-run Chinook salmon from seasonal operations	No Action	No expected change from current operations.
		• **Fall-run**
		  • *Beneficial:* Ramping Rates, Minimum Instream Flows, Pulse Flows, Water Temperature Management, and Spawning and Rearing Habitat.
		  • *Adverse and/or Beneficial:* Summer and Fall Operations and Segregation Weir.
		• **Late Fall-run**
		  • *Beneficial:* Ramping Rates, Minimum Instream Flows, Pulse Flows, Water Temperature Management, and Spawning and Rearing Habitat,
		  • *Adverse and/or Beneficial:* Summer and Fall Operations.

	Alternative 1	• **Fall-run Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat. Negligible impacts from *water temperatures* on egg incubation, spawning initiation, pathogen virulence, and incubation/emergence. • **Fall-run Juvenile Rearing and Emigration:** Beneficial impacts from *flow* on fry but an adverse impact on juvenile rearing habitat. • **Fall-run Adult Migration and Holding:** Adverse impacts from decreased *flow*. • **Late Fall-run Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat. Negligible impacts from *water temperatures* on egg incubation, spawning initiation, pathogen virulence, and incubation/emergence. • **Late Fall-run Juvenile Rearing and Emigration:** Adverse impacts from *flow* on juvenile rearing habitat. • **Late Fall-run Adult Migration and Holding:** Adverse impacts from *flow*.
	Alternative 2	• **Fall-run Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat. • **Fall-run Juvenile Rearing and Emigration:** Beneficial impacts from *flow* on fry but adverse impacts on juvenile rearing habitat. • **Fall-run Adult Migration and Holding:** Adverse impacts from decreased *flow*. • **Late Fall-run Spawning and Egg/Alevin Incubation:** Adverse to beneficial impacts from *flow* on spawning habitat. No anticipated impact from *water temperatures*. • **Late Fall-run Juvenile Rearing and Emigration:** Adverse to beneficial impacts from *flow*. • **Late Fall-run Adult Migration and Holding:** Beneficial impacts from *flow*.
	Alternative 3	• **Fall-run Spawning and Egg/Alevin Incubation:** Beneficial impacts from *flow* in critically dry years and below normal years, but a negligible impact in all other water years

Impact	Alternative	Direction of Impacts
		• **Fall-run Juvenile Rearing and Emigration:** Decrease from *flow* on fry and juvenile rearing habitat. • **Fall-run Adult Migration and Holding:** Negative and beneficial impacts from decreased *flow* in July through October and increased flow in November and January. • **Late Fall-run Spawning and Egg/Alevin Incubation:** Adverse impacts and minor to moderate beneficial impacts from *flow* on spawning habitat. • **Late Fall-run Juvenile Rearing and Emigration:** Adverse impacts and beneficial impacts from *flow*. • **Late Fall-run Adult Migration and Holding:** Beneficial impacts from *flow*.
	Alternative 4	• **Fall-run Spawning and Egg/Alevin Incubation:** Beneficial impacts from *flow* on spawning habitat. No anticipated impacts from *water temperatures* on spawning and egg incubation. • **Fall-run Juvenile Rearing and Emigration:** Adverse impacts from *flow* on fry rearing and emigration habitat and juvenile rearing habitat. • **Fall-run Adult Migration and Holding:** Adverse and beneficial impacts from *flow*. • **Late Fall-run Spawning and Egg/Alevin Incubation:** Beneficial and adverse impacts from *flow* on spawning habitat. • **Late Fall-run Juvenile Rearing and Emigration:** Beneficial and adverse impacts from *flow*. • **Late Fall-run Adult Migration and Holding:** Beneficial impacts from *flow*.
Lower American River		
Potential changes to fall-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Spring Pulse Flows, Redd Dewatering Adjustments, Water Temperature Management, and Spawning and Rearing Habitat Restoration. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg/Alevin Incubation:** Adverse impact on spawning habitat and redd dewatering potential from *flow*. Adverse and beneficial impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse impacts from *flow* in below normal and dry years, but beneficial impacts from *flow* in critically dry years. Adverse and beneficial impacts from *water temperatures* on growth, smoltification, and predation vulnerability, and adverse impacts on pathogen virulence. • **Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on adult migration. Adverse and beneficial impacts from *water temperatures* on growth, smoltification, and predation vulnerability. Adverse impacts on pathogen virulence.

Impact	Alternative	Direction of Impacts
	Alternative 2	• **Spawning and Egg/Alevin Incubation:** Adverse impacts from *flow* on spawning habitat and increase in redd dewatering potential. Negligible impacts from *water temperatures.* • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow*. Adverse and beneficial impacts from *water temperatures*. • **Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on upstream migration. Adverse and beneficial impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg/Alevin Incubation:** Adverse and beneficial impact from *flow* on spawning habitat. Beneficial impacts from *flow* on redd dewatering potential. Adverse and beneficial impacts from *water temperatures* on spawning initiation, pathogen virulence, and egg incubation and fry emergence. • **Juvenile Rearing and Emigration:** Adverse impacts from *flow* in June and July. Adverse and beneficial impacts from *water temperatures* on spawning initiation, pathogen virulence, and egg incubation and fry emergence. • **Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on adult migration. Adverse and beneficial impacts from *water temperatures* on migration, and adverse impacts on pathogen virulence.
	Alternative 4	• **Spawning and Egg/Alevin Incubation:** Adverse impact from *flow* on spawning habitat area and redd dewatering potential in non-critically dry water years. Beneficial impact from *flow* on redd dewatering potential during critically dry years. Adverse and beneficial impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* during critically dry years. Adverse and beneficial impacts from *water temperatures*. • **Adult Migration and Holding:** Adverse and beneficial impacts from *flow* during critically dry years. Adverse and beneficial impacts from *water temperatures* on adult migration and pathogen virulence.
San Joaquin River		
Potential changes to fall-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	**Migration:** Adverse impacts from *flow* on migrating adults and beneficial impacts on migrating juveniles. Negligible impacts from *water temperatures*.
	Alternative 2	**Migration:** Negligible impacts from *water temperatures*.
	Alternative 3	**Migration:** Adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	**Migration:** Minimal impacts from *flow* on migrating adults and juveniles. Negligible impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
Bay-Delta		

Potential changes to fall-run and late fall-run Chinook salmon from seasonal operations	No Action	No measurable change from current operations.
		• **Fall-run:**
		  • *Adverse:* Agricultural Barriers.
		  • *Beneficial:* Spring Delta Outflow
		  • *Adverse and/or Beneficial:* Seasonal Operations.
		• **Late Fall-run:**
		  • *Beneficial:* Spring Delta Outflow.
		  • *Adverse and/or Beneficial:* Seasonal Operations.

	Alternative 1	**Juvenile–Yearling Rearing and Emigration:** Possibly less flow into CVP under OMR -2,000 and -5,000; possibly less flow into HOR. Impacts of pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 2	**Juvenile–Yearling Rearing and Emigration:** Negligible impacts on *flow* into HOR. Alternatives without VA may have minimal less flow into CVP under OMR -2,000; alternatives with VA may have negligible impacts on flow into CVP. Impacts of pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 3	**Juvenile–Yearling Rearing and Emigration:** Less flow into CVP under OMR -3,500; no change in flow into HOR. Impacts of pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
	Alternative 4	**Juvenile–Yearling Rearing and Emigration:** Less *flow* into CVP under OMR -2,000; no change in flow into HOR. Impacts of pumping smaller at more upstream locations (e.g., Jersey Point) and greater at Turner Cut.
Potential changes to entrainment of fall-run and late fall-run Chinook salmon	No Action	No measurable change from current conditions, continuation of current trends. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, Tracy Fish Collection Facility and John E. Skinner Delta Fish Protective Facility.
	Alternative 1	**Fall-run / Late Fall-run Rearing and Emigration:** Adverse impacts from exports on the entrainment of the juvenile fall-run and late fall-run Chinook in the Delta at both fish facilities.
	Alternative 2	**Fall-run Rearing and Emigration:** Adverse impacts from exports on entrainment at Banks Pumping Plant under all phases, Adverse impacts on entrainment at the Jones Pumping Plant in Critically Dry years.
	Alternative 3	• **Fall-run Rearing and Emigration:** Adverse impacts from exports on entrainment at Banks and Jones Pumping Plants. • **Late Fall-run Rearing and Emigration:** Adverse impacts on entrainment at both Banks and Jones Pumping Plants.
	Alternative 4	• **Fall-run Rearing and Emigration:** Adverse impacts from exports on entrainment at Banks Pumping Plant.

Impact	Alternative	Direction of Impacts
		• **Late Fall-run Rearing and Emigration:** Adverse and beneficial impacts from exports on entrainment at Banks Pumping Plant.
Potential changes to through Delta survival of fall-run and late fall-run Chinook salmon	No Action	No measurable change from current conditions included under seasonal operations.
	Alternative 1	**Fall-run / Late Fall-run Rearing and Emigration:** Negligible impacts on through Delta survival.
	Alternative 2	**Fall-run / Late Fall-run Rearing and Emigration:** Negligible impacts on through Delta survival.
	Alternative 3	**Fall-run / Late Fall-run Rearing and Emigration:** Similar to No Action on through Delta survival.
	Alternative 4	**Fall-run / Late Fall-run Rearing and Emigration:** Negligible impacts on through Delta survival.
Stanislaus River		
Potential changes to fall-run Chinook salmon from seasonal operations	No Action	No change from current operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Winter Instability Flows, Spring Pulse Flows, Fall Pulse Flows, and Spawning and Rearing Habitat Restoration. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg/Alevin Incubation:** Beneficial impacts from *flow* on spawning habitat. Adverse impacts from *water temperatures* on spawning initiation and spawning pathogen virulence. • **Juvenile Rearing and Emigration:** Beneficial impacts from *flow*. Adverse and beneficial impacts from *water temperatures* on growth, smoltification and predation vulnerability, adverse impacts on pathogen virulence. • **Adult Migration and Holding:** Adverse impacts and beneficial impacts on adult migration. Beneficial impacts from *water temperatures* on migration, but adverse impacts on pathogen virulence.
	Alternative 2	• **Spawning and Egg/Alevin Incubation:** Beneficial impacts from *flow* on spawning habitat area. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on rearing habitat area. • **Adult Migration and Holding:** Adverse and beneficial impacts from *flow* on adult migration.
	Alternative 3	• **Spawning and Egg/Alevin Incubation:** Negligible adverse and beneficial impacts from *flow* on spawning habitat area. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on rearing habitat area. • **Adult Migration and Holding:** Adverse impacts from *flow* on adult migration. Adverse impacts from *water temperatures* on growth, smoltification, predation vulnerability and pathogen virulence.

Impact	Alternative	Direction of Impacts
	Alternative 4	• **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* on rearing habitat area. Beneficial impacts from *water temperatures* on growth, smoltification, predation vulnerability and pathogen virulence. • **Adult Migration and Holding:** Negligible adverse impacts and beneficial impacts from *flow* on adult migration.
WHITE STURGEON		
Sacramento River		
Potential changes to white sturgeon from seasonal operations	No Action	No measurable change from current operations. • **Adverse Components:** Fall and Winter Refill and Redd Maintenance. • **Beneficial Components:** Ramping Rates, Spring Pulse Flows, Water Temperature Management. • **Adverse and/or Beneficial Components:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Potential beneficial impacts from *flow* on spawning habitat. Possible beneficial impacts from *water temperatures*. • **Rearing and Emigration:** Potential beneficial impacts from *flow* on rearing and emigration habitat. Beneficial impacts from *water temperatures* on rearing and emigration.
	Alternative 2	**Spawning and Egg Incubation:** Potential beneficial impacts from *flow* on spawning habitat.
	Alternative 3	**Spawning and Egg Incubation:** Potential beneficial impacts from *flow* on spawning habitat. Adverse impacts from *water temperatures*.
	Alternative 4	**Rearing and Emigration:** Potential adverse impacts from *flow*.
Lower American River		
Potential changes to white sturgeon from seasonal operations	No Action	No measurable change from current operations. • **Adverse and Beneficial:** Seasonal Operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Spring Pulse Flows, Redd Dewatering Adjustments, Water Temperature Management, and Spawning and Rearing Habitat Restoration.
	Alternative 1	**Adult White Sturgeon:** No impacts from *flow* and *water temperatures*.
	Alternative 2	**Adult White Sturgeon:** No impacts from *flow* and *water temperatures*.
	Alternative 3	**Adult White Sturgeon:** No impacts from *flow* and *water temperatures*.
	Alternative 4	**Adult White Sturgeon:** Negligible impacts from *water temperatures*.
San Joaquin River		
Potential changes to white sturgeon from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	**Adult White Sturgeon:** Negligible impacts from *water temperatures*.
	Alternative 2	**Adult White Sturgeon:** Negligible impacts from *water temperatures*.
	Alternative 3	**Adult White Sturgeon:** Potential adverse impacts from *flow* on habitat. Negligible impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
	Alternative 4	**Adult White Sturgeon:** Negligible impacts from *water temperatures*.
Bay-Delta		
Potential changes to white sturgeon from seasonal operations	No Action	No measurable change from current operations. • **Adverse:** Agricultural Barriers, RRDS Fall Flood-up. • **Beneficial:** Spring Delta Outflow • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Juvenile Rearing and Emigration:** Potential beneficial impacts from *flow* on juvenile year class strength. • **Subadult and Adult Residency:** Potential beneficial impacts on year class strength.
	Alternative 2	• **Juvenile Rearing and Emigration:** Potential beneficial impacts from *flow* on juvenile year class strength. • **Subadult and Adult Residency:** Potential beneficial impacts from *flow* on year class strength.
	Alternative 3	• **Juvenile Rearing and Emigration:** Potential beneficial impacts from *flow* on juvenile year class strength. • **Subadult and Adult Residency:** Possible beneficial impacts from *flow* on year class strength.
	Alternative 4	• **Juvenile Rearing and Emigration:** No impacts from *flow* on juvenile year class strength. • Subadult and Adult Residency: No impacts from *flow* on year class strength.
Potential changes to entrainment of white sturgeon	No Action	No measurable change from current conditions, continuation of current trends. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, Tracy Fish Collection Facility and John E. Skinner Delta Fish Protective Facility.
	Alternative 1	• **Juvenile Rearing and Emigration:** No impacts from exports on juvenile entrainment.
	Alternative 2	• **Juvenile Rearing and Emigration:** No impacts from exports on juvenile entrainment.
	Alternative 3	• **Juvenile Rearing and Emigration:** No impacts from exports on juvenile entrainment.
	Alternative 4	• **Juvenile Rearing and Emigration:** No impacts from exports on juvenile entrainment.

Impact	Alternative	Direction of Impacts
NATIVE MINNOWS		
Sacramento River		

Potential changes to Sacramento splittail, Sacramento hitch, and hardhead from seasonal operations	No Action	No measurable change from current operations.
		• **Hardhead:**
		  • *Adverse Component:* Rice Decomposition Smoothing.
		  • *Beneficial Components:* Ramping Rates and Water Temperature Management.
		  • *Adverse and/or Beneficial Components:* Spring Pulse Flows, Fall and Winter Refill and Redd Maintenance and Seasonal Operations.
		• **Sacramento Splittail:**
		  • *Adverse Component:* Rice Decomposition Smoothing.
		  • *Beneficial components:* Ramping Rates.
		  • *Adverse and/or Beneficial Components:* Fall and Winter Refill and Redd Maintenance and Seasonal Operations.
		• **Sacramento Hitch:**
		  • *Adverse Component:* Rice Decomposition Smoothing.
		  • *Beneficial Components:* Ramping Rates and Spring Pulse Flows.
		  • *Adverse and/or Beneficial Components:* Fall and Winter Refill and Redd Maintenance and Seasonal Operations.

	Alternative 1	• **Hardhead:** Negligible impacts from *flow*. Adverse impacts from *water temperatures*. • **Sacramento Splittail and Hitch:** Negligible impacts from *flow* and *water temperatures*.
	Alternative 2	• **Hardhead:** Negligible impacts from *flow*. Adverse impacts from *water temperatures* on spawning and non-spawning life stages. • **Sacramento Splittail and Hitch:** Negligible impacts from *flow* and *water temperatures*.
	Alternative 3	• **Hardhead:** Beneficial impacts from *flow* in the month of May for the lower river, possibly allowing for higher levels of downstream migration. Adverse and beneficial impacts from *water temperatures* on spawning. • **Sacramento Splittail and Hitch:** Beneficial impacts from *flow* in the month of May for the lower river, possibly allowing for higher levels of downstream migration. Negligible impacts from *water temperatures*.
	Alternative 4	• **Hardhead:** Negligible impacts from *flow*. Adverse impacts from *water temperatures* on spawning and negligible adverse and beneficial impacts on non-spawning. • **Sacramento Splittail and Hitch:** Negligible impacts from *flow*. Negligible impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
Clear Creek		
Potential changes to hardhead from seasonal operations	No Action	No change from current operations. Components of current operations by direction of impact are as follows: • **Adverse:** Seasonal Operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Water Temperature Management, Spawning and Rearing Habitat (targeted for salmonids). • **Adverse and/or Beneficial:** Pulse Flows
	Alternative 1	• Negligible impacts from *flow*. • Negligible impacts from *water temperatures*.
	Alternative 2	• Negligible impacts from *flow*. • Negligible impacts from *water temperatures*.
	Alternative 3	• Negligible impacts from *flow* on migrating and spawning adult hardhead. Adverse impacts in the fall on juvenile and non-spawning adults. • Negligible impacts from *water temperatures*.
	Alternative 4	• Negligible impacts from *flow* on migrating and spawning adult hardhead. Adverse impacts in the fall on juvenile and non-spawning adults. • Negligible impacts from *water temperatures*.
Lower American River		

Potential changes to Sacramento splittail and hardhead from seasonal operations	No Action	No change from current operations. Components of current operations by direction of impact are as follows:
		• **Hardhead**
		  • *Adverse:* Seasonal Operations.
		  • *Beneficial:* Ramping Rates, Minimum Instream Flows, Redd Dewatering Adjustments, Water Temperature Management, Spawning and Rearing Habitat Restoration (targeted for salmonids).
		  • *Adverse and/or Beneficial:* Spring Pulse Flows.
		• **Sacramento Splittail**
		  • *Adverse:* Seasonal Operations.
		  • *Beneficial:* Ramping Rates, Minimum Instream Flows, Redd Dewatering Adjustments, Spawning and Rearing Habitat Restoration (targeted for salmonids).

	Alternative 1	• **Hardhead:** Negligible impacts from *flow* on adult migration and spawning. Adverse impacts from *water temperature* on spawning. Negligible impacts from *water temperatures* on non-spawning. • **Sacramento Splittail:** Negligible impacts from *flow* on adult migration and spawning. Negligible impacts from *water temperatures* on spawning.

Impact	Alternative	Direction of Impacts
	Alternative 2	• **Hardhead:** Negligible impacts from *flow* on adult migration and spawning. Adverse impacts from *water temperatures* on spawning during some phases of Alternative 2. Negligible impacts from *water temperature* on non-spawning. • **Sacramento Splittail:** Negligible impacts from *flow* on adult migration and spawning. No anticipated impacts from *water temperatures* on spawning.
	Alternative 3	• **Hardhead:** Adverse impacts from *flow* on outmigration success, but beneficial impacts on spawning adults. Adverse and beneficial impacts from *water temperatures* on spawning and non-spawning, depending on the location. • **Sacramento Splittail:** Adverse impacts from *flow* on outmigration success, but beneficial impacts on spawning adults. Negligible impacts from *water temperatures* on spawning.
	Alternative 4	• **Hardhead:** Negligible impacts from *flow*. Beneficial and adverse impacts from *water temperatures* on spawning and non-spawning. • **Sacramento Splittail:** Negligible impacts from *flow*. No anticipated impacts from *water temperatures* on spawning.
Stanislaus River		
Potential changes to hardhead from seasonal operations	No Action	No change from current operations. Components of current operations by direction of impact are as follows: • **Adverse:** Fall Pulse Flows. • **Beneficial:** Seasonal Operations, Ramping Rates, Minimum Instream Flows, Winter Instability Flows, Spawning and Rearing Habitat Restoration (targeted for salmonids). • **Adverse and/or Beneficial:** Spring Pulse Flows.
	Alternative 1	Negligible impacts from *flow*. Adverse impacts from *water temperatures*.
	Alternative 2	Negligible impacts from *flow*. Adverse impacts from *water temperatures*.
	Alternative 3	Substantial beneficial impacts from *flow* on spawning, rearing, and outmigration. Negligible impacts from *water temperatures*.
	Alternative 4	Adverse impacts from *water temperatures* in dry water year types in the Stanislaus River below Goodwin. Negligible impacts from *water temperatures*.
San Joaquin River		
Potential changes to Sacramento splittail, Sacramento hitch, and hardhead from seasonal operations	No Action	The No Action Alternative reflects the 2020 Record of Decision evaluation of habitat restoration in concert with operations.
	Alternative 1	Negligible impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 2	Negligible impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 3	Substantial adverse impacts from *flow*. Negligible impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
	Alternative 4	Negligible impacts from *flow*. Negligible impacts from *water temperatures*.
Bay-Delta		
Potential changes to Sacramento splittail, Sacramento hitch, and hardhead from seasonal operations	No Action	No change from current operations. Components of current operations by direction of impact are as follows: • **Adverse:** Agricultural Barriers. • **Beneficial:** Spring Delta Outflow and Delta Smelt SFH. • **Adverse and/or Beneficial:** Seasonal Operations. • **Uncertain:** CCF Weed Management.
	Alternative 1	Negligible impacts and substantial adverse impacts from *flow* in below normal, dry, and critically dry water years on native minnows.
	Alternative 2	Adverse impacts from *flow* depending on month.
	Alternative 3	Beneficial impacts from *flow*.
	Alternative 4	Adverse impacts from *flow*.
Potential changes to entrainment of Sacramento splittail, Sacramento hitch, and hardhead	No Action	No measurable change from current operations. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	Adverse impacts from exports on entrainment.
	Alternative 2	Adverse impacts from exports on entrainment.
	Alternative 3	Beneficial impacts from exports on entrainment
	Alternative 4	Adverse and beneficial impacts from exports on entrainment
PACIFIC LAMPREY		
Trinity River		
Potential changes to Pacific lamprey from seasonal operations	No Action	• **Spawning and Egg Incubation:** Adverse impacts of *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse impacts of *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** Negligible impacts of *flow* and *water temperatures*.
	Alternative 1	• **Spawning and Egg Incubation:** Adverse impacts from *flow* and *water temperatures*. • **Ammocoete Rearing and Emigration:** Negligible adverse to beneficial impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** Beneficial to adverse impacts from *flow* and *water temperatures*
	Alternative 2	• **Spawning and Egg Incubation:** Adverse impacts from *flow* and *water temperatures*. • **Ammocoete Rearing and Emigration:** Adverse impacts from *flow* and *water temperatures*.

Impact	Alternative	Direction of Impacts
		• **Adult Upstream Migration and Holding:** Adverse impacts from *flow* and *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Adverse impacts from *flow* and *water temperatures*. • **Ammocoete Rearing and Emigration:** Negligible adverse to beneficial impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** Negligible adverse to beneficial impacts from *flow* and *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Negligible adverse impacts from *flow* and *water temperatures*. • **Ammocoete Rearing and Emigration:** Adverse impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** Adverse impacts from *flow* and *water temperatures*.
Sacramento River		
Potential changes to Pacific lamprey from seasonal operations	No Action	No measurable change from current operations. • **Adverse components:** Rice Decomposition Smoothing. • **Beneficial Components:** Ramping Rates, Spring Pulse Flows, Water Temperature Management. • **Adverse and/or Beneficial Components:** Seasonal Operations, Fall and Winter Refill and Redd Maintenance.
	Alternative 1	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negative impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Negligible impacts from *flow* and *water temperatures*.
Clear Creek		
Potential changes to Pacific lamprey from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Pulse Flows, Water Temperature Management, Spawning and Rearing Habitat (targeted to salmonids). • **Adverse:** Segregation Weir.

Impact	Alternative	Direction of Impacts
		• **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Adverse impacts from *flow*. Beneficial impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Beneficial impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Beneficial impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Beneficial impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
Lower American River		
Potential changes to Pacific lamprey from seasonal operations	No Action	No measurable change expected from current operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Spring Pulse Flows, Redd Dewatering Adjustments, Water Temperature Management, Spawning and Habitat Restoration (targeted for salmonids). • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow* and *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Adverse impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow* and *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Beneficial impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
Stanislaus River		
Potential changes to Pacific lamprey from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Spring Pulse Flows, Winter Instability Flows, Fall Pulse Flows, Spawning and Rearing Habitat Restoration (targeted for salmonids). • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
San Joaquin River		
Potential changes to Pacific lamprey from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	**Ammocoete Rearing and Emigration:** Beneficial to adverse impacts on rearing from *flow*. Beneficial impacts on emigration from *flow*. Negligible impacts on both life stages from *water temperatures*.
	Alternative 2	**Ammocoete Rearing and Emigration:** Beneficial impacts on rearing and negligible impacts on emigration from *flow*. Negligible impacts on both life stages from *water temperatures*.
	Alternative 3	**Ammocoete Rearing and Emigration:** Adverse impacts from *flow*. Negligible impacts on both life stages from *water temperatures*.
	Alternative 4	**Ammocoete Rearing and Emigration:** Negligible adverse to beneficial impacts from *flow*. Negligible impacts on both life stages from *water temperatures*.

Impact	Alternative	Direction of Impacts
Bay-Delta		
Potential changes to Pacific lamprey from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Spring Delta Outflow, and Delta Smelt SFH. • **Adverse:** Agricultural Barriers. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Ammocoete Rearing and Emigration:** Beneficial impacts from *flow* on juvenile emigration in critically dry years, Negligible impacts from *flow* on ammocoete rearing. • **Adult Migration:** Beneficial impacts from *flow* in critically dry water years
	Alternative 2	• **Ammocoete Rearing and Emigration:** Beneficial impacts from *flow* on juvenile emigration in critically dry years. Negligible impacts from *flow* on ammocoete rearing. • **Adult Migration:** Beneficial impacts from *flow* in the summer of critically dry years.
	Alternative 3	• **Ammocoete Rearing and Emigration:** Adverse and beneficial impacts from *flow* on juvenile emigration. Negligible impacts from *flow* on ammocoete rearing. • **Adult Migration:** Adverse impacts from *flow* in September of critically dry years.
	Alternative 4	• **Ammocoete Rearing and Emigration:** Beneficial impacts from *flow* on juvenile emigration in April of critically dry years. Negligible impacts from *flow* on ammocoete rearing. • **Adult Migration:** Beneficial impacts from *flow* in April of critically dry years.
Potential changes to entrainment of Pacific lamprey	No Action	No measurable change from current operations. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, and Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	Adverse impacts from exports on entrainment, increased loss predicted at CVP facility.
	Alternative 2	Beneficial to adverse impacts from exports on entrainment, loss increases and decreases at CVP facility
	Alternative 3	Beneficial impacts from exports on entrainment, decreased loss predicted at CVP facility.
	Alternative 4	Negligible impacts from *flow* on entrainment

Impact	Alternative	Direction of Impacts
WESTERN RIVER LAMPREY		
Sacramento River		
Potential changes to Western river lamprey from seasonal operations	No Action	No expected change from current operations. • **Beneficial Components:** Ramping Rates, Spring Pulse Flows, Water Temperature Management. • **Adverse and/or Beneficial Components:** Seasonal Operations, Fall and Winter Refill and Redd Maintenance.
	Alternative 1	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Adverse impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Beneficial impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Minor beneficial to minor adverse Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Beneficial impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
Lower American River		
Potential changes to Western river lamprey from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Spring Pulse Flows, Redd Dewatering Adjustments, Water Temperature Management, Spawning and Habitat Restoration (targeted for salmonids). • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Adverse to beneficial impacts from *flow*. Beneficial to adverse impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Adverse impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Adverse and beneficial impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Adverse and beneficial impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
Stanislaus River		
Potential changes to Western river lamprey from seasonal operations	No Action	No change from current operations. • **Beneficial:** Ramping Rates, Minimum Instream Flows, Spring Pulse Flows, Winter Instability Flows, Fall Pulse Flows, Spawning and Rearing Habitat Restoration (targeted for salmonids). • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow* and *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Beneficial impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*. • **Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	**Spawning and Egg Incubation:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
San Joaquin River		
Potential changes to Western River lamprey from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	**Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 2	**Ammocoete Rearing and Emigration:** Negligible adverse to beneficial impacts from *flow*. Negligible impacts on both life stages from *water temperatures*.
	Alternative 3	**Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.
	Alternative 4	**Ammocoete Rearing and Emigration:** Beneficial to adverse impacts from *flow*. Negligible impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
Bay-Delta		
Potential changes to Western river lamprey from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Spring Delta Outflow, and Delta Smelt SFH. • **Adverse:** Agricultural Barriers. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Ammocoete Rearing and Emigration:** Negligible adverse impacts from *flow* on ammocoete rearing. Beneficial impacts from *flow* on juvenile emigration in critically dry years. • **Adult Migration:** Negligible impacts from *flow*.
	Alternative 2	• **Ammocoete Rearing and Emigration:** Negligible impacts from *flow* on ammocoete rearing. Minor beneficial impacts from *flow* on juvenile emigration in critically dry years. • **Adult Migration:** Negligible impacts from *flow*.
	Alternative 3	• **Ammocoete Rearing and Emigration:** Negligible adverse impacts from *flow* on ammocoete rearing. Beneficial and adverse impacts from *flow* on juvenile emigration. • **Adult Migration:** Adverse impacts from *flow* in September of critically dry years.
	Alternative 4	• **Ammocoete Rearing and Emigration:** Negligible adverse impacts from *flow* on ammocoete rearing. Beneficial impacts from *flow* on juvenile emigration in April of critically dry water year types. • **Adult Migration:** Negligible impacts from *flow*.
Potential changes to entrainment of Western river lamprey	No Action	No measurable change from current operations. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** DCC Gates, Suisun March RRDS Fall Flood-up, Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	Adverse impacts from exports on entrainment predicted at CVP facility.
	Alternative 2	Beneficial impacts from exports on entrainment at the CVP facility in most water year types and negligible adverse impacts in wet years.
	Alternative 3	Beneficial impacts from exports on entrainment in most water years at the CVP facility.
	Alternative 4	Beneficial impacts from exports on entrainment in above normal and below normal years at the CVP facility. Adverse impacts from exports on entrainment in critically dry years.

Impact	Alternative	Direction of Impacts
STRIPED BASS		
Sacramento River		
Potential changes to striped bass from seasonal operations	No Action	No measurable change from current operations. • **Beneficial Component:** Water Temperature Management. • **Adverse and/or Beneficial Components:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Beneficial impacts from *flow* and *water temperatures*. • **Larval–Juvenile Rearing and Emigration:** Beneficial impacts from *flow* on rearing and emigration habitat. Negligible adverse impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Adverse impacts from *flow* on spawning habitat. Beneficial impacts from *water temperatures*. • **Larval–Juvenile Rearing and Emigration:** Adverse impacts from *flow* and negligible adverse impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Adverse impacts from *flow* and *water temperatures* on spawning habitat, spawning, and egg incubation. • **Larval–Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow*. Beneficial and adverse impacts from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Negligible adverse impacts from *flow* and negligible adverse and negligible beneficial impacts from *water temperatures* on spawning habitat, spawning, and egg incubation. • **Larval–Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and negligible beneficial impacts from *water temperatures* on rearing and emigration.
Lower American River		
Potential changes to striped bass from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Minimum Instream Flows, and Water Temperature Management, and Spawning and Habitat Restoration (targeted for salmonids). • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Adults:** Adverse impacts from flow. No anticipated impacts from *water temperatures*. • **Juvenile Rearing:** Minimal beneficial impacts from *flow* and *water temperatures*.
	Alternative 2	• **Adults:** Negligible adverse impacts from *flow* and no anticipated impacts from *water temperatures* on adults. • **Juvenile Rearing:** Negligible adverse impacts from *flow*. Adverse impacts from *water temperatures*.
	Alternative 3	• **Adults:** Beneficial and adverse impacts from *flow*. No anticipated impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
		• **Juvenile Rearing:** Beneficial and adverse impacts from *flow*. Beneficial (Hazel Avenue) and adverse (Watt Avenue) impacts from *water temperatures*.
	Alternative 4	• **Adults:** Negligible adverse impacts from *flow* and no anticipated impacts from *water temperatures*. • **Juvenile Rearing:** Negligible adverse impacts from *flow*. Beneficial and adverse impacts from *water temperatures*.
Stanislaus River		
Potential changes to striped bass from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Minimum Instream Flows, Spawning and Rearing Habitat Restoration (targeted for salmonids). • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Egg Incubation:** Beneficial impacts from *flow*. Adverse impacts from *water temperatures*. • **Larval–Juvenile Rearing and Emigration:** Beneficial impacts from *flow*. Beneficial and adverse impacts from *water temperatures*.
	Alternative 2	• **Spawning and Egg Incubation:** Adverse impacts from *flow*. Beneficial impacts from *water temperatures*. • **Larval–Juvenile Rearing and Emigration:** Beneficial impacts from *flow*. Adverse impacts from *water temperatures*.
	Alternative 3	• **Spawning and Egg Incubation:** Beneficial impacts from *flow*. Negligible adverse impacts from *water temperatures*. • **Larval–Juvenile Rearing and Emigration:** Beneficial and adverse impacts from *flow* on rearing and emigration. Adverse impacts (above confluence with San Joaquin) from *water temperatures*.
	Alternative 4	• **Spawning and Egg Incubation:** Adverse impacts from *flow* in April. Negligible impacts from *water temperatures*. • **Larval–Juvenile Rearing and Emigration:** Beneficial impacts from *flow*. Negligible adverse and negligible beneficial impacts from *water temperatures* on rearing.
San Joaquin River		
Potential changes to striped bass from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	**All Life Stages:** Beneficial and adverse impacts from *flow*. Negligible adverse impacts from *water temperatures*.
	Alternative 2	**All Life Stages:** Negligible adverse impacts from *flow* and beneficial impacts from flow in June through September of dry years. Negligible adverse impacts from *water temperatures*.
	Alternative 3	**All Life Stages:** Adverse impacts from *flow*. Negligible adverse impacts from *water temperatures*.
	Alternative 4	**All Life Stages:** Negligible adverse impacts from *flow* and beneficial impacts from flow in critically dry years. Negligible adverse impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
Bay-Delta		
Potential changes to striped bass from seasonal operations	No Action	No change from current operations. • **Adverse:** CCF Weed Management. • **Beneficial:** Agricultural Barriers. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	**All Life Stages:** Mixed adverse and beneficial impacts from *flows* at Delta export facilities and OMR. Negligible adverse impacts in most water years and beneficial impacts during critically dry years from Delta Outflow.
	Alternative 2	**All Life Stages:** Adverse and beneficial impacts from *flows*. Negligible adverse impacts in most water year types and beneficial impacts during critically dry years from Delta Outflow.
	Alternative 3	**All Life Stages:** Adverse and beneficial impacts from *flows*. Adverse impacts at Delta export facilities and OMR and beneficial impacts from Delta Outflow.
	Alternative 4	**All Life Stages:** Beneficial impacts from *flows* at Delta export facilities and OMR.
Potential changes to entrainment of striped bass	No Action	No measurable change from current operations. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, and Tracy Fish Collection Facility and John E. Skinner Delta Fish Protective Facility.
	Alternative 1	Adverse impacts from exports on entrainment at SWP Banks Pumping Plant export facility.
	Alternative 2	**Adult:** Beneficial and adverse impacts from exports on entrainment; beneficial impacts at CVP Jones Pumping Plant in most water year types on entrainment.
	Alternative 3	**Adult:** Beneficial impacts from exports on entrainment.
	Alternative 4	**Adult:** Beneficial and adverse impacts from exports on entrainment; adverse impacts at SWP Banks Pumping Plant and beneficial impacts at CVP Jones Pumping Plant on entrainment.
AMERICAN SHAD		
Sacramento River		
Potential changes to American Shad from seasonal operations	No Action	No measurable change from current operations. • **Adverse and/or Beneficial components:** Seasonal Operations.
	Alternative 1	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow*. Beneficial *water temperatures* impact.

Impact	Alternative	Direction of Impacts
	Alternative 2	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*.
	Alternative 3	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow*. Beneficial impact from *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow*. Beneficial impacts from *water temperatures*.
	Alternative 4	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and beneficial impacts from *water temperatures*.
Lower American River		
Potential changes to American shad from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Minimum Instream Flows. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow*. Beneficial impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible impacts from *flow*. Beneficial impacts from *water temperatures*.
	Alternative 2	• **Spawning and Larval Rearing:** Negligible impacts from *flow*. Beneficial and adverse impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse and beneficial impacts from *flow* and *water temperatures*.
	Alternative 3	• **Spawning and Larval Rearing:** Negligible adverse impact from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible impacts from *flow*. Beneficial impacts from *water temperatures*.
	Alternative 4	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow*. Adverse and beneficial impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow*. Adverse and beneficial impacts from *water temperatures*.
Stanislaus River		
Potential changes to American shad from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Minimum Instream Flows. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow*. Adverse impacts from *water temperatures*. • **Juvenile Rearing and Emigration:** Adverse impacts from *flow*. Beneficial impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
	Alternative 2	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*.
	Alternative 3	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*.
	Alternative 4	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*.
San Joaquin River		
Potential changes to American shad from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*.
	Alternative 2	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*.
	Alternative 3	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*.
	Alternative 4	• **Spawning and Larval Rearing:** Negligible adverse impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*.
Bay-Delta		
Potential changes to American shad from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Agricultural Barriers. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	Adverse impacts from *flow* on American shad abundance.
	Alternative 2	Negligible adverse impacts from *flow* on American shad abundance
	Alternative 3	Beneficial impacts from *flow* on American shad abundance.
	Alternative 4	Negligible adverse impacts from *flow* on American shad abundance.

Impact	Alternative	Direction of Impacts
Potential changes to entrainment of American shad	No Action	No measurable change from current conditions, continuation of current trends. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	Adverse impacts from exports on entrainment.
	Alternative 2	Adverse and beneficial impacts from exports on entrainment.
	Alternative 3	Beneficial impacts from exports on entrainment.
	Alternative 4	Adverse and beneficial impacts from exports on entrainment.
THREADFIN SHAD		
Sacramento River		
Potential changes to threadfin shad from seasonal operations	No Action	No measurable change from current operations. • **Adverse and/or Beneficial Components:** Seasonal Operations.
	Alternative 1	Negligible adverse impacts from *flow*. Beneficial and adverse impacts from *water temperatures* on spawning.
	Alternative 2	Negligible adverse impacts from *flow*. Negligible and adverse impacts from *water temperatures* on spawning.
	Alternative 3	Negligible impacts from *flow*. Beneficial and adverse impacts from *water temperatures* on spawning.
	Alternative 4	Negligible impacts from *flow*. Negligible impacts from *water temperatures* on spawning.
Lower American River		
Potential changes to threadfin shad from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Minimum Instream Flows. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	Negligible impacts from *flow*. Beneficial impacts from *water temperatures* on spawning.
	Alternative 2	Negligible adverse impacts from *flow*. Adverse and beneficial impacts from *water temperatures* on spawning.
	Alternative 3	Negligible impacts from *flow* and *water temperatures* on spawning.
	Alternative 4	Negligible impacts from *flow* and beneficial impacts from *water temperatures* on spawning.

Impact	Alternative	Direction of Impacts
Stanislaus River		
Potential changes to threadfin shad from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Spawning and Rearing Habitat Restoration (targeted for salmonids). • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	Negligible adverse impacts from *flow*. Adverse impacts from *water temperatures* on threadfin shad spawning.
	Alternative 2	Negligible impacts from *flow* and *water temperatures* on spawning.
	Alternative 3	Negligible impacts from *flow* and *water temperatures* on spawning.
	Alternative 4	Negligible impacts from *flow* and *water temperatures* on spawning.
San Joaquin River		
Potential changes to threadfin shad from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	Negligible impacts from *flow* and *water temperatures*.
	Alternative 2	Negligible impacts from *flow* and *water temperatures*.
	Alternative 3	Negligible impacts from *flow* and *water temperatures*.
	Alternative 4	Negligible impacts from *flow* and *water temperatures*.
Bay-Delta		
Potential changes to threadfin shad from seasonal operations	No Action	No measurable change from current operations. • **Adverse:** CCF Weed Management. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	Negligible impacts from *flow*.
	Alternative 2	Negligible impacts from *flow*.
	Alternative 3	Negligible impacts from *flow*.
	Alternative 4	Negligible impacts from *flow*.
Potential changes to entrainment of threadfin shad	No Action	No measurable change from current operations. • **Beneficial:** Seasonal and Real-Time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	Adverse and beneficial impacts from exports on entrainment.
	Alternative 2	Adverse and beneficial impacts from exports on entrainment.
	Alternative 3	Beneficial impacts from *flow* on entrainment.
	Alternative 4	Adverse and beneficial impacts from exports on entrainment.

Impact	Alternative	Direction of Impacts
BLACK BASSES		
Sacramento River		

Potential changes to largemouth, smallmouth, and spotted bass from seasonal operations	No Action	No measurable change from current operations.
		• **Largemouth and Spotted Bass**
		  • *Adverse Components:* Water Temperature Management.
		  • *Adverse and/or Beneficial Components:* Seasonal Operations.
		• **Smallmouth Bass**
		  • *Adverse and/or Beneficial Components:* Seasonal Operations.

	Alternative 1	• **Spawning Adults**
		  • *Largemouth, Smallmouth, and Spotted Bass:* Beneficial impacts from *flow*. No anticipated impacts from *water temperatures* on spawning.
		  • .
		• **Non-Spawning Adults**
		  • *Largemouth Bass:* Adverse impacts from *flow*. No anticipated impacts from *water temperatures*.
		  • *Smallmouth Bass:* Adverse impacts from *flow* and *water temperatures*.
		  • *Spotted Bass:* Adverse impacts from *flow*. Beneficial impacts from *water temperatures*.

	Alternative 2	• **Spawning Adults**
		  • *Largemouth, Smallmouth, and Spotted Bass:* Adverse impacts from *flow* on spawning habitat in June and July. No anticipated impacts from *water temperatures*.
		• **Non-Spawning Adults**
		  • *Largemouth and Spotted Bass:* Adverse impacts from *flow*. No anticipated impacts from *water temperatures*.
		  • *Smallmouth Bass:* Adverse impacts from *flow* and *water temperatures*.

	Alternative 3	• **Spawning Adults**
		  • *Largemouth and Spotted Bass:* Adverse impacts from *flow* on spawning habitat. No anticipated impacts from *water temperatures* on spawning.
		  • *Smallmouth Bass:* Adverse impacts from *flow* on spawning habitat. Adverse impacts from *water temperatures* on spawning.
		• **Non-Spawning Adults**
		  • *Largemouth Bass:* Adverse impacts from *flow*. No anticipated impacts from *water temperatures*.
		  • *Smallmouth Bass:* Adverse and beneficial impacts from *flow* and *water temperatures*.
		  • *Spotted Bass:* Adverse impacts from *flow*. No anticipated impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts

	Alternative 4	• **Spawning Adults**
		  • *Largemouth, Smallmouth, and Spotted Bass:* Negligible adverse impacts from *flow* on spawning habitat. No anticipated impacts from *water temperatures* on spawning.
		• **Non-Spawning Adults**
		  • *Largemouth Bass:* Adverse and beneficial impacts from *flow*. No anticipated impacts from *water temperatures*.
		  • *Smallmouth Bass:* Adverse and beneficial impacts from *flow*. Adverse and beneficial impacts from *water temperatures*.
		  • *Spotted Bass:* Adverse and beneficial impacts from *flow*. No Anticipated impacts from *water temperatures*.

Lower American River		

Potential changes to largemouth, smallmouth, and spotted bass from seasonal operations	No Action	No measurable change from current operations.
		• **Largemouth and spotted bass**
		  • *Beneficial:* Spawning and Habitat Restoration (targeted for salmonids).
		  • *Adverse and/or Beneficial:* Seasonal Operations.
		  • *Adverse:* Water Temperature Management.
		• **Smallmouth bass**
		  • *Beneficial:* Spawning and Habitat Restoration (targeted for salmonids).
		  • *Adverse and/or Beneficial:* Seasonal Operations.

	Alternative 1	• **Spawning Adults**
		  • *Largemouth Bass:* Beneficial and adverse impacts from *flow* on spawning habitat. Negligible beneficial impacts from *water temperatures* on spawning.
		  • *Smallmouth Bass:* Beneficial and adverse impacts from *flow* on spawning habitat. Beneficial and negligible adverse impacts from *water temperatures* on spawning.
		  • *Spotted Bass:* Beneficial and adverse impacts from *flow* on spawning habitat. Negligible adverse and beneficial impacts from *water temperatures* on spawning.
		• **Non-Spawning Adults**
		  • *Largemouth Bass:* Beneficial impacts from *flow*. No anticipated impacts from *water temperatures*.
		  • *Smallmouth Bass:* Beneficial impacts from *flow*. Adverse impacts from *water temperatures*.
		  • *Spotted Bass:* Beneficial impacts from *flow*. No anticipated impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts

	Alternative 2	• **Spawning Adults**
		  • *Largemouth Bass:* Negligible adverse impacts from *flow* on spawning habitat, except for beneficial impacts in April. Adverse impacts from *water temperatures*.
		  • *Spotted Bass:* Negligible adverse impacts from *flow* on spawning habitat, except for beneficial impacts in April. Beneficial and adverse impacts from *water temperatures*.
		  • *Smallmouth Bass:* Negligible adverse impacts from *flow* on spawning habitat, except for beneficial impacts in April. Negligible adverse impacts from *water temperatures*.
		• **Non-Spawning Adults**
		  • *Largemouth Bass*: Negligible adverse impacts from *flow*. No anticipated impacts from *water temperatures*.
		  • *Spotted Bass:* Negligible adverse impacts from *flow*. Negligible adverse impacts from *water temperatures*.
		  • *Smallmouth Bass:* Negligible impacts from *flow*. Adverse and beneficial impacts from *water temperatures* in the summer.

	Alternative 3	• **Spawning Adults**
		  • *Largemouth Bass:* Beneficial impacts from *flow* on spawning habitat in March through April and adverse impacts in June through July. Adverse and beneficial impacts from *water temperatures*.
		  • *Smallmouth Bass:* Beneficial impacts from *flow* on spawning habitat in March through April and adverse impacts in June through July. Adverse impacts from *water temperatures*.
		  • *Spotted Bass:* Beneficial impacts from *flow* on spawning habitat in March through April and adverse impacts in June through July. Adverse and beneficial impacts from *water temperatures*.
		• **Non-Spawning Adults**
		  • *Largemouth Bass:* Adverse impacts from *flow* below Nimbus Dam; beneficial impacts at H Street in June and July. No anticipated impacts from *water temperatures*.
		  • *Smallmouth and Spotted Bass:* Adverse impacts from *flow* below Nimbus Dam; beneficial impacts at H Street in June and July. Beneficial impacts from *water temperatures* at Watt Ave in the summer.

	Alternative 4	• **Spawning Adults**
		  • *Largemouth Bass:* Negligible adverse impacts from *flow* on spawning habitat. No anticipated impacts from *water temperatures*.
		  • *Smallmouth Bass:* Negligible adverse impacts from *flow* on spawning habitat. Adverse impacts from *water temperatures*.
		  • *Spotted Bass:* Negligible impacts from *flow* on spawning habitat. Beneficial impacts from *water temperatures*.
		• **Non-Spawning Adults**
		  • *Largemouth Bass:* Adverse and beneficial impacts from *flow*. No anticipated impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
		• *Smallmouth Bass:* Adverse and beneficial impacts from *flow*. Adverse and negligible beneficial impacts from *water temperatures* in the summer. • *Spotted Bass:* Adverse and beneficial impacts from *flow*. Beneficial impacts from *water temperatures*.
Stanislaus River		

Potential changes to largemouth, smallmouth, and spotted bass from seasonal operations	No Action	No measurable change from current operations.
		• **Largemouth and spotted bass**
		  • *Adverse:* Minimum Instream Flows.
		  • *Beneficial:* Spawning and Rearing Habitat Restoration (targeted for salmonids).
		  • *Adverse and/or Beneficial:* Seasonal Operations
		• **Smallmouth bass**
		  • *Beneficial:* Spawning and Rearing Habitat Restoration (targeted for salmonids).
		  • *Adverse and/or Beneficial:* Seasonal Operations

	Alternative 1	• **Spawning Adults**
		  • *Largemouth Bass:* Beneficial impacts from *flow* on spawning habitat. Negligible adverse impacts from *water temperatures* on spawning.
		  • *Spotted Bass:* Beneficial impacts from *flow* on spawning habitat. Adverse impacts from *water temperatures*.
		• **Non-Spawning Adults (largemouth, smallmouth, and spotted bass):** Beneficial impacts from *flow*. Negligible adverse impacts from *water temperatures*.

	Alternative 2	• **Spawning Adults (largemouth and spotted bass):** Negligible adverse impacts from *flow* on spawning habitat. Beneficial impacts from *water temperatures* on spawning. • **Non-Spawning Adults (largemouth, smallmouth, and spotted bass):** Beneficial impacts from *flow*. Negligible adverse impacts from *water temperatures*.

	Alternative 3	• **Spawning Adults**
		  • *Largemouth Bass:* Beneficial impacts from *flow* on spawning habitat. Adverse impacts from *water temperatures* on spawning.
		  • *Spotted Bass:* Beneficial impacts from *flow* on spawning habitat. Negligible adverse impacts from *water temperatures* on spawning.
		• **Non-Spawning Adults (largemouth, smallmouth, and spotted bass):** Beneficial impacts from *flow*. Negligible adverse impacts from *water temperatures*.

	Alternative 4	• **Spawning Adults (largemouth and spotted bass):** Negligible adverse impacts from *flow* on spawning habitat. Adverse impacts from *water temperatures* on spawning. • **Non-Spawning Adults (largemouth, smallmouth, and spotted bass):** Beneficial and adverse impacts from *flow*. Negligible adverse impacts from *water temperatures*.

Impact	Alternative	Direction of Impacts
San Joaquin River		
Potential changes to largemouth, smallmouth, and spotted bass from seasonal operations	No Action	No measurable change from current operations.
	Alternative 1	**Spawning Adults:** Beneficial impacts from *flow* on spawning habitat. Negligible adverse impacts from *water temperatures*.
	Alternative 2	**Spawning Adults:** Negligible adverse to beneficial impacts from *flow* during dry years on spawning habitat. Negligible adverse impacts from *water temperatures*.
	Alternative 3	**Spawning Adults:** Adverse and beneficial impacts from *flow* on spawning habitat. Negligible adverse impacts from *water temperatures*.
	Alternative 4	**Spawning Adults:** Negligible adverse to beneficial impacts from *flow* during critically dry years on spawning habitat. Negligible adverse impacts from *water temperatures*.
Bay-Delta		

Potential changes to largemouth, smallmouth, and spotted bass from seasonal operations	No Action	No measurable change from current operations.
		• **Largemouth Bass**
		  • *Adverse:* CCF Weed Management.
		  • *Beneficial:* Agricultural Barriers.
		  • *Adverse and/or Beneficial:* Seasonal Operations.
		• **Smallmouth and Spotted Bass**
		  • *Beneficial:* Agricultural Barriers.
		  • *Adverse and/or Beneficial:* Seasonal Operations.

	Alternative 1	**Non-Spawning Adults:** Beneficial impacts from *flow* on foraging habitat; adverse impact in November, and negligible adverse impacts in June and July.
	Alternative 2	**Non-Spawning Adults:** Adverse and beneficial impacts from *flow* on foraging habitat.
	Alternative 3	**Non-Spawning Adults:** Adverse impacts from *flow* on foraging habitat at one location, and beneficial impacts at two Delta locations.
	Alternative 4	**Non-Spawning Adults:** Beneficial impacts from *flow* on foraging habitat.
Potential changes to entrainment of largemouth, smallmouth, and spotted bass	No Action	No measurable change from current conditions, continuation of current trends. • **Beneficial:** Seasonal and Real-time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** DCC Gates, RRDS Fall Flood-up, Tracy Fish Collection Facility and John E Skinner Delta Fish Protective Facility.
	Alternative 1	**Juveniles:** Beneficial and adverse impacts from exports on entrainment. Adverse impacts on entrainment for all black bass species, except for a beneficial impact on spotted bass in November during dry years.

Impact	Alternative	Direction of Impacts
	Alternative 2	**Juveniles:** Beneficial impacts from exports on entrainment. Beneficial impacts on entrainment for black bass species, except for largemouth bass where adverse impacts would occur during below normal and critically dry years.
	Alternative 3	**Juveniles:** Adverse impacts from exports on entrainment. Beneficial impacts on entrainment for black bass species at CVP Jones and adverse impacts at SWP.
	Alternative 4	**Juveniles:** Beneficial impacts from exports on entrainment. Beneficial impacts on largemouth and smallmouth bass, and adverse and beneficial impacts on entrainment for spotted bass.
STARRY FLOUNDER		
Bay-Delta		
Potential changes to starry flounder from seasonal operations	No Action	No measurable change from current operations. • **Beneficial:** Spring Delta Outflow. • **Adverse and/or Beneficial Components:** Seasonal Operations.
	Alternative 1	Adverse impacts from *flow* on abundance, except in critically dry years.
	Alternative 2	Adverse impacts from *flow* on abundance, except in critically dry years.
	Alternative 3	Beneficial impacts from *flow* on abundance.
	Alternative 4	Adverse impacts from *flow* on abundance.
Potential changes to entrainment of starry flounder	No Action	No measurable change from current conditions, continuation of current trends. • **Beneficial:** Seasonal and Real-time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** RRDS Fall Flood-up, DCC Gates, and Tracy Fish Collection Facility and John E. Skinner Delta Fish Protective Facility.
	Alternative 1	Adverse impacts from exports on entrainment expected at both pumping plants, with SWP Banks pumping plant having a greater adverse impact.
	Alternative 2	Adverse impacts from exports on entrainment. Increased loss in all water year types except critically dry years at SWP Banks, minimal changes at CVP Jones across all water year types.
	Alternative 3	Beneficial impacts from exports on entrainment. Average monthly loss was beneficial at both facilities in wet years, negligible in dry years, and adverse in critically dry years.
	Alternative 4	Adverse impacts from exports on entrainment. Predicted average monthly loss was higher across all water year types at SWP Banks. At CVP Jones, loss was negligible across all water year types.

Impact	Alternative	Direction of Impacts
COASTAL PELAGIC SPECIES		
Bay-Delta		
Potential changes to Pacific herring and Northern anchovy from seasonal operations	No Action	No measurable change from current operations. • **Adverse and/or Beneficial:** Seasonal Operations.
	Alternative 1	• **Northern Anchovy:** Negligible adverse impacts on *flow* on habitat extent and indices of abundances. • **Pacific Herring:** Negligible impacts on *flow* on abundances.
	Alternative 2	• **Northern Anchovy:** Negligible adverse impacts on *flow* on habitat extent and indices of abundances. • **Pacific Herring:** Negligible adverse impacts on *flow* indices of abundances.
	Alternative 3	• **Northern Anchovy:** Negligible adverse impacts on flow on habitat extent and indices of abundances. • **Pacific Herring:** Negligible adverse impacts on *flow* on indices of abundances.
	Alternative 4	• **Northern Anchovy:** Negligible adverse impacts on flow habitat extent and indices of abundances. • **Pacific Herring:** Negligible adverse impacts on *flow* on indices of abundances.
Potential changes to entrainment of Pacific herring and Northern anchovy	No Action	No measurable change from current operations. • **Northern Anchovy:** Adverse –RRDS Fall Flood-Up. • **Pacific Herring:** Adverse –RRDS Fall Flood-Up. • **Beneficial:** Seasonal and Real-time Management of OMR Reverse Flow. • **Adverse and/or Beneficial:** Tracy Fish Collection Facility and John E. Skinner Delta Fish Protective Facility.
	Alternative 1	• **Northern Anchovy:** Negligible adverse impacts of flow on entrainment. • **Pacific Herring:** Potential adverse impacts from exports on entrainment in drier years.
	Alternative 2	• **Northern Anchovy:** Negligible impacts of flow on entrainment. • **Pacific Herring:** Negligible impacts from exports on entrainment.
	Alternative 3	• **Northern Anchovy:** Negligible impacts of flow on entrainment. • **Pacific Herring:** Potential beneficial impacts from exports on entrainment during drier years.
	Alternative 4	• **Northern Anchovy:** Negligible impacts of flow on entrainment. • **Pacific Herring:** Negligible impacts from exports on entrainment.

Impact	Alternative	Direction of Impacts
SOUTHERN OREGON/NORTHERN CALIFORNIA COAST COHO SALMON		
Trinity River		
Potential changes to coho salmon from seasonal operations	No Action	• **Spawning and Egg/Alevin Incubation:** No measurable changes in the availability or suitability of coho salmon spawning and egg/alevin incubation habitat. No adverse impacts of *flow* or *water temperatures* are expected. • **Juvenile Rearing and Emigration:** Substantial adverse changes in the availability or suitability of coho salmon rearing and emigration habitat are unlikely. No adverse impacts of *flow* or *water temperatures* are expected. • **Adult Upstream Migration and Holding:** Negligible adverse changes in the availability or suitability of coho salmon adult migration and holding habitat due to flow changes. No adverse impacts of *water temperatures* are expected.
	Alternative 1	• **Spawning and Egg/Alevin Incubation:** Spatially variable but negligible impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** No adverse impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** Spatially variable but negligible impacts from *flow* and *water temperatures*.
	Alternative 2	• **Spawning and Egg/Alevin Incubation:** Spatially variable negligible adverse to beneficial impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Spatially variable negligible adverse to beneficial impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** Adverse to no impacts from *flow* and *water temperatures*.
	Alternative 3	• **Spawning and Egg/Alevin Incubation:** Spatially variable adverse to beneficial impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Spatially variable adverse to beneficial impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** No impacts from *flow* or *water temperature*s
	Alternative 4	• **Spawning and Egg/Alevin Incubation:** Spatially variable but negligible adverse to beneficial impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Spatially variable but negligible adverse to beneficial impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** Negligible adverse to no impacts from *flow* and *water temperatures*.

Impact	Alternative	Direction of Impacts
UPPER KLAMATH-TRINITY RIVER SPRING-RUN CHINOOK SALMON		
Trinity River		
Potential changes to spring-run Chinook salmon from seasonal operations	No Action	• **Spawning and Egg/Alevin Incubation:** No adverse changes in the availability or suitability of spawning and egg/alevin incubation habitat. • **Juvenile Rearing and Emigration:** No adverse changes in the availability or suitability of rearing and emigration habitat. • **Adult Upstream Migration and Holding:** No adverse changes in the availability or suitability of adult migration and holding habitat.
	Alternative 1	• **Spawning and Egg/Alevin Incubation:** Spatially variable but negligible impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Spatially variable but negligible impacts from *flow* and *water temperatures*.
	Alternative 2	• **Spawning and Egg/Alevin Incubation:** Spatially variable negligible to minor beneficial impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Spatially variable negligible adverse impacts from *flow* and *water temperatures*.
	Alternative 3	• **Spawning and Egg/Alevin Incubation:** Spatially variable negligible adverse to beneficial impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Spatially variable negligible adverse impacts from *flow* and *water temperatures*.
	Alternative 4	• **Spawning and Egg/Alevin Incubation:** Spatially variable negligible adverse to beneficial impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Spatially variable negligible adverse impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** No impacts from *flow* and *water temperatures*.
UPPER KLAMATH-TRINITY RIVER FALL-RUN CHINOOK SALMON		
Trinity River		
Potential changes to fall-run Chinook salmon from seasonal operations	No Action	• **Spawning and Egg/Alevin Incubation:** No adverse changes in the availability or suitability of spawning and egg/alevin incubation habitat. • **Juvenile Rearing and Emigration:** Negligible changes in the availability or suitability of rearing and emigration habitat. • **Adult Upstream Migration and Holding:** Negligible changes in the availability or suitability of adult migration and holding habitat.
	Alternative 1	• **Spawning and Egg/Alevin Incubation:** Spatially variable and negligible impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible impacts from *flow* and *water temperatures*.

Impact	Alternative	Direction of Impacts
	Alternative 2	• **Spawning and Egg/Alevin Incubation:** Spatially variable and negligible impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Negligible impacts from *flow* and *water temperatures*.

	Alternative 4	• **Spawning and Egg/Alevin Incubation:** Spatially variable and negligible impacts from *flow* and *water temperatures*. • **Juvenile Rearing and Emigration:** Spatially variable and negligible impacts from *flow* and *water temperatures*.
KLAMATH MOUNTAINS PROVINCE STEELHEAD DPS		
Trinity River		
Impact Statement	No Action	Negligible adverse impacts from *flow* and *water temperatures* for all life stages.
	Alternative 1	Negligible adverse impacts from *flow* and *water temperatures* for all life stages.
	Alternative 2	Negligible adverse impacts from *flow* and *water temperatures* for all life stages.
	Alternative 3	Negligible adverse impacts from *flow* and *water temperatures* for all life stages.
	Alternative 4	Negligible impacts from *flow* and *water temperatures* for all life stages except for adverse flow impacts to adult holding habitat in wet and above normal years.
NORTHERN DPS GREEN STURGEON		
Trinity River		
Potential changes to northern DPS green sturgeon from seasonal operations	No Action	No adverse impacts from *flow* and *water temperatures* in all life stages.
	Alternative 1	No adverse impacts from *flow* and *water temperatures* in all life stages.
	Alternative 2	Negligible adverse impacts from *flow* and *water temperatures* in all life stages.
	Alternative 3	• **Spawning and Egg Incubation:** Negligible adverse impacts from *flow* and *water temperatures*. • **Larval and Juvenile Rearing and Emigration:** Negligible adverse impacts from *flow* and *water temperatures*. • **Adult Upstream Migration and Holding:** Beneficial impacts from *flow* and *water temperatures* on migration and habitat.
	Alternative 4	• Negligible impacts from *flow* and *water temperatures* in all life stages.

Impact	Alternative	Direction of Impacts
EULACHON		
Trinity River		
Potential changes to Eulachon from seasonal operations	No Action	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 1	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 2	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 3	Negligible adverse impacts from *flow* and *water temperatures* on all life stages. Potential benefits on larval emigration from *flow* in January and February.
	Alternative 4	Negligible impacts from *flow* and *water temperatures* on all life stages.
COASTAL CUTTHROAT TROUT		
Trinity River		
Potential changes to coastal cutthroat trout from seasonal operations	No Action	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 1	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 2	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 3	Negligible adverse impacts from *flow* and *water temperatures* on all life stages. Potential benefits on larval emigration from *flow* in January and February
	Alternative 4	Negligible impacts from *flow* and *water temperatures* on all life stages.
BROWN TROUT		
Trinity River		
Potential changes to brown trout from seasonal operations	No Action	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 1	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 2	Negligible adverse impacts from *flow* and *water temperatures* on all life stages.
	Alternative 3	Negligible adverse impacts from *flow* and *water temperatures* on all life stages. Potential benefits on larval emigration from *flow* in January and February.
	Alternative 4	Negligible impacts from *flow* and *water temperatures* on all life stages.

Impact	Alternative	Direction of Impacts
TRINITY RESERVOIR SPECIES		
Trinity River		
Potential changes to Trinity reservoir species from seasonal operations	No Action	Negligible adverse impacts from *storage* and *water temperatures* on all species and life stages.
	Alternative 1	Negligible adverse impacts from *storage* and *water temperatures* on all species and life stages.
	Alternative 2	Negligible adverse impacts from *storage* and *water temperatures* on all species and life stages across all Alternative 2 phases
	Alternative 3	Negligible adverse impacts from *storage* and *water temperatures* on all species and life stages.
	Alternative 4	Negligible adverse impacts from *storage* and *water temperatures* on all species and life stages.
DELTA-MENDOTA CANAL / CALIFORNIA AQUEDUCT SPECIES		
Potential changes from seasonal operations	No Action	No adverse effect from water surface elevation and velocity changes.
	Alternative 1	No adverse effect from water surface elevation and velocity changes.
	Alternative 2	No adverse effect from water surface elevation and velocity changes.
	Alternative 3	No adverse effect from water surface elevation and velocity changes.
	Alternative 4	No adverse effect from water surface elevation and velocity changes.
CENTRAL VALLEY RESERVOIR SPECIES		
Shasta Reservoir		
Potential changes to Shasta reservoir species from seasonal operations	No Action	No adverse effect from reservoir storage on reproductive success and habitat availability.
	Alternative 1	No adverse effect from reservoir storage on reproductive success and habitat availability.
	Alternative 2	Beneficial effect from reservoir storage on reproductive success and habitat availability.
	Alternative 3	Beneficial effect from reservoir storage on reproductive success and habitat availability.
	Alternative 4	**Warmwater Species:** Beneficial effect from reservoir storage on reproductive success and habitat availability.
Whiskeytown Reservoir		
Potential changes to Whiskeytown reservoir species from seasonal operations	No Action	No adverse effect from reservoir storage on reproductive success or habitat availability.
	Alternative 1	No adverse effect from reservoir storage on reproductive success or habitat availability.
	Alternative 2	No adverse effect from reservoir storage on reproductive success or habitat availability.

Impact	Alternative	Direction of Impacts
	Alternative 3	No adverse effect from reservoir storage on reproductive success or habitat availability.
	Alternative 4	No adverse effect from reservoir storage on reproductive success or habitat availability.
Folsom Reservoir		
Potential changes to Folsom reservoir species from seasonal operations	No Action	No adverse effect from reservoir storage on reproductive success or habitat availability.
	Alternative 1	• **Warmwater Species:** Adverse effect from reservoir storage on reproductive success. • **Coldwater Species:** Beneficial effect from reservoir storage on habitat availability.
	Alternative 2	• **Warmwater Species:** No adverse effect from reservoir storage on reproductive success. • **Coldwater Species:** Adverse effect from reservoir storage on habitat availability, particularly in critically dry years.
	Alternative 3	• **Warmwater Species:** Beneficial effect from reservoir storage on reproductive success. • **Coldwater Species:** Both beneficial and adverse effect from reservoir storage on habitat availability.
	Alternative 4	• **Warmwater Species:** No adverse effect from reservoir storage on reproductive success. • **Coldwater species:** Both beneficial and adverse effect from reservoir storage on habitat availability.
New Melones Reservoir		
Potential changes to New Melones reservoir species from seasonal operations	No Action	No adverse effect from reservoir storage on reproductive success and habitat availability.
	Alternative 1	• **Warmwater Species:** Negligible adverse effect from reservoir storage on reproductive success. • **Coldwater Species:** Beneficial to adverse effect from reservoir storage on habitat availability.
	Alternative 2	• **Warmwater Species:** No adverse effect from reservoir storage on habitat availability. • **Coldwater Species:** No adverse effect in 3 phases from reservoir storage on habitat availability. Beneficial and adverse effects in Alternative 2 without TUCP Systemwide VA.
	Alternative 3	• **Warmwater Species:** Beneficial effect from reservoir storage on reproductive success. • **Coldwater Species:** No adverse effect from reservoir storage on habitat availability.
	Alternative 4	No adverse effect from reservoir storage on habitat availability.

Impact	Alternative	Direction of Impacts
San Luis Reservoir		
Potential changes to New Melones reservoir species from seasonal operations	No Action	No adverse effect from reservoir storage on reproductive success.
	Alternative 1	Beneficial effect from reservoir storage on habitat availability.
	Alternative 2	Beneficial or no effect from reservoir storage on habitat availability.
	Alternative 3	Mostly adverse effect with some beneficial effect from reservoir storage on habitat availability.
	Alternative 4	Beneficial or no effect from reservoir storage on habitat availability.
SOUTHERN RESIDENT KILLER WHALE DPS		
Pacific Ocean		
Impact Statement	No Action	No adverse impacts expected from modeled changes on adult Chinook salmon production in the Ocean.
	Alternative 1	Negligible beneficial impacts from modeled changes on adult Chinook salmon production in the Ocean.
	Alternative 2	Negligible adverse impacts from modeled changes on adult Chinook salmon production in the Ocean for Alternative 2 without TUCP without VAs, Alternative 2 with TUCP without VAs, and Alternative 2 without TUCP with Delta Vas. No adverse to beneficial impacts from modeled changes on adult Chinook salmon production in the ocean under Alternative 2 without TUCP all VAs.
	Alternative 3	Beneficial impacts and from modeled changes on adult Chinook salmon production in the Ocean.
	Alternative 4	Negligible beneficial impacts from modeled changes on adult Chinook salmon production in the Ocean.

O.9 Mitigation Measures

O.9.1 Alternative 1

O.9.1.1 Avoidance and Minimization Measures

Table O-283. Summary of Alternative 1 Avoidance and Minimization Measures

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
Ramping Rates	• Sacramento River (salmonids and sturgeon) • Clear Creek (salmonids) • American River (salmonids and sturgeon) • Stanislaus River (salmonids)	Changes in river elevation from reservoir releases can strand fishes. Ramping rates can decrease the risk of stranding of fishes; however, this benefit comes at the consequence of increasing water temperatures and dissolved oxygen levels.
Minimum Instream Flows	• Sacramento River (salmonids and sturgeon) • Clear Creek (salmonids) • American River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Certain hydrologic circumstances may cause short-term periods of high flows. Minimum instream flows are temporary reductions in reservoir releases to preserve water storage. Minimum instream flows store water in reservoirs and decrease flows resulting in increased and decreased water temperatures and dissolved oxygen levels, decreased and increased refuge habitat and spawning habitat dependent on geography, muted outmigration cues as a consequence of flattening the hydrograph, increased stranding and dewatering of eggs, decrease stranding and juvenile dewatering, and decreased food availability for smelt and the size of the Low Salinity Zone as a consequence of decreasing Delta inflow.
Water Temperature Management	• Sacramento River (salmonids and sturgeon) • Clear Creek (salmonids) • American River (salmonids and sturgeon)	Cooler water improves habitat.

O.9.1.2 Additional Mitigation

- **Mitigation Measure AQUA-1: Develop and Implement Program to Expand Adult Holding, Spawning, Egg Incubation, and Fry/Juvenile Rearing Habitat:** Reclamation will develop and implement a program to expand suitable adult holding, spawning, egg incubation, and fry/juvenile rearing habitat for Central Valley spring-run Chinook salmon, fall- /late fall-run Chinook salmon, and Central Valley steelhead elsewhere in the Northwestern California Diversity Group. The program will be designed to prevent hybridization and improve genetic integrity of spring-run Chinook salmon, and to improve spawning success, fry/juvenile survival, and production of all three species, thereby contributing to their recovery. Increases in Salmon and Steelhead production potential created by the program will equal or exceed the reduced production potential in Clear Creek that would result from cessation of the Clear Creek Restoration Program and reduced flows below Whiskeytown Dam.
- **Mitigation Measure AQUA-2: Delta Smelt Monitoring:** Reclamation will continue to monitor Delta smelt.
- **Mitigation Measure AQUA-3: Longfin Smelt Monitoring:** Reclamation will continue to monitor Longfin smelt.
- **Mitigation Measure AQUA-4: Fall-run Chinook Salmon Brood Year Assessment:** To assess the condition of fall-run Chinook salmon populations on CVP tributaries, a fall-run Chinook salmon brood year assessment for the previous year's cohort and the cohort of returning adults that hatched three years prior will be completed. The brood year assessment will be based on the best available science each year and teams may consider using indicators similar to the *Annual Winter-run Chinook Brood Year Assessment* that is part of Alternative 2. Information will be reviewed by technical teams coordinating specific divisions or watersheds and attached to the LTO Annual Report by Reclamation.

O.9.2 Alternative 2

O.9.2.1 Avoidance and Minimization Measures

Table O-284. Summary of Alternative 2 Avoidance and Minimization Measures

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
Ramping Rates = limit how quickly releases are reduced.	• Sacramento River (salmonids and sturgeon) • Clear Creek (salmonids) • American River (salmonids and sturgeon) • Stanislaus River (salmonids)	Changes in river elevation from reservoir releases can strand fishes. Ramping rates can decrease the risk of stranding of fishes; however, this benefit comes at the consequence of increasing water temperatures and dissolved oxygen levels.

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
Minimum Instream Flows	• Sacramento River (salmonids and sturgeon) • Clear Creek (salmonids) • American River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Certain hydrologic circumstances may cause short-term periods of high flows. Minimum instream flows are the lowest level of flow allowed and are prescribed to protect beneficial uses. Minimum instream flows store water in reservoirs and decrease flows resulting in increased and decreased water temperatures and dissolved oxygen levels, decreased and increased refuge habitat and spawning habitat dependent on geography, muted outmigration cues as a consequence of flattening the hydrograph, increased stranding and dewatering of eggs, decrease stranding and juvenile dewatering, and decreased food availability for smelt and the size of the Low Salinity Zone as a consequence of decreasing Delta inflow.
Pulse Flows = releases of water from reservoirs can result in pulses of flows in rivers.	• Sacramento River (salmonids and sturgeon) • Clear Creek (salmonids) • Bay-Delta (salmonids, sturgeon, and smelt) • American River (salmonids and sturgeon)	Pulse flows are spatiotemporally coordinated releases to benefit migration of fish. Pulse flows can decrease and increase water temperature stressors, increase outmigration travel Rate and decrease outmigration travel time, decrease entrainment risk, increase redd dewatering potential, and increase food availability for smelt and size of the Low Salinity Zone as a consequence of increased Delta inflow.
Fall and Winter Baseflows for Shasta Reservoir Refill and Redd Maintenance	• Sacramento River (salmonids and sturgeon)	Required storage management or flood control releases must be balanced with supporting refill capabilities for Shasta Reservoir to build the coldwater pool for the following year. Fall and Winter Baseflows build and conserve storage to balance pool management with salmonid redd dewatering risk and baseflows are set annually to balance that risk in the coming fall and winter with the following year. Fall and Winter Baseflows may increase or decrease the risk of redd dewatering, water temperatures, refuge habitat and food availability, and outmigration cues.
Adult Migration & Holding Water Temperature Objectives	• Sacramento River (salmonids and sturgeon)	Under a circumstance where low flows combined with warm air temperatures and/or an intentional warmwater power bypass cause water temperatures to rise to concerning levels prior to the final Temperature Management Plan, Reclamation will begin temperature management as early as March 1st through May to target water temperatures of 58°F daily average at CCR.

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
SRS Contractors: Delaying or Shifting Spring Diversions, Shifting Timing of Delivery of Transfer Water, Rice Decomposition Smoothing	• Sacramento River (salmonids)	Reclamation may request that the Sacramento River Settlement Contractors (SRSC) delay diversions in the spring to increase the likelihood that Shasta Reservoir elevations reach the upper gates on the Temperature Control Device. Reclamation may request that the SRSC shift timing of delivery of transfer water to increase the amount of water in Shasta Reservoir through the water temperature management season. Final decision making is done by the SRSC; therefore, these two actions are not analyzed. Rice decomposition smoothing involves coordination of diversions to lower peak rice decomposition demand. Early reductions balance the potential for winter-run Chinook salmon dewatering with water demands. The measure may impact stranding, redd dewatering, refuge habitat, and outmigration in the fall.
Flow and Non-Flow Measures from the Voluntary Agreements	• Sacramento River (salmonids) • Bay-Delta (salmonids and smelt)	Flow and non-flow measures may increase flows in the spring prior to the water temperature management season, at the cost of depleting the coldwater pool, to advance inflows to the Delta. These measures may also decrease flows in the summer. Increased flows from increased spring releases may lower water temperatures for adult salmonids while decreased flows in the summer may increase water temperatures. Juvenile and yearling salmonids may benefit from increased spring flows which would decrease travel time and increase migration rates. Flow and non-flow measures from the VAs may also increase Delta inflow increasing food availability for smelt and the size / location of the Low Salinity Zone.
Wilkins Slough Minimum Flow Criteria Relief	• Sacramento River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Minimum flows at Wilkins Slough are targeted in certain driest of year water years, particularly summer flows. Minimum flows are met under considerations for storage, fisheries, and water deliveries. Minimum flow criteria relief may decrease water temperatures in the following year if Shasta Reservoir coldwater pool is conserved; however, this benefit comes at the consequence of increasing water temperatures by decreasing spring and summer releases. Minimum flow criteria may also decrease Delta inflow decreasing food availability for smelt.

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
Rebalancing between other CVP Reservoirs	• Sacramento River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Rebalancing between reservoirs can be used to conserve Shasta Reservoir storage and operate the TCD to temperature targets. Rebalancing allows for temperature management during critical salmonid spawning and egg incubation; however, this benefit comes at the consequence of increased water temperatures when spring and summer flows are reduced. Rebalancing may also decrease Delta inflow decreasing food availability for smelt and size / location of the Low Salinity Zone.
Limitation on CVP Allocations for EOS storage	• Sacramento River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Water supply reductions may occur in dry water years, with the goal of conserving storage and meeting minimal water temperature objectives. The goal of reductions is to increase end of September storage for Shasta Reservoir. Limitation on allocations may increase end of September storage which may provide increased coldwater pool in the following year; however, this benefit may come at the cost of increased water temperatures when summer flows are reduced. Limitations may also decrease Delta inflow decreasing food availability for smelt.
Modifications to Water Transfers	• Sacramento River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Modifications to water transfers involve shifting the timing of delivery of transfer water during the typical irrigation season. Water transfer modifications may help improve water temperature management, protect winter-run Chinook salmon redds from dewatering, and fall-run Chinook salmon from stranding; however, this benefit of increased Sacramento River flows may come at the cost of decreased storage in Shasta Reservoir and subsequent decreased coldwater pool volume the following year. Water transfer modifications may also increase Delta inflow increasing food availability for smelt.
Situation-Specific Adjustments to Delta Water Quality Standards	• Sacramento River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Sacramento River flows may decrease in dry years as one approach to conserving storage in Shasta Reservoir. Relaxation of Delta outflow and salinity requirements historically occur in the winter, spring, and summer. The measure may increase or decrease the water temperature related impacts. Water temperatures may increase with lower flows in the Sacramento River during the summer and may decrease the following year by increasing the volume of water in storage. The measure

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
		may impact outmigration and refuge habitat with lower flows in the Sacramento River during the winter.
Limitations in SRS Contractors Water Available Under Contract	• Sacramento River (salmonids and sturgeon)	Sacramento River flows may decrease in the spring, summer, and fall of dry years as one approach to conserving storage in Shasta Reservoir. The measure may increase or decrease the water temperature related impacts. Water temperatures may increase with lower flows in the Sacramento River during the spring, summer, and fall; and may decrease temperatures the following year by increasing the volume of water in storage. The measure may impact entrainment through routing and migration timing, outmigration cues, and refuge habitat.
Refuge Coordination for Instream Flow, Lake Levels, and Refuge Needs	• Sacramento River (salmonids and sturgeon)	Shasta Reservoir releases to refuges in the summer and fall may decrease during the driest of years to increase Shasta Reservoir storage. The measure may increase or decrease water temperatures. Decreasing Sacramento River flows may warm in-river temperatures; however, conserving Shasta Reservoir storage may reduce water temperatures in the following year. The measure may also impact outmigration by decreasing Sacramento River flows.
Egg Incubation and Emergence Water Temperature Objectives	• Sacramento River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Water temperature management would target 53.5°F through operation of the Temperature Control Device on Shasta Dam, selectively withdrawing and blending water from different elevations within Shasta Reservoir. Water temperatures are typically targeted from May 15 – October 30; however, start and end dates may be adjusted through coordination with the SRG and SHOT based on the winter-run Chinook salmon spawning and emergence. The measure may increase or decrease water temperatures. Water temperature management may reduce stress May 15 - October 30; however, reducing Shasta Reservoir storage may increase water temperatures in the following year. The measure may impact outmigration and refuge habitat in the fall and winter by decreasing Sacramento River flows.
Annual Winter-Run Chinook	• Sacramento River	Based on the outcome of the broodyear assessment prepared by the Winter-run JPE sub-team, Reclamation, NMFS, USFWS and CDFW will convene appropriate

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
Salmon Brood Year Assessment		technical staff to make recommendations if it is necessary to increase the production of winter-run Chinook salmon associated with the Integrated-Recovery Supplementation Program or take other actions to protect production of winter-run Chinook salmon at the LSNFH. USFWS, through coordination with the SHOT, will implement measures as appropriate. The outcome of the broodyear assessment may also be considered in implementing actions within the drought toolkit. Reclamation believes this is a USFWS action.
Drought Operations Priority Framework	• Sacramento River (salmonids and sturgeon) • Bay-Delta (salmonids, sturgeon, and smelt)	Reclamation will develop a Drought Emergency Plan that establishes system priorities and seeks to provide Winter-run Chinook salmon spawning water temperatures. The measure may increase or decrease the water temperatures by decreasing Sacramento River flows into the Delta; however, increasing Shasta Reservoir storage may provide for more suitable water temperatures in the following year. The measure may also impact outmigration by decreasing Sacramento River flows into the Delta.
Clear Creek Water Temperature Management	• Clear Creek (salmonids and sturgeon)	Reclamation will target Whiskeytown Dam releases to not exceed the mean daily temperatures at Igo gage: • 61°F from June 1 through August 15. • 60°F from August 16 through September 15. • 56°F from September 16 through November 15. In dry, critical, or transfer curtailment years, Reclamation may not be able to meet these water temperatures and will operate Whiskeytown Dam as close to these water temperatures as practical. Water temperature management in Clear Creek will subsequently impact salmonids in the Sacramento River below the confluence. Cooler water temperatures below Whiskeytown may provide a benefit to salmonids.
Redd Dewatering Protective Adjustment	• American River (salmonids)	Adjusts the minimum release requirements to account for hydrology and potential dewatering impacts to fall-run Chinook salmon redds in January and February and steelhead redds in February through May based on the minimum release requirements. The measure may decrease stranding and dewatering by softening changes in the minimum release requirements.

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
Folsom Reservoir Flow and Temperature Management	• American River (salmonids)	Reclamation will implement the Automated Temperature Selection Procedure, which was developed in consultation with representatives of state and federal agencies and prioritizes water temperatures during the summer to support steelhead rearing over water temperatures in the fall to support fall-run Chinook salmon spawning. The measure is expected to be beneficial by targeting lower water temperatures in the summer, at the consequence of potentially increasing water temperatures in the fall due to release of cold water.
Winter Instability Flows	• Stanislaus River (salmonids)	Reclamation releases additional flow in February to simulate natural variability in the winter hydrograph and to enhance access to varied rearing habitats. Reclamation, through the Stanislaus Watershed Team, schedules the winter instability flow volume. Whenever possible, the pulse is scheduled to coincide with a natural storm event, which may naturally cue outmigration. In some years, natural rain events may provide sufficient natural variability in the hydrograph and an additional pulse may be determined to be necessary. The measure may decrease water temperatures and provide more rearing habitat in the winter at the consequence of reducing reservoir storage and potentially increasing water temperatures in subsequent months.
DCC Gates Closures	• Bay-Delta (salmonids, sturgeon and smelt)	Reclamation closes the Delta Cross Channel during the late fall, winter, and spring to reduce straying of fall-run Chinook salmon, protect outmigrating salmonids from entering the interior Delta, facilitate the State Water Board D-1641 Rio Vista flow objectives for fish passage, and reduce potential scouring and flooding that might occur in the channels on the downstream side of the gates when Sacramento River flows exceed 20,000 cfs on a sustained basis. The measure may decrease entrainment risk by potentially aquatic species from being diverted into the interior Delta.

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
Barker Slough Pumping Plant	• Bay-Delta (smelt)	DWR proposes to operate the BSPP to protect larval Delta Smelt from March 1 to June 30 of dry and critical water years. If the water year type changes after March 1 to below normal, above normal, or wet, this action will be no longer in effect. If the water year type changes after March 1 to dry or critical, DWR proposes to operate according to this measure. The measure may benefit Delta smelt and longfin smelt through reduced entrainment risk.
Tracy Fish Collection Facility and Skinner Delta Fish Protective Facility	• Bay-Delta (salmonids, sturgeon and smelt)	Reclamation will operate the Tracy Fish Collection Facility to screen fish from Jones Pumping Plant. The primary channel is a behavioral barrier with effectiveness that depends on the pumping Jones Pumping Plant. The secondary channel is a positive fish barrier. When south Delta hydraulic conditions allow and conditions are within the original design criteria for the Tracy Fish Collection Facility, the secondary channel is operated to achieve water approach velocities for striped bass of approximately 1 to 2.5 feet per second from June 1 through October 31 and for salmon of approximately 3 feet per second from November 1 through May 31. The measure may decrease entrainment risk by potentially preventing aquatic species from being entrained at the export facility.
Old and Middle River Flow Management Start	• Bay-Delta (salmonids, sturgeon and smelt)	Reclamation will reduce exports to achieve a 7-day average OMR value no more negative than -5,000 cfs for seven consecutive days when the genetically verified 7-day rolling sum of winter-run early season migration and spring-run Chinook salmon loss, calculated daily, exceeds the following annually calculated thresholds. The measure may decrease entrainment risk by potentially preventing aquatic species from being entrained at the export facility.
Old and Middle River Management Real Time Operation	• Bay-Delta (salmonids, sturgeon and smelt)	Reclamation and DWR will manage diversion rates from the South of Delta modified based on abiotic and biotic factors for several listed species. The measure may decrease entrainment risk by potentially preventing aquatic species from being entrained at the export facility.

Avoidance and Minimization Measure	Geography and Listed Species Impacted	Impact
Summer and Fall Delta Outflow and Habitat	• Bay-Delta (salmonids, sturgeon and smelt)	Reclamation and DWR will maintain a 30-day average X2 ≤ 80 km for September through November in Wet and Above Normal years. The measure may decrease entrainment risk by increasing flows in the Delta and, thus, benefiting the migratory transport to the estuary and potentially preventing entrainment at the export facility. The measure may also benefit outmigration and food availability by increasing flow through the Delta.
Spring Delta Outflow	• Bay-Delta (salmonids, sturgeon and smelt)	Reclamation and DWR will take actions intended to supplement Delta outflow per the terms of the VAs approved by the SWRCB and executed agreements by Voluntary Agreement (VA) Parties. The measure may decrease entrainment risk by increasing migratory transport to the estuary, potentially preventing entrainment at the export facility. The measure may also benefit outmigration cues and food availability by increased flow through the Delta.
Delta Smelt Supplementation	• Bay-Delta (smelt)	Reclamation and DWR, through the Culture and Supplementation of Smelt Steering Committee, will continue to collaborate with USFWS and CDFW on the development of a program to conduct supplementation of the wild Delta smelt population with propagated fish consistent with USFWS' Supplementation Strategy (USFWS 2020), which document is currently being updated by CDFW and USFWS. The measure is expected to be generally beneficial to the Delta smelt population due to the increased releases into the Delta.

O.9.2.2 Additional Mitigation

Same as Alternative 1.

O.9.3 Alternative 3

O.9.3.1 Avoidance and Minimization Measures

Water Temperature Clear Creek

Relevant to fish and aquatic resources because it will improve the water temperature conditions for relevant fisheries. Reclamation will manage Whiskeytown Dam releases to not exceed mean daily water temperatures of 60°F at the Igo gauge from June 1 through September 15 and 56°F from September 15 through November 15.

Minimum Instream Flows (Minimum Release Requirements) American River

Relevant to fish and aquatic resources because it will improve coldwater pool and habitat conditions for steelhead and fall-run Chinook salmon. Reclamation would incorporate the following Folsom Reservoir storage requirements:

- **EOS:** 300 TAF (230 TAF in a second consecutive dry or critical water year type).
- **EOD:** 300 TAF. Reclamation would prioritize minimum flows under the MRR, then storage, then additional Delta outflow in the winter and spring, then water deliveries.

Old and Middle River Reverse Flows

Relevant to fish and aquatic resources because this measure may decrease entrainment risk by potentially preventing aquatic species from being entrained at the export facility.

- From the earlier of January 1 or the onset of OMR management, until the earlier of June 30 or the offramp of OMR Management, OMR flows shall not exceed -5,000 cfs on a 14-day running average. These requirements do not apply when San Joaquin River flows at Vernalis are greater than 20,000 cfs. In addition, when the SVI has been classified as a critically dry year for a second (or more) consecutive year, OMR flows shall not exceed -2,500 cfs on a 14-day running average.
- From April 1 to May 31, Reclamation and DWR shall operate to achieve a 2:1 ratio of San Joaquin River inflow at Vernalis to combined CVP/SWP exports in all water year types.

Winter and Spring Delta Outflow

Relevant to fish and aquatic resources because it is intended to reduce the adverse impacts of CVP/SWP operations on listed species, by increasing abundance and productivity of longfin smelt, increasing survival of winter-run Chinook salmon, spring-run Chinook salmon, and Central Valley steelhead (as a result of increased flows that increased survival in the Sacramento River and increase survival through the Delta), increasing recruitment of Delta smelt, and increasing survival and abundance of green sturgeon. Reclamation and DWR shall operate to meet the Delta Outflow criteria in Appendix E, Table E.6 1 for the months of July to November. For the months of December through June, on a monthly basis, Reclamation and DWR shall operate to meet Delta Outflow that is the lesser of 65 percent of unimpaired Delta inflow or the Delta Outflow criteria in Table E.6 1.

- Reclamation and DWR shall bypass 55% of unimpaired inflow to Shasta, Folsom, and Oroville reservoirs and 40% of unimpaired inflow to New Melones Reservoir. If the storage requirements and monthly Delta Outflow criteria in Alternative 3 are met, then releases from Shasta, Folsom, and Oroville reservoirs that month may be reduced to 45% of unimpaired inflows from December through May. Reclamation and DWR may release stored water to meet Delta outflow criteria in May through November.
- Reclamation and DWR would prioritize meeting the storage requirements described in Alternative 3 before making additional reservoir releases beyond what is required to meet D-1641 and human health and safety.

Delta Smelt Summer and Fall Habitat

Relevant to fish and aquatic resources because it may decrease entrainment risk by increasing flows in the Delta and, thus, benefitting the migratory transport to the estuary and potentially preventing entrainment at the export facility. The measure may also benefit outmigration and food availability by increasing flow through the Delta. Releases from upstream reservoirs are constrained to a Delta outflow of 7,100 cfs in November of wet and above normal years. Fall salinity may vary based on the ability of export reductions to achieve Fall X2 subject to public health and safety.

Drought

Relevant to fish and aquatic resources because it improves temperature conditions, migration, and increase hatchery production for relevant fisheries. Alternative 3 prohibits the use of a temporary urgency change petition. Alternative 3 does not include construction nor operation of the Drought Barrier in West False River.

Other actions may be considered and analyzed as necessary. Reclamation and DWR, through Governance, may update the toolkit.

O.9.3.2 Additional Mitigation

Same as Alternative 1.

O.9.4 Alternative 4

O.9.4.1 Avoidance and Minimization Measures

Water Temperature Management

Relevant to fish and aquatic resources because it will improve the temperature conditions for relevant fisheries.

Reclamation will target Whiskeytown Dam releases to not exceed the mean daily water temperatures at Igo gauge:

- 61°F from June 1 through August 15.
- 60°F from August 16 through September 15.
- 56°F from September 15 through November 15.

Water temperature management on Clear Creek is implemented through changes in guard gate configurations and flow manipulations. In dry, critical, or import curtailment years, Reclamation may not be able to meet these water temperatures, and will operate Whiskeytown Dam as close to these temperatures as practicable.

By June 15, Reclamation, through Governance, will annually prepare a TMP for the summer through fall. By May 15, Reclamation will provide a draft TMP to solicit input through tributary groups, in this case the American River Group. The priority for use of the lowest water temperature control shutters at Folsom Dam, within operational constraints, would be to achieve the water temperature requirement for steelhead, and may also be used to provide cold water for fall-run Chinook salmon spawning. During plan implementation, if the water temperature is exceeded for three consecutive days, or is exceeded by more than 3°F for a single day, Reclamation, will notify NMFS through Governance, and outline steps to realign lower American River water temperatures with the TMP. Reclamation will implement the ATSP described in the 2023 Updates and Refinements to the Lower American River 2017 Flow Management Standard Technical Memorandum.

Minimum Instream Flows (Minimum Release Requirement) American River

Relevant to fish and aquatic resources because it will improve coldwater pool and habitat conditions for steelhead and fall-run Chinook salmon. Reclamation would adopt the minimum flow schedule outlined in the 2023 Updates and Refinements to the Lower American River 2017 Flow Management Standard Technical Memorandum. The 2023 Updates and Refinements to the Lower American River 2017 Flow Management Standard Technical Memorandum includes MRR ranges from 500 to 2000 cfs based on time of year and annual hydrology. The flow schedule is intended to improve coldwater pool and habitat conditions for steelhead and fall-run Chinook salmon.

Old and Middle River Flow Management

Relevant to fish and aquatic resources because it may decrease entrainment risk by potentially preventing aquatic species from being entrained at the export facility.

Reclamation and DWR will reduce exports to achieve OMR no more negative than -5,000 cfs when one or more of the following conditions have occurred:

- **"First Flush":** In addition to the reduction in exports described in the No Action Alternative, Reclamation and DWR may initiate the "first flush" if, through Governance, monitoring indicates a high risk of migration and dispersal of smelt into areas at high risk of future entrainment. "First Flush" may be offramped to OMR no more negative than -5,000 cfs if the San Joaquin River at Vernalis is flowing at 10,000 cfs or more.
- **Delta Smelt Salvage:** After December 1 if the Enhanced Delta Smelt Monitoring Program observes Delta smelt in the Lower San Joaquin River and Southern Delta region or if any salvage of Delta smelt occurs. Reclamation and DWR, through Governance, may cease OMR restrictions related to this trigger or adjust the trigger requirements if hatchery release and monitoring data indicate that Delta smelt catch within the south Delta represent <5% of the overall catch.

- **Adult Longfin Salvage:** After December 1 if monitoring data indicates that longfin smelt catch within the south Delta represent ≥5% of the overall catch or if any salvage of longfin smelt occurs. Reclamation and DWR, through Governance, may cease OMR restrictions related to this trigger if monitoring data (e.g., Enhanced Delta Smelt Monitoring Program, Bay Study, Fall Midwater Trawl) indicate that longfin smelt catch within the south Delta represent <5% of the overall catch.

- **Juvenile Salmonid Salvage:** After December 1, Reclamation and DWR, through Governance, may incorporate additional or different predictive models as necessary to improve the onset of OMR management season for salmonid species if any of the following occurs: Gaeta et al.'s (2023) machine learning model predicts one week in advance the presence of winter-run length-at-date juvenile Chinook salmon across all 30 submodels, or salvage of genetically confirmed juvenile winter-run or spring-run Chinook salmon, or annual cumulative loss total reaches 60 or above for wild Central Valley steelhead.

- **Real-time Adjustments:** In addition to "First Flush", additional restrictions use real-time monitoring to identify an increased risk of entrainment. Reclamation and DWR will manage to a more positive OMR than -5,000 cfs under the following conditions:

- **Adult Delta Smelt Turbidity Protection:** Reclamation and DWR would manage exports to OMR no more negative than -2,000 cfs when daily average turbidity at both Holland Cut, and Old River at Bacon Island are at or above 12 FNU. Reclamation and DWR will maintain OMR at no more negative than -2,000 cfs for one week, and then no more negative than -3,500 cfs until measured daily average turbidity at both sensors are less than 12 FNU, or as revised through Governance.

    - Adult Delta smelt protection will off-ramp when three-day average water temperature at Jersey Point reaches 59ºF. This off ramp will be based on data from the San Joaquin River at Jersey Point averaged over three days.

- **Delta Smelt Larvae and Juveniles Protection:** Larval and juvenile Delta smelt management period will initiate when detected within the entrainment zone based on real-time sampling, or adult Delta smelt protection has off-ramped based on water temperature, whichever comes first. The presence of Delta smelt larvae and juveniles can also be identified through a detection of spent adult females in survey or salvage. Reclamation and DWR will restrict exports to allow OMR no more negative than -3,500 cfs when Secchi depth average measurement is equal or less than one meter.

- **Longfin Smelt Larvae and Juveniles Protection:** Recent studies indicated that regulations limiting Delta export for salmonids and Delta smelt since 2008-2009 have been protective for populations of longfin smelt.

- **Winter-run Annual Cumulative Loss Thresholds:** Reclamation and DWR will manage OMR to remain below the total annual loss thresholds for genetically-verified winter-run Chinook salmon at the Tracy and Skinner fish facilities:
    - Natural Winter-run Chinook salmon: Salvage Loss <0.5% of JPE (same as the No Action Alternative)
    - Hatchery Winter-run Chinook salmon: Salvage Loss <0.5% of JPE

During the brood year, if at any time cumulative loss of natural or hatchery winter-run Chinook salmon exceed the total annual loss threshold, DWR and Reclamation would restrict south Delta exports to maintain an OMR value of no more negative than -3,500 cfs for 14 days. Reclamation and DWR, through Governance, will also develop, implement, and update weekly an OMR schedule for the rest of the OMR management season to avoid further exceeding the annual loss thresholds using entrainment prediction tools and documented in an assessment.

- **Winter-run Chinook Salmon High Salvage Avoidance:** Reclamation and DWR will reduce exports to achieve OMR of no more negative than -3,500 cfs for at least seven days when Gaeta et al.'s (2023) machine learning model predicts one week in advance the high presence of winter-run length-at-date juvenile Chinook salmon across all 30 submodels. High presence is defined as seven-day moving average of more than 4.29 winter-run Chinook salmon expanded salvage at the salvage facilities. This action can only occur in the months of February, March, and April. OMR would continue to be managed to be no more negative than -3,500 cfs for longer than seven days until Gaeta et al.'s (2023) model no longer predicts high presence across all submodels.
- **Spring-Run Chinook Salmon Surrogate Thresholds:** Reclamation and DWR will reduce exports to achieve OMR no more negative than -3,500 cfs for seven days the first instance cumulative salvage loss of a release group equals or exceeds 0.5% of the releases group at Delta entry. Reclamation and DWR, through Governance, will develop the locations and times of in-river surrogate releases to best represent natural juvenile spring-run Chinook salmon migration into the Sacramento River and Delta. The percentage of the release group at Delta entry will be determined by survival from the release site to the Delta, similar to the development of the winter-run Chinook salmon JPE.
- **Storm Flex:** Reclamation and DWR may operate to an OMR no more negative than -6,250 cfs to capture peak flows during storm-related events when no backstop conditions are triggered and following conditions are met:
    - The Delta is in excess conditions as defined in 2018 amendment to the COA, and
    - QWEST is greater than 0.

DWR and Reclamation, through Governance, will use estimates of the real-time distribution of winter-run Chinook salmon, Particle Track Model, and prediction tool output to assess potential winter-run Chinook salmon entrainment risk differences using OMR inputs of -5000, and -6250 cfs. If the assessment indicates that additional entrainment protections are unlikely to be triggered, Reclamation and DWR may operate to OMR no more negative than -6,250 cfs and

will update the assessment no less than weekly. If conditions indicate a backstop condition is likely to trigger, Reclamation and DWR will resume OMR no more negative than -5,000 cfs. If a backstop condition is triggered, Reclamation and DWR will cease storm-flex and implement the backstop.

O.9.4.2 Additional Mitigation

Same as Alternative 1.

O.10 Cumulative Impacts

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Impacts Technical Appendix*, may have cumulative effects on fish and aquatic resources, to the extent that they could affect potential changes in habitat, water storage capacity, water conveyance infrastructure, water recycling capacity, and the reoperation of existing water supply infrastructure.

Past and present actions contribute to the existing condition of the affected environment in the project area while reasonably foreseeable actions are those that are likely to occur in the future that are not speculative. Past, present, and reasonably foreseeable projects include actions to develop water storage capacity, water conveyance infrastructure, water recycling capacity, the reoperation of existing water supply infrastructure, including surface water reservoirs and conveyance infrastructure, and habitat restoration actions. The projects identified in Appendix Y that have the most potential to contribute to cumulative impact on fish and aquatics resources are:

- B.F. Sisk Dam Raise and Reservoir Expansion Project (except for Alternative 2)
- Sites Reservoir Project (except for Alternative 2)
- Delta Conveyance Project (except for Alternative 2)
- Fremont Weir Adult Fish Passage Modification Project
- Knights Landing Outfall Gates (KLOG) Fish Barrier Project
- Wallace Weir Fish Rescue Facility Project
- California Eco Restore
- Lower Yolo Restoration Project
- Yolo Bypass Habitat Restoration Project
- Suisun Habitat Management, Preservation and Restoration Plan
- Construction of Folsom Lake Temperature Control Device
- Red Bluff Diversion Dam Passage Improvement Project
- Upper Sacramento River Anadromous Fish Habitat Restoration Project

- Lower American River Anadromous Fish Habitat Restoration Project
- Franks Tract Project
- San Joaquin River Restoration Program
- San Francisco Bay Delta Action Plan
- Bay-Delta Water Quality Control Plan Update
- Feather River Fish Hatchery
- Coleman National Fish Hatchery
- Nimbus Fish Hatchery
- Mokelumne Fish Hatchery
- Merced River Fish Facility
- Bradmoor Island
- Lookout Slough
- Prospect Island
- Chipps Island
- Cache Slough Area Restoration
- Prospect Island Tidal Habitat Restoration Project

O.10.1 Sacramento River

Major factors contributing to the cumulative impacts on aquatic biological resources in the Sacramento River have included major instream water storage dams, hydropower development and operations, hatchery management from the Coleman National Fish Hatchery and the Feather River Fish Hatchery, water withdrawals for irrigation and other uses, agricultural and urban development, channelization and levee construction, mining activities, recreational use and development, sport and commercial fisheries, introduction of nonnative fish species, and other management actions, water uses, and land uses (Appendix Y, *Cumulative Methodology*). These actions have resulted in highly altered flow regimes, loss and disconnection of floodplains from the river channel, altered sediment transport, reduced aquatic habitat complexity, loss of riparian and off-channel aquatic habitat, loss of upstream habitat, elevated water temperature, degraded water quality, habitat fragmentation by physical barriers, and other adverse effects on aquatic biological resources. Several ecosystem improvement projects and actions, including the Central Valley Project Improvement Act (CVPIA), the CALFED Bay-Delta Program, California EcoRestore, CDFW Ecosystem Restoration Program, and various other conservation, management, and restoration programs (Appendix Y), have been initiated to offset the adverse effects of previous and ongoing activities.

In addition to the ongoing activities, several probable future projects and programs may affect listed fishes and other aquatic biological resources in the Sacramento River. New projects and programs recently implemented or likely to be implemented in the near future are listed in Appendix Y, *Cumulative Methodology*. Some of these projects and programs may negatively impact status fishes and critical habitat in the Sacramento River, but others are likely to be beneficial. While some projects and actions have had beneficial effects, the net short-term effect of many new and ongoing programs, projects, and restoration efforts remains uncertain. In the long term, however, the net effects are expected to include substantial improvements in river habitat conditions and conservation or recovery of special-status fish populations. Despite ongoing and potential future projects that could benefit native Sacramento River fishes and their habitat, it is apparent that the effects of past and present actions have resulted in a cumulative adverse effect on winter-run Chinook salmon, spring-run Chinook salmon, steelhead, green sturgeon, and designated critical habitat in the Sacramento River for each of these species.

O.10.1.1 Anadromous Salmonids

No Action Alternative

The following components of the No Action Alternative have been identified as potentially resulting in impacts (adverse or beneficial) on one or more of the anadromous salmonid species or runs, green and white sturgeon, and other focal fish species. These components include seasonal operations, rice decomposition smoothing, ramping rates, fall and winter refill and redd maintenance, spring pulse flows, Shasta Reservoir coldwater pool management, winter-run Chinook salmon supplementation and spawning and rearing habitat restoration.

The No Action Alternative is expected to result in infrequent exposure of eggs and alevins to injuriously warm water temperatures during summer and fall, dropping water levels that lead to redd dewatering during the fall, or inadequate pulse flows for rearing and emigrating juveniles in the spring. These changes are expected to contribute to cumulative effects on winter-run Chinook salmon and spring-run Chinook salmon.

Steelhead, fall-run Chinook salmon, and late fall–run Chinook salmon are less affected by the management tradeoffs between storing and releasing water between under the No Action Alternative because they spawn when river water temperatures are cooler. Under the No Action Alternative there is a mixture of potential negative and positive changes.

Alternatives 1–4

Components that may impact anadromous salmonids under the action alternatives include seasonal operations (Alternative 1, 2, 3, 4), rice decomposition smoothing (Alternative 1, 2, 3, 4), ramping rates (Alternative 1, 2, 3), fall and winter baseflows for Shasta refill and redd maintenance (Alternative 2), CVP spring pulse flows (Alternative 2), winter and spring pulses and Delta outflow (Alternative 3), Sacramento River Settlement Contractors voluntary agreements spring pulse flows (Alternative 2), Shasta Reservoir water temperature management (Alternative 1, 3, 4), Shasta Reservoir water temperature and storage management (Alternative 2), minimum instream flows (Alternative 1, 2), fall and winter instream flows (Alternative 4), and adult migration and holding temperature objectives (Alternative 2).

Past, present and reasonably foreseeable projects include components that affect the timing and magnitude of flow releases and seasonal water temperatures and components that improve habitat of rearing and migrating salmonids in the Sacramento River. Flow and water temperature effects of completed projects are generally accounted for in the operational modeling of the No Action Alternative and Alternatives 1-4. Of the water supply and water quality projects that have not been completed, the most likely to have cumulative effects related to the flow and water temperature effects of Alternative 2 is the Bay-Delta Water Quality Control Plan Update.

The Bay-Delta Water Quality Control Plan Update has the potential to modify Sacramento River flow. Potential effects from the Bay-Delta Water Quality Control Plan Update would result in increased flows in spring and decreased flows in summer, with subsequent decreased water temperature in spring and increased water temperature in summer. This increase in flows may have a cumulative beneficial flow effect on salmonids, particularly juveniles, which are migrating downstream towards the Delta. The decrease in summer flows may contribute to a potential negative effect.

Relative to the No Action Alternative, Alternative 2 and Alternative 4 would have impacts on Sacramento River anadromous salmonids. For winter-run Chinook salmon, these would include beneficial water temperature effects for incubating eggs and alevins (Alternative 2) and minor adverse to beneficial rearing habitat flow effects. For spring-run Chinook salmon, water temperature effects and flow effects of Alternative 2 and Alternative 4 would be similar to the No Action Alternative for incubating eggs and alevins and on rearing habitat. For steelhead, these would include beneficial water temperature effects (Alternative 2) and adverse to beneficial water temperature effects (Alternative 4) for incubating eggs and adverse to beneficial rearing habitat flow effects (Alternative 2 and 4). For fall-run Chinook salmon, these benefits would include adverse to beneficial impacts from flow (Alternative 2 and 4) on egg incubation and rearing habitat and adverse to beneficial impacts from water temperature (Alternative 2) on rearing habitat. For late fall-run Chinook salmon, these would include beneficial water temperature effects (Alternative 2) for incubating eggs and adverse to beneficial (Alternative 2) and adverse (Alternative 4) rearing habitat flow effects. Relative to the No Action Alternative, Alternative 1 and Alternative 3 would also result in impacts on Sacramento River anadromous salmonids. For winter-run Chinook salmon, these impacts would include adverse (Alternative 1) and adverse or beneficial (Alternative 3) water temperature effects for incubating eggs and alevins. For spring-run Chinook salmon, Alternative 1 and Alternative 3 would have similar effects as for winter-run Chinook salmon. For steelhead, these impacts would include adverse water temperature effects (Alternative 1) and adverse to beneficial water temperature effects (Alternative 3) for incubating eggs and adverse to beneficial rearing habitat flow effects (Alternative 1 and 3). For fall-run Chinook salmon, these impacts would include adverse impacts from water temperature on rearing (Alternative 1 and 3), beneficial impacts (Alternative 1) and adverse to beneficial impacts (Alternative 3) from flow on egg incubation, and adverse impacts from flow (Alternative 1 and 3) on rearing habitat. For late fall-run Chinook salmon, these would include adverse (Alternative 1) and beneficial water temperature effects (Alternative 3) for incubating eggs and adverse (Alternative 1) and adverse to beneficial (Alternative 3) flow effects on rearing habitat.

Given the mixture of potential adverse and beneficial effects from the components in the action alternatives, and related actions in the Bay-Delta Water Quality Control Plan Update, there is some uncertainty in how these alternatives would ultimately affect salmonids. Under Alternative 1 may contribute to water temperature cumulative impacts for all salmonids while Alternatives 2, 3 and 4, population level effects are not expected to contribute to cumulative impacts.

O.10.1.2 Green and White Sturgeon

Most of the proposed components primarily target anadromous salmonids, but many of them potentially affect sturgeon as well. Green sturgeon is generally more likely to be affected than white sturgeon because its spawning, holding and rearing habitats are further upstream than those of white sturgeon and most of the proposed components primarily target conditions in the upper Sacramento River.

The projects to be considered cumulatively include components that affect the timing and magnitude of flow releases and seasonal water temperatures, and components that improve habitat of rearing and migrating green sturgeon in the Sacramento River. Flow and water temperature effects of completed projects are generally accounted for in the operational modeling of the No Action Alternative and the action alternatives of the water supply and water quality projects that have not been completed, those most likely to have cumulative effects related to the flow and water temperature is the Bay-Delta Water Quality Control Plan Update. The Bay-Delta Water Quality Control Plan Update has the potential to modify Sacramento River flow. Potential effects from the Bay-Delta Water Quality Control Plan Update would result in increased flows in spring and decreased flows in summer, with subsequent decreased water temperature in spring and increased water temperature in summer. This increase in spring flows may add to the potential beneficial effect on green sturgeon, but the decrease in summer flows may contribute to a potential negative effect.

No Action Alternative

Given the mixture of potential adverse and beneficial changes from the components in the No Action Alternative and related actions in the Bay-Delta Water Quality Control Plan Update, there is some uncertainty in how these alternatives would ultimately affect green sturgeon. However, the No Action Alternative is not expected to result in population level effects to green sturgeon and, hence, will not contribute to cumulative effects on green sturgeon.

Alternative 1–4

Given the mixture of potential adverse and beneficial effects from the components in the action alternatives, and related actions in the Bay-Delta Water Quality Control Plan Update, there is some uncertainty in how the action alternatives would ultimately affect green sturgeon. Relative to the No Action Alternative, Alternative 1 is not expected to have population level effects on green sturgeon, except minor negative flow effects to all life stages. Alternative 2 compared to the No Action Alternative is not expected to result in population level effects on green sturgeon. Alternative 3 is not expected to result in population level effects on green sturgeon, except for adverse flow effects on larval and juvenile rearing and emigration. Alternative 4 is not expected to result in impacts on green sturgeon, except for minor beneficial flow effects on larval and juvenile rearing and adult upstream migration. Therefore, Alternatives 1-4 are not expected to contribute to cumulative impacts on green sturgeon.

None of the proposed components under the action alternatives are expected to result in a population level effect on white sturgeon. For all white sturgeon life stages and behaviors, the alternatives are not expected to include flow or water temperature changes that would cause adverse impacts. Thus, the action alternatives are not expected to contribute to cumulative impacts on white sturgeon.

O.10.1.3 Other Focal Fish Species

This section addresses cumulative effects on the remaining Sacramento River populations of the focal fish species not included as anadromous salmonids or green sturgeon and white sturgeon: Sacramento splittail, hardhead, Sacramento hitch, Pacific lamprey, western river lamprey, striped bass, American shad, threadfin shad, largemouth bass, smallmouth bass, and spotted bass. None of these is a federally listed species.

The proposed components under both the No Action Alternative and Alternatives 1-4 primarily target anadromous salmonids and none of them are expected to result in population level effects to other focal species listed above. Therefore, the No Action Alternative and Alternatives 1-4 are not expected to result in cumulative impacts on these species.

O.10.2 Clear Creek

Major factors contributing to cumulative impacts on aquatic biological resources in Clear Creek have included hydropower development and operations, water withdrawals for irrigation and other uses, agriculture, timber harvest, roadbuilding, mining activities, channelization and levee construction, recreational use and development, sport and commercial fisheries, introduction of nonnative fish species, and other management actions, water uses, and land uses (Appendix Y, *Cumulative Methodology*). These actions have resulted in highly altered flow regimes, loss and disconnection of floodplains from the river channel, altered sediment transport, reduced aquatic habitat complexity, loss of riparian and off-channel aquatic habitat, elevated water temperature, degraded water quality, habitat fragmentation by physical barriers, and other adverse effects on aquatic biological resources. Several ecosystem improvement projects and actions, including the Central Valley Project Improvement Act (CVPIA), the CALFED Bay-Delta Program, the Clear Creek Restoration Program, the CDFW Ecosystem Restoration Program and various other conservation, management, and restoration programs (Appendix Y), have been initiated to offset the adverse effects of previous and ongoing activities.

In addition to the ongoing activities, several probable future projects and programs may affect listed fishes and other aquatic biological resources in Clear Creek. New projects and programs recently implemented or likely to be implemented in the near future are listed in Appendix Y, *Cumulative Methodology*. Some of these projects and programs may negatively impact special-status fishes and critical habitat in Clear Creek, but others are likely to be beneficial. While some projects and actions have had beneficial effects, the net short-term effect of many new and ongoing programs, projects, and restoration efforts remains uncertain. In the long term, however, the net effects are expected to include substantial improvements in river habitat conditions and conservation or recovery of special-status fish populations. Despite ongoing and potential future projects that could benefit native fishes and their habitat in Clear Creek, it is apparent that the effects of past and present actions have resulted in a cumulative adverse effect on Central Valley spring-run Chinook salmon, Central Valley steelhead, and their designated critical habitat in

Clear Creek. Also, these actions have resulted in a cumulative adverse effect on fall-run Chinook salmon in Clear Creek.

O.10.2.1 Anadromous Salmonids

This section addresses cumulative impacts on the Clear Creek populations of the following anadromous salmonids: spring-run Chinook salmon, Central Valley steelhead, fall-run Chinook salmon and late fall–run Chinook salmon.

No Action Alternative

The following components of the No Action Alternative have been identified as potentially resulting in impacts (adverse or beneficial) on anadromous salmonids in Clear Creek. These components include seasonal operations, ramping rates, segregation weir, minimum instream flows, pulse flows and water temperature management.

The expected benefits and impacts typically involve a tradeoff between the benefit of release water from storage in one year and with the impact of conserving insufficient storage for the next year. For instance, seasonal operations must balance providing cool water for releases to Clear Creek for water temperature control objectives and maintaining water temperature objects in the Sacramento River by supplying water to Keswick Reservoir with the impact of providing storage for the following year. This applies to seasonal operations of all the alternatives including the No Action Alternative. The costs and benefits of using water in one year versus using it in the following year are difficult to gage and likely vary from year to year, so the net effect on the salmonid populations is uncertain. For some of the other components, such as use of a segregation weir, there would be expected benefits primarily to spring-run Chinook salmon. However, weir location and timing would be planned to minimize effects to other salmonids utilizing Clear Creek.

The No Action Alternative is expected to have effects on anadromous salmonids in Clear Creek. However, these effects are not expected to result in adverse population-level impacts. Thus, the No Action Alternative is not expected to contribute to cumulative impacts on Clear Creek anadromous salmonids.

Alternatives 1–4

The following components of the action alternatives have been identified as potentially resulting in impacts (adverse or beneficial) on anadromous salmonids in Clear Creek. These components include seasonal operations (Alternatives 1-4), ramping rates (Alternatives 1-4), segregation weir (Alternatives 1-4), minimum instream flows (Alternatives 1-4), pulse flows (Alternatives 2-4), and water temperature management (Alternatives 1-4).

Relative to the No Action Alternative, Alternative 1 is expected to result in effects on Clear Creek anadromous salmonids. For spring-run Chinook salmon, this effect would include negative and beneficial flow effects with potential negative flow effects on spawning and fry/juvenile rearing habitat and negligible water temperature effects except potential beneficial effects on spawning and egg incubation. For steelhead, this effect would include negative and beneficial flow effects with potential adverse flow effects on spawning habitat and negative flow effects on fry and juvenile rearing habitat and negligible water temperature effects except possible beneficial effects on spawning and incubation.

Relative to the No Action Alternative, Alternatives 2, 3, and 4 would have an effect on Clear Creek anadromous salmonids. For both steelhead and spring-run Chinook salmon, this would include adverse and beneficial flow and temperature effects. Alternatives 2, 3, and 4 would not include population level flow or temperature effects on steelhead or spring-run Chinook salmon.

Given the mixture of potential adverse and beneficial effects from the action alternative, there is some uncertainty in how these alternatives would ultimately affect anadromous salmonids. However, in consideration that Alternatives 2, 3, and 4 are unlikely to cause population level effects, these alternatives are not expected to contribute to cumulative effects on anadromous salmonids in Clear Creek. Alternative 1, on the other hand, may result in adverse flow effects on steelhead spawning and fry/juvenile rearing habitat. Thus, Alternative 1 may contribute to cumulative effects on steelhead in Clear Creek.

O.10.2.2 Other Focal Fish Species

This section addresses cumulative effects on the remaining Clear Creek populations of the non-salmonid focal fish species: hardhead and Pacific lamprey. Neither of these is a federally listed species.

The proposed components under both the No Action Alternative and Alternatives 1-4 primarily target anadromous salmonids and none of them are expected to result in population level effects to other focal species listed above. Therefore, the No Action Alternative and Alternatives 1-4 are not expected to result in cumulative impacts on these species.

O.10.3 Lower American River

The lower American River is a highly altered watershed. Historical and management actions led to the reduction of available habitat, degraded habitat conditions, and substantial reduction of fish populations in the river. While these impacts were acknowledged as a trade-off for other water management priorities in the past, measures have been taken to improve conditions in the lower American River (Appendix Y). As such, there are numerous ongoing actions in and around the American River that may result in cumulative effects. Many of these actions are working to restore or improve conditions, so the resultant effect may not necessarily be an adverse cumulative impact. For example, the proposed Folsom Reservoir Temperature Control Device would withdraw water from the warm upper reaches of the lake while preserving the coldwater pool at the bottom of the reservoir to protect downstream aquatic species. Implementation of these measures to would help to improve habitat conditions in the American River, particularly in dry years, by maintaining minimum instream flows and suitable water temperatures.

The following components of the action alternatives have been identified as potentially resulting in impacts (adverse or beneficial) on anadromous salmonids in the lower American River. These components include seasonal operations (Alternatives 1-4), ramping rates (Alternatives 1-4), minimum instream flows (Alternatives 1-4), spring pulse flows (Alternatives 2-4), winter and spring pulses (Alternatives 3), Delta outflow (Alternatives 3), redd dewatering adjustments and water temperature management (Alternatives 1, 2 and 4).

O.10.3.1 Anadromous Salmonids

This section addresses cumulative impacts on the lower American River populations of steelhead and fall-run Chinook salmon.

No Action Alternative

The following components of the No Action Alternative have been identified as potentially resulting in impacts (adverse or beneficial) on anadromous salmonids in the lower American River. These components include seasonal operations, ramping rates, minimum instream flows, spring pulse flows, redd dewatering adjustments and water temperature management.

The expected benefits and impacts typically involve a tradeoff between the benefit of release water from storage in one year and with the impact of conserving insufficient storage for the next year. For instance, seasonal operations, limited coldwater pool, and limited storage require balancing releases and shutter operations to maximize the ability to maintain suitable water temperatures for steelhead rearing and fall-run Chinook salmon spawning. This applies to seasonal operations of all the alternatives including the No Action Alternative. The costs and benefits of using water in one year versus using it in the following year are difficult to gage and likely vary from year to year, so the net effect on the salmonid populations is uncertain. For some of the other components, such as implementation of redd dewatering adjustments, there would be expected benefits because projective adjustments may limit potential steelhead redd dewatering.

The No Action Alternative is expected to have effects on anadromous salmonids in the lower American River. The No Action Alternative may result in adverse flow effects on steelhead fry/juvenile rearing habitat. Thus, the No Action Alternative may contribute to cumulative effects on steelhead in the lower American River.

Alternatives 1–4

Relative to the No Action Alternative, Alternative 2 would have an effect on lower American River anadromous salmonids. For both steelhead and fall-run Chinook salmon, this would include adverse and beneficial flow and temperature effects. Alternatives 3 and 4 would have adverse and beneficial flow and temperature effects, including beneficial flow effects on redd dewatering in drier water year types. For fall-run Chinook salmon, Alternative 3 and 4 would include adverse and beneficial flow effects; however, none of these effects is expected to result in population level effects. Relative to the No Action Alternative, Alternative 1 would also have an effect on lower American River anadromous salmonids. For steelhead, this would include adverse and beneficial flow effects, including flow effects on redd dewatering potential in drier water year types. For fall-run Chinook salmon, this effect would include adverse and beneficial flow effects, including adverse flow effects on spawning and egg incubation and beneficial flow effects on juvenile rearing and emigration.

All the action alternatives are expected to result in cumulative effects on steelhead in the lower American River. Alternative 1 may contribute to cumulative effects on fall-run Chinook salmon.

O.10.3.2 Other Focal Fish Species

This section addresses cumulative effects on the remaining American River populations of the focal fish species not included as anadromous salmonids: white sturgeon, Sacramento splittail,

hardhead, Pacific lamprey, western river lamprey, striped bass, American shad, threadfin shad, largemouth bass, smallmouth bass, and spotted bass.

The proposed components under both the No Action Alternative and Alternatives 1-4 primarily target anadromous salmonids and none of them are expected to result in population level effects to other focal species listed above. Therefore, the No Action Alternative and Alternatives 1-4 are not expected to result in cumulative impacts on these species.

O.10.4 Bay-Delta

Major factors contributing to cumulative impacts on aquatic biological resources in the Bay-Delta have included water withdrawals for irrigation and other uses, agriculture, channelization and levee construction, recreational use and development, sport and commercial fisheries, introduction of nonnative fish species, and other management actions. Of the water supply and water quality projects not included in the modeling, those most likely to have cumulative effects are the Bay-Delta Water Quality Control Plan Update, and Cache Slough Area Restoration. The Bay-Delta Water Quality Control Plan has the potential to increase Delta inflow and outflow during spring months, reduce Delta inflow and outflow during fall months, and reduce south Delta exports. The Cache Slough Area Restoration project has the potential to improve habitat and lower food web conditions by increasing floodplain, riparian, marsh, and open water habitat. The construction and operation of Agricultural barriers in Old River, Middle River and Grant Line Canal have the potential to alter hydrology. The proposal of expanding the Los Vaqueros Reservoir (Phase 2) including improvements to water quality and supply reliability which may impact water diversions. Despite ongoing and potential future projects that could benefit native fishes and their habitat in Delta, it is apparent that the effects of past and present actions have resulted in a cumulative adverse effect on Delta smelt, longfin smelt, winter-run Chinook salmon, spring-run Chinook salmon, fall-run Chinook salmon, late fall-run Chinook salmon, steelhead and green sturgeon.

O.10.4.1 Osmerids

This section addresses cumulative impacts on Delta smelt and longfin smelt.

No Action Alternative

The proposed components under the No Action Alternative may cause potential effects (adverse or beneficial) on Delta smelt (e.g., operations of Barker Slough Pumping Plant, Delta smelt supplementation, OMR management).

The No Action Alternative would contribute to cumulative effects on Delta smelt and longfin smelt from seasonal operations and Delta smelt habitat operations (e.g., food availability, habitat extent) and OMR management (i.e., south Delta entrainment risk). Also, there may be offsetting, potential positive effects on Delta smelt under the No Action Alternative from food subsidies (studies related to Sacramento Deepwater Ship Channel, North Delta/Colusa Basin Drain, and Suisun Marsh RRDS) and reintroduction of Delta smelt by the Fish Conservation and Culture Laboratory and the Delta Fish Species Conservation Hatchery. Except for Delta smelt supplementation, these offsetting effects under the No Action Alternative also would benefit longfin smelt. The No Action Alternative would still be expected to contribute to cumulative effects, both positive and negative, on Delta smelt and longfin smelt.

Alternatives 1–4

The action alternatives would contribute to cumulative effects on Delta smelt from seasonal operations and Delta smelt habitat operations (e.g., food availability, habitat extent) and OMR management (i.e., south Delta entrainment risk). Also, there may be offsetting, potential positive effects on Delta smelt under the action alternatives from food subsidies (studies related to Sacramento Deepwater Ship Channel, North Delta/Colusa Basin Drain, and Suisun Marsh RRDS) and reintroduction of Delta smelt by the Fish Conservation and Culture Laboratory and the Delta Fish Species Conservation Hatchery. Nevertheless, the action alternatives would still be expected to contribute to cumulative effects on Delta smelt. Expansion of the Los Vaqueros Reservoir may adjust the timing of its Delta water diversions to accommodate the life cycles of Delta aquatic species including osmerids; thus, this project would reduce species impact and providing a net benefit to the Delta environment and not contribute to cumulative effects for these species under any alternative.

Alternatives 1, 2, and 4 may result in adverse impacts on longfin smelt due to entrainment. There may be offsetting potential positive effects on Delta smelt under the action alternatives from food subsidies (studies related to Sacramento Deepwater Ship Channel, North Delta/Colusa Basin Drain, and Suisun Marsh RRDS). Nevertheless, Alternatives 1, 2, and 4 would still be expected to contribute to cumulative effects on Delta smelt. Alternative 3 may result in a benefit lessening entrainment of longfin smelt; therefore, lessening cumulative effects on Delta smelt.

O.10.4.2 Anadromous Salmonids

No Action Alternative

The No Action Alternative would contribute to cumulative effects on anadromous salmonids from seasonal operations, OMR management (south Delta entrainment risk), and Delta Cross Channel operations. However, there may be offsetting, potential positive effects under the No Action for winter-run Chinook salmon from improvements at the Tracy and Skinner fish facilities, real-time OMR restrictions and performance objectives, real-time decision-making and salvage thresholds.

Alternatives 1–4

Alternatives 1, 2 and 4 may result in adverse impacts on both entrainment risk and survival of winter-run Chinook salmon, spring-run Chinook salmon, fall-run Chinook salmon and late fall-run Chinook salmon. Thus, Alternatives 1, 2, and 4 may contribute to cumulative effects on these species. Alternatives 2 and 4 are not anticipated to contribute to cumulative effects on steelhead. However, Alternative 1 is expected to result in adverse flow effects on entrainment risk of steelhead; thus contributing to cumulative effects for this species. Construction and operations of the agricultural barriers does not coincide with the majority of juvenile salmonids migrating through the Delta; thus, these barriers would not contribute to cumulative effects for these species under any alternative.

Alternative 3 may result in a beneficial impact on both entrainment risk and survival of winter-run Chinook, particularly in wet, above normal, and below normal water year types. requirements. However, Alternative 3 would result in adverse impacts on spring-run Chinook salmon, fall-run Chinook salmon and late fall-run Chinook salmon due to entrainment.

Alternative 3 is expected to result in beneficial flow effects on entrainment risk of steelhead, relative to the No Action Alternative. Thus, Alternative 3 would contribute to cumulative impacts on spring-run Chinook salmon, fall-run Chinook salmon and late fall-run Chinook but lessen cumulative impacts on steelhead and winter-run Chinook salmon.

O.10.4.3 Green and White Sturgeon

No Action Alternative

The No Action Alternative may result in cumulative effects to green and white sturgeon from seasonal operations, OMR management (south Delta entrainment risk), and Delta Cross Channel operations. There may be offsetting, potential positive effects for green and white sturgeon from improvements at the Tracy and Skinner fish facilities, real-time OMR restrictions and performance objectives, real-time decision-making and salvage thresholds. Nevertheless, the No Action Alternative may still contribute to cumulative effects on green and white sturgeon in the Delta.

Alternatives 1–4

The action alternatives (Alternatives 1-4) are expected to result in negative effects on green and white sturgeon from seasonal operations, OMR management (south Delta entrainment risk), and Delta Cross Channel operations. There may be offsetting, potential positive effects for green and white sturgeon from improvements at the Tracy and Skinner fish facilities, real-time OMR restrictions and performance objectives, real-time decision-making and salvage thresholds. Nevertheless, the No Action Alternative may still contribute to cumulative effects on green and white sturgeon in the Delta.

O.10.4.4 Other Focal Fish Species

This section addresses cumulative effects on the Delta populations of the focal fish species not included as anadromous salmonids or green sturgeon and white sturgeon: Sacramento hitch, Sacramento splittail, hardhead, Pacific lamprey, western river lamprey, striped bass, American shad, threadfin shad, largemouth bass, smallmouth bass, spotted bass, and starry flounder. None of these is a federally listed species.

The proposed components under both the No Action Alternative and Alternatives 1-4 primarily target anadromous salmonids but some may result in population level effects to other focal species listed above. For example, reductions in Delta outflow and increased exports under Alternative 1 could have substantial adverse effects on Sacramento splittail and other native minnows due to increased entrainment and unfavorable habitat conditions in the Delta. Alternatives 1, 2, and 4 would increase exports during critical times for some native focal species, likely leading to increased entrainment. Alternative 3, on the other hand, may benefit several of the other focal species. Additionally, components like the agricultural barriers and CCF weed management under the No Action Alternative would likely have adverse effects on other focal species. Therefore, the No Action Alternative and Alternatives 1-4 may result in cumulative impacts on these species.

O.10.5 San Joaquin River

The San Joaquin River is a highly altered watershed that is currently discontinuous. Historical actions and management led to the extirpation of native fishes, including spring-run Chinook salmon that once persisted. While these impacts were acknowledged as a trade-off for other water management priorities in the past, current policy has worked to reverse the degraded river. As such, there are numerous ongoing actions in and around the San Joaquin River that may result in cumulative effects. Many of these actions are working to restore or improve conditions, so the resultant effect may not necessarily be an adverse cumulative impact.

The San Joaquin River Restoration Program (SJRRP) is a large and comprehensive effort to reverse some of the negative alterations to the upper San Joaquin River aquatic habitat while reintroducing spring-run Chinook salmon. The project manages for both fall-run and spring-run Chinook salmon alike, but has reintroduced spring-run Chinook salmon through an experimental population. The salmon population will be supported by a conservation hatchery, which operates under more significant scrutiny considering genetic diversity and overall viability. The program seeks to connect flow from Friant Dam down to the mouth of the Merced River to provide habitat capable of supporting populations of Chinook salmon in good condition. While water management and habitat restoration are significant components to the project, the overall impact on irrigators is required to be *de minimus*. In addition, hatchery production occurs in the San Joaquin watershed along the Mokelumne and Merced Rivers, at the Mokelumne Fish Hatchery and Merced River Fish Facility. Production includes fall-run Chinook salmon, which further supports the population.

Several regulatory processes are currently underway that might lead to general revisions to flow in the San Joaquin River. The Bay-Delta Water Quality Control Plan Update is seeking potential instream flow changes in increments of 10 from 35% of unimpaired flow up to 75% unimpaired flow from the lower San Joaquin, Merced, Tuolumne, and Stanislaus Rivers. This level of unimpaired flow would significantly increase outflow through the lower San Joaquin River to the Delta. FERC relicensing activity in the Merced and Tuolumne Rivers will eventually result in a new license that may increase required base flows from these tributaries to the San Joaquin River.

The No Action Alternative and the action alternatives (Alternative 1-4) do not include actions that target the San Joaquin River. Reclamation will continue to operate the San Joaquin River in accordance with the SJRRP, which is an independent action. Thus, the No Action Alternative and the action alternatives are not expected to contribute to cumulative impacts on San Joaquin River aquatic resources.

O.10.6 Stanislaus River

Natural hydrologic processes have been altered on the Stanislaus River, as they have been on most California rivers. More than 40 dams exist on the Stanislaus River. The lower Stanislaus River has been extensively developed to provide water, flood control, hydroelectric power, gravel, and conversion of floodplain habitat for agricultural and residential uses (Merz n.d.). The construction of New Melones Reservoir and its operation have resulted in a highly altered channel that has experienced gravel extraction, levee construction and removal of woody debris.

Processes and measures have occurred within the watershed to restore or improve conditions within the river, so the resultant effect may not necessarily be an adverse cumulative effect.

Processes and measures are underway in the Stanislaus River watershed. The SWRCB is updating the 2006 Bay-Delta Water Quality Control Plan (WQCP) in two phases (SWRCB 2018). The first Plan amendment (Phase 1) is focused on San Joaquin River flows and southern Sacramento-San Joaquin Delta (Delta) salinity and would modify water quality objectives (i.e., establishes minimum flows) on the Stanislaus River to protect the beneficial use of fish and wildlife and modifies the water quality objectives in the southern Delta to protect the beneficial use of agriculture. The proposed final amendments to the Bay-Delta Plan and the Final Supplemental Environmental Document for Phase I was released in July 2018 and the SED was approved in December 2018. Additionally, FERC relicensing activity of hydropower in the Stanislaus River will eventually result in a new license that may increase flows into the Stanislaus River.

The following are the proposed components that were identified in the evaluation of the alternatives to have potential effects (adverse or beneficial) on one or more of the anadromous salmonid species or runs, green and white sturgeon, and other focal fish species:

O.10.6.1 Anadromous Salmonids

This section addresses cumulative impacts on the Stanislaus River populations of steelhead and fall-run Chinook salmon.

No Action Alternative

The following components of the No Action Alternative have been identified as potentially resulting in impacts (adverse or beneficial) on anadromous salmonids in the Stanislaus River. These components include seasonal operations, ramping rates, minimum instream flows, winter instability flows and spring and fall pulse flows.

The No Action Alternative is expected to result in adverse and beneficial flow and temperature changes for both steelhead and fall-run Chinook salmon. However, these effects are not expected to reach population level impacts. Thus, the No Action Alternative is not expected to contribute to cumulative effects of anadromous salmonids in the Stanislaus River.

Alternatives 1–4

The following components of the action alternatives have been identified as potentially resulting in impacts (adverse or beneficial) on anadromous salmonids in the Stanislaus River. These components include seasonal operations (Alternatives 1-4), ramping rates (Alternatives 1-4), minimum instream flows (Alternatives 1-4), winter instability flows (Alternatives 2 and 3), spring pulse flows (Alternative 3 and 4) and fall pulse flows (Alternatives 2, 3 and 4).

All action alternatives are expected to result in beneficial and adverse flow and temperature related impacts on anadromous salmonids in the Stanislaus River. However, these effects are not expected to reach population level impacts. Thus, the action alternatives are not expected to contribute to cumulative effects of anadromous salmonids in the Stanislaus River.

O.10.6.2 Other Focal Fish Species

This section addresses cumulative effects on the Stanislaus River populations of focal fish species outside of anadromous salmonids: hardhead, Pacific lamprey, western river lamprey, striped bass, American shad, threadfin shad, largemouth bass, smallmouth bass, and spotted bass.

The proposed components under both the No Action Alternative and Alternatives 1-4 primarily target anadromous salmonids and none of them are expected to result in population level effects to other focal species listed above. Therefore, the No Action Alternative and Alternatives 1-4 are not expected to result in cumulative impacts on these species.

O.10.7 Trinity River

Major factors contributing to the cumulative adverse impacts (cumulative effects) on aquatic biological resources in the Trinity River in the project area have included dam construction, hydropower development and operations, mining and dredging in the river corridor, hatchery management, water diversions, recreational use, sport fisheries, introduction of nonnative fish species, illegal marijuana cultivation, and other management actions, water uses, and land uses. Many of these actions have resulted in altered flows on the Trinity River, reduced sediment input to downstream locations, hindered important fluvial processes which support riparian habitat and river channel dynamics, increased riparian vegetation encroachment through the reduction of vegetation scouring high flow events, reduced channel movement and the creation of unnatural levees isolating the channel from the floodplain, and other adverse effects on aquatic habitat. These alterations have led to a reduction in channel complexity and aquatic habitat for several fish species in the mainstem Trinity River downstream of Lewiston Dam. Other activities have contributed to cumulative effects by degrading habitat in the mainstem Trinity River and tributaries, increasing competition and predation on listed and sensitive fishes, and altering population genetics of listed salmonids.

Several management components have been established to mitigate for the adverse effects of dam construction on the Trinity River and are included in the TRRP and the Trinity River ROD. The TRRP includes instream flow management, mechanical channel rehabilitation, fine and coarse sediment management, watershed restoration, infrastructure improvement, and adaptive environmental assessment and monitoring. Components including sediment management and channel rehabilitation are focused on the 40-mile section of the Trinity River from Lewiston Dam to the confluence with the North Fork Trinity River (TRRP 2014). The effects of other components, including instream flow management, are intended to extend throughout the mainstem Trinity River downstream of Lewiston Dam. Since 2008, over 75 projects have been completed under the TRRP. The ROD documents actions intended to restore and maintain anadromous fishery resources in the Trinity River based on the best available scientific information, while continuing to provide water supplies for beneficial uses and power generation. The ROD specifies variable annual instream flows for the Trinity River, physical channel rehabilitation, sediment management, watershed restoration efforts, and infrastructure improvements and modifications (USDOI 2000). The Trinity River Hatchery (TRH) produces coho salmon, Chinook salmon, and steelhead to supplement regional populations of these species as mitigation for habitat and fish production lost from construction and operation of Lewiston Dam. The TRH has been in operation since 1960 but is not a component of the ROD or the TRRP.

The Klamath Dam removal and Klamath River Project are two other present actions that will contribute benefits to fish and aquatic resources in the Trinity River and Lower Klamath River by improving aquatic habitat and fish passage in the watershed. These actions involve the removal of four dams and water management in the Klamath River mainstem.

Despite ongoing and potential future projects that could benefit native Trinity River fishes and their habitat, it is apparent that the effects of past and present actions have resulted in a cumulative adverse effect on coho salmon, Chinook salmon, steelhead, green sturgeon, white sturgeon, Pacific lamprey, and American shad.

O.10.7.1 Anadromous Salmonids

No Action Alternative

The No Action Alternative will continue to implement the 2000 Trinity ROD. Although, the No Action Alternative may result in negative and beneficial changes to parameters (e.g., flows, water temperatures) important for anadromous species in the Trinity River, population level adverse impacts are not identified under the No Action Alternative. Thus, the No Action Alternative is not expected to contribute to cumulative impacts on anadromous salmonids in the Trinity River.

Alternatives 1–4

The action alternatives will continue to implement the 2000 Trinity ROD. Although, the action alternatives may result in negative and beneficial changes to parameters (e.g., flows, water temperatures) important for anadromous species in the Trinity River, population level adverse impacts are not identified under these alternatives. Thus, the action alternatives are not expected to contribute to cumulative impacts on anadromous salmonids in the Trinity River.

O.10.7.2 Green and White Sturgeon

No Action Alternative

The No Action Alternative will continue to implement the 2000 Trinity ROD. Although, the No Action Alternative may result in negative and beneficial changes to parameters (e.g., flows, water temperatures) important for green and white sturgeon in the Trinity River, population level adverse impacts are not identified under the No Action Alternative. Thus, the No Action Alternative is not expected to contribute to cumulative impacts on green and white sturgeon in the Trinity River.

Alternatives 1–4

The action alternatives will continue to implement the 2000 Trinity ROD. Although, the action alternatives may result in negative and beneficial changes to parameters (e.g., flows, water temperatures) important for green and white sturgeon in the Trinity River, population level adverse impacts are not identified under these alternatives. Thus, the action alternatives are not expected to contribute to cumulative impacts on green and white sturgeon in the Trinity River.

O.10.7.3 Other Focal Species

These species include Pacific Lamprey and American shad.

No Action Alternative

The No Action Alternative will continue to implement the 2000 Trinity ROD. The No Action Alternative is not expected to negatively impact Pacific lamprey and American shad. Thus, the No Action Alternative is not expected contribute to cumulative impacts on these species.

Alternatives 1–4

The action alternatives will continue to implement the 2000 Trinity ROD. The action alternatives are not expected to negatively impact Pacific lamprey and American shad. Thus, the action alternatives not expected contribute to cumulative impacts on these species.

O.10.8 Nearshore Pacific Ocean of the California Coast

O.10.8.1 Southern Resident Killer Whale

In general, the analysis of the No Action Alternative and Alternatives 1–4 noted that potential effects on Chinook Salmon prey for Southern Resident Killer Whale (Southern Residents) may be limited because of negligible differences between adult Chinook salmon abundance and biomass for adult Chinook salmon that occur in the Pacific Ocean that originate from the Central Valley or Trinity River. This coupled with the relatively high representation in the stocks by hatchery-origin fish, many of which are released downstream of the Delta, mean there would be limited impacts of the No Action Alternative and the action alternatives (Alternatives 1-4). Thus, the No Action Alternative and Alternatives 1-4 are not expected to contribute to cumulative impacts on Southern Resident Killer Whales.

O.10.9 Sites Reservoir and Delta Conveyance Project

The operation of Sites Reservoir may result in cumulative impacts on aquatic resources through the timing and magnitude of flow releases and seasonal water temperatures when combined with the ongoing water operations of the CVP and SWP and associated flow alterations. Potential cumulative impacts would be anticipated to be limited both spatially and temporally and minimized by operational criteria for migrating juvenile salmonids or managing to reduce potential water quality-related effects on delta smelt.

The operation of water conveyance facilities related to the Delta Conveyance Project may result in cumulative impacts on aquatic resources for winter-run Chinook salmon), Central Valley steelhead, delta smelt, and longfin smelt. Operational effects of the CVP and SWP could combine with the effects of operations of the Delta Conveyance Project. Potential cumulative impacts could result from diversions from the Sacramento River under operation of the CVP could affect fish and aquatic species in an analogous manner to that which could occur under the DCP, e.g., by reducing river flow, thereby potentially affecting migration survival for juvenile salmonids or abundance of longfin smelt through Delta outflow-abundance relationships (Sites, 2023).
