THE RELATIONSHIP BETWEEN INSTREAM FLOW AND PHYSICAL HABITAT AVAILABILITY FOR CHINOOK SALMON IN THE STANISLAUS RIVER, CALIFORNIA

ABSTRACT

In 1989 the U.S. Fish and Wildlife Service's Instream Flow Incremental Methodology (IFIM) was applied to the Stanislaus River between Goodwin Dam and the town of Riverbank, California (approximately 24 river miles). The purpose was to help determine the instream flow needs for chinook salmon, Onchorhynchus tshawytscha, in the Stanislaus River downstream of the New Melones Unit of the Central Valley Project. The streamflow versus physical habitat relationship is described using the physical habitat simulation (PHABSIM) model and is based on the relationship established for three calibration flows measured as releases below Goodwin Dam (1,250 cfs, 700 cfs, and 125 cfs).

An instream flow of 300 cfs provides the greatest amount of salmon spawning habitat. Available habitat for egg incubation is maximized at 150 cfs. Fry habitat appears to be relatively limited and does not increase or decrease appreciably with streamflow. Juvenile salmon habitat availability is highest at 200 cfs. In general, an annual fishery flow release of 156,000 acre-feet would provide maximum physical habitat availability within the 24 mile study reach.

Additional water is recommended, as provided in an interim agreement between the U.S. Bureau of Reclamation and the California Department of Fish and Game, for further investigations to define flow needs for: 1) spring outmigration; 2) water temperature control; 3) fall "attraction" of migrating adults; and 4) maintenance of water quality (i.e., dissolved oxygen) or other benefits to the salmon population. These investigations must be completed before the instream flow requirements for chinook salmon protection on the Stanislaus River can be determined.
This investigation was funded through Federal transfer monies provided by the U.S. Bureau of Reclamation, Mid-Pacific Region. The studies described, and this report, were completed as part of a cooperative Stanislaus River Fishery Investigation, involving the Bureau of Reclamation, the U.S. Fish and Wildlife Service, and the California Department of Fish and Game. Jim Denny was the Bureau of Reclamation contact throughout this investigation. Many others also contributed to the completion of this report, especially in gathering the field data. Fish and Wildlife Service personnel Phil North (field crew leader), Nadine Kanim, Roger Guinee, Vicky Campbell, Mike Sullivan, Rich Williams, and Larry Hanson all worked diligently in gathering the field data. Volunteer workers Steve Elliot and Rick Howard also provided valuable field assistance. James Carson, of the Service's Sacramento Field Office, helped with editorial review and Jeff Thomas provided a thorough review, and improved calibration, of the PHABSIM input data for the final analysis.
PREFACE

The draft of this report, dated February 20, 1992, was titled Instream Flow Requirements for Fall Run Chinook Salmon Spawning and Rearing, Stanislaus River, California. The title has been changed to more accurately reflect the product of this study, which is a description of the relationship between physical or micro-habitat availability (expressed as suitable combinations of water velocity, depth, and substrate) for chinook salmon and streamflow in the Stanislaus River, California. Additional studies describing the relationship between streamflow and suitable macrohabitat conditions, such as water quality or temperature and conveyance flows (also called migration or "pulse" flows) necessary for salmon survival, must be completed in order to fully describe the relationship between instream flow and suitable habitat conditions for chinook salmon in the Stanislaus River.

A water temperature model is currently being developed for the Stanislaus River by the Bureau of Reclamation and salmon survival studies are being conducted by the Department of Fish and Game as part of the Stanislaus River Fishery Investigation. Once completed, the results of the temperature model, salmon survival studies, and the instream flow study described in this report will be "integrated" so that the overall relationship between streamflow and suitable habitat conditions for chinook salmon can be described. Only then can instream flows necessary to protect and preserve the salmon population of the Stanislaus River be determined and long term instream flow requirements be established.

Furthermore, due to interest from Bureau of Reclamation and Department of Fish and Game staff, a PHABSIM analysis was added using habitat suitability criteria for resident rainbow trout and anadromous steelhead trout.
Finally, those readers who reviewed the draft report may notice some differences in the relationship between weighted usable area and streamflow as described in this report. The primary reason for these differences are the result of a more detailed, and exhaustive, review of the physical and hydraulic input data applied to the PHABSIM. In addition, rather than running three separate data sets (high, middle, and low flow) for each study site, as was done in the draft, all velocity data was combined into one input deck for each study site in the final analysis. The input decks were thoroughly calibrated so that predicted water depths and velocities best matched those actually recorded at the three measured stream flows. Through this process it was not necessary to combine the PHABSIM results from three separate runs for each study site to provide the best overall picture of the physical habitat versus streamflow relationship, as was done in the draft. Instead the results from the combined velocity data sets used in the final analysis for each study site can be used directly. Therefore, the results presented in this report supersede those presented in the February 20, 1992 draft and should be used in negotiations where the relationship between weighted usable area of habitat and streamflow needs to be understood.

THE RELATIONSHIP BETWEEN INSTREAM FLOW AND PHYSICAL HABITAT AVAILABILITY FOR CHINOOK SALMON IN THE STANISLAUS RIVER, CALIFORNIA

INTRODUCTION

Historically, the Stanislaus River, along with other San Joaquin River tributaries and the mainstem of the San Joaquin, had sizeable populations of chinook salmon, *Onchorhynchus tshawytscha*. Since the early 1900's, however, the number of salmon returning to the system each year to spawn has fallen dramatically. The spring-run chinook populations are extinct in the San Joaquin River system and the fall-run populations have declined significantly. Currently, there is no access for salmon to the upper San Joaquin River, due to diminished river flows. Spawning now occurs only in the major tributaries of the San Joaquin River -- the Merced, the Tuolumne, the Calaveras, and the Stanislaus Rivers.

Efforts are underway to protect, restore, or enhance the dwindling populations of fall-run chinook salmon within the San Joaquin River system. An early effort on the Stanislaus River began with the authorization of the New Melones Project, a Federal water project operated by the U.S. Bureau of Reclamation as part of the Central Valley Project. Among the authorized project purposes, (which include flood control, irrigation and municipal water supply, power generation, recreation, and water quality control) is fish and wildlife enhancement, including provision for fishery flows.

Pursuant to project authorization, the U.S. Fish and Wildlife Service (Service), the California Department of Fish and Game (Department), and the Bureau of Reclamation (Reclamation) have cooperatively undertaken a series of investigations aimed at determining the measures necessary to improve the chinook salmon population in the Stanislaus River. Study tasks were designed to identify factors limiting chinook salmon survival in the Stanislaus and to
develop alternative management programs to increase the population. One task was specifically to conduct an instream flow study to assist in the identification of acceptable flow regimes for all life stages of chinook salmon which occur in the Stanislaus River. This report describes the instream flow study and presents the results.

DESCRIPTION OF STUDY AREA

General Setting

The headwaters of the Stanislaus River originate at an elevation of approximately 7,000 feet on the western slope of the Sierra Nevada, approximately 125 miles due east of the San Francisco Bay area. The Stanislaus flows in a southwesterly direction from the Sierra crest and joins the San Joaquin River on the floor of the Central Valley (Figure 1). Draining northward through the valley, the San Joaquin River meets the southward draining Sacramento River to form the Sacramento-San Joaquin Delta. Delta waters flow through the San Pablo Bay-San Francisco Bay complex and eventually into the Pacific Ocean, passing through San Francisco’s Golden Gate.

Goodwin Dam is located in the Sierra foothills at an elevation of approximately 300 feet above mean sea level, and is a barrier to salmon migration on the Stanislaus River. Between the San Joaquin River and Goodwin Dam approximately 59 river miles of anadromous fish habitat is available in the Stanislaus. However, only the reach from approximately river mile 36 to Goodwin Dam (a distance of approximately 23 river miles) is defined as salmon spawning habitat by the California Department of Fish and Game (California Fish and Game code section 1505).

Field reconnaissance and aerial photos indicate that the lower Stanislaus...
The Stanislaus River (i.e., that section below Goodwin Dam) can be divided into upper, middle, and lower segments. They are distinguished from one another primarily by differences in stream gradient, substrate composition, and channel configuration. Two intermittent streams, Owl Creek and Wildcat Creek, enter the Stanislaus River in the upper and middle segments. Their contributions to river flow are generally not significant, however.

The upper river segment is the reach between Goodwin Dam and the town of Knights Ferry, a distance of approximately 4 river miles. Here the river is moderate in gradient (approximately 0.7%) and is confined by a narrow, steep-sided bedrock canyon. Approximately 80 percent of this river segment is composed of long deep pools and runs interspersed with short cascades. Substrate is predominantly sand and bedrock. The remaining 20 percent of this
segment is lower in gradient and the channel is less confined. The primary habitat types here are pools, runs, and riffles with gravel and cobble the predominant substrate. Also, sand and bedrock are present to a lesser degree. Approximately 10 percent of all chinook salmon spawning in the Stanislaus River occurs within this river segment.

The middle river segment is the reach between the towns of Knights Ferry and Riverbank, a distance of approximately 20 river miles. As the river flows downstream from the upper, bedrock canyon segment, a well-defined channel continues with a low gradient (0.1%). Steep banks of erodible soils and of bedrock are common and are often situated opposite large flood plains. This river segment displays a typical pool, run, and riffle habitat-type sequence, although individual habitat areas are frequently long and often variable in occurrence. Large, deep dredge pools add to the diversity of stream habitat types within this river segment. The predominant substrate is sand, gravel, and cobble. Approximately 90 percent of all chinook salmon spawning in the Stanislaus River is found within this reach.

The lower river segment is the reach between the town of Riverbank and the San Joaquin River, a distance of approximately 35 river miles. As the river flows into the San Joaquin Valley the gradient is nearly flat (approximately 0.03%) and the river meanders more as it flows through the valley lowlands. Deep pool and run habitat types predominate. The river substrate is composed mainly of sand and fine organic material. Salmon use this segment primarily for migration, although some juvenile rearing occurs when water temperatures are satisfactory. No spawning has been observed within this segment.

**Hydrology**

River flows within the study reach are controlled by Reclamation through the
Figure 2. Mean monthly discharge (streamflow) for the Stanislaus River measured just below Goodwin Dam for years 1981 through 1989.

New Melones Unit of the Central Valley Project. The authorized fishery flow release from New Melones Reservoir is 98,300 acre-feet annually with provisions for release of 69,000 acre-feet in critically dry years. However, an interim agreement, executed in 1987, between the Bureau and the Department, provides for variable flow releases from 98,300 acre-feet to 302,000 acre-feet annually, based on inflow, reservoir storage, and water demands. In addition to the fishery flow agreement, the Bureau has an interim arrangement with the South Delta Water Agency to provide an annual release of up to 70,000 acre-feet or more, if adequate supply exists, for water quality control purposes. Recent mean monthly Stanislaus River flows measured at the U.S. Geological
Survey river gage just below Goodwin Dam are illustrated in Figure 2.

Fishery Resources

In addition to chinook salmon, a considerable population of resident rainbow trout, *Onchorhynchus mykiss*, exists within the Stanislaus River between Goodwin Dam and Riverbank. The Department also has anecdotal information regarding the occurrence of the anadromous steelhead trout within the Stanislaus River (Bill Loudermilk, DFG, personal communication). Striped bass, *Morone saxatilis*, and American shad, *Alosa sapidissima*, have been reported to have migrated to, and spawned in, the extreme lower reaches of the Stanislaus River. Sturgeon, *Acipenser spp.*, have also been reported within the lower Stanislaus but are not known to spawn in the river.

Fall-run chinook salmon generally begin to migrate into the lower Stanislaus in late September and continue through mid-December. Spawning begins in mid-October and continues through early January. Incubation, and fry and juvenile rearing, occur from the spawning period through mid-May. Juvenile smoltification begins as early as late March and generally continues to early June. Although most juvenile chinook salmon emigrate as smolts the first spring after hatching and emergence, some remain in the Stanislaus beyond this period. These yearling chinook juveniles have become more common within the Stanislaus in recent years (CDFG, 1987). Yearling chinook salmon have been observed in the river through the summer months and into early fall.

Snorkeling surveys suggest that yearling emigration takes place when ambient air and water temperatures cool in October or November (CDFG, 1992). Table I is a life stage periodicity chart for chinook salmon in the Stanislaus River.

Late fall-run chinook salmon are also reported to spawn and rear in the Stanislaus River below Goodwin Dam (Alice Low, CDFG, personal communication).
Late fall-run spawn from December through early March. Fry and juveniles remain in the river throughout the summer, and migrate out of the system the following fall. Although a much smaller part of the Stanislaus River chinook salmon fishery, the late fall-run, nevertheless, is an important component.

IFIM Study Reach

The study reach for habitat mapping and collection of hydraulic and physical habitat data within the Stanislaus River was located in the upper and middle river segments, between Goodwin Dam and the town of Riverbank (a distance of approximately 24 river miles). The study reach was divided into four study areas, each designated by the name given to the study site within the study area, as follows: 1) Two Mile Bar area - from Goodwin Dam to the covered bridge at Knights Ferry (approximately 3.5 river miles); 2) Six Mile Bar study
Figure 3. Location of IFIM study sites on the Lower Stanislaus River.

area - from the covered bridge at Knights Ferry to the upstream boundary of the Horseshoe Road Park (approximately 3.6 river miles); 3) Honolulu Bar study area - from Horseshoe Road Park to the Orange Blossom Road bridge (approximately 3.8 river miles); and, 4) Valley Oak State Recreation Area (SRA) study area - from the Orange Blossom Road bridge to about 1/2 mile upstream of the Santa Fe road bridge in Riverbank (approximately 13.1 river miles). Study site locations are shown in Figure 3.

The study sites were selected so that habitat types representative of the overall study areas were included, yet recognizing that each habitat type has variability between locations. For example, a pool by our definition is one that is over 4 feet in depth with an average water velocity of less than 1 foot per second. However, a given pool may be 6 feet deep and another 20 feet deep. Transects were established at the study sites to sample the major
habitat types and provide enough repetition to account for natural variation. This resulted in 7 to 10 transects at each study site. Study site maps, including transect locations and habitat distribution, are included in Appendix A.

METHODS

The Service’s Instream Flow Incremental Methodology (IFIM) (Bovee and Milhous 1978; Milhous et al. 1981; Bovee 1982) was used for this evaluation. The IFIM was developed to facilitate evaluation of water resource developments and effective stream management. Basically, the methodology uses a computer-based physical habitat simulation model (PHABSIM) to combine various stream hydraulic and physical parameters with fish habitat requirements. The product of the PHABSIM allows investigators to relate changes in streamflow to physical habitat availability. Important components of this technique are the development of a calibrated hydraulic stream model and knowledge of the suitability of specific microhabitat conditions (i.e., water depths, velocity, and substrate) for individual fish species and life stages.

Field Techniques

Permanent markers (pins) were placed at the ends of each transect and a benchmark established as reference points. For each transect, water velocities, depths, and substrates were recorded at vertical measuring points distributed across the wetted perimeter of the river for each of three "calibration" flows. Generally, the distance between each measuring point was kept constant. As needed, however, additional measuring points were added at gradient breaks in bottom profile or where significant changes in water velocities or substrate were observed. A rule of thumb was established that no more than 10 percent of the total measured streamflow for any transect
would occur within any given "cell" (i.e., the area between vertical measuring points). As a result, the number of vertical measuring points varied from transect to transect depending on stream hydrology and streambed morphology. Generally, the number ranged between 20 and 30 per transect.

Water depths and velocities were measured at each transect for three release flows from Goodwin Dam and New Melones Reservoir. These "calibration" flows were 1,250 cubic feet per second (cfs), 700 cfs, and 125 cfs. The water velocity and depth data collected for the calibration flows where subsequently used to establish the water surface elevation (stage) versus streamflow (discharge) relationship and to calibrate the hydraulic simulation incorporated within the physical habitat simulation program. Data was collected on the following dates in 1989: May 2 to 6 for the 1,250 cfs release; July 10 to 13 for the 700 cfs release; and September 19 to 22 for the 125 cfs release. The flow for each study site was determined by calculating the mean of the flows recorded for each transect within the study site.

Mean water column velocities were measured at 0.6 of the total depth (measured from the water surface) for water depths less than or equal to 2.5 feet. At depths greater than 2.5 feet but less than or equal to 5.0 feet, velocities were measured at 0.2 and 0.8 of the total water depth. For water depths greater than 5.0 feet, velocities were measured at 0.2, 0.6 and 0.8 of the total water depth. Water velocity measurements were made with either a Price AA or Gurley water velocity meter. In extremely slow velocity areas, with water depths of less than 1 foot, a Pygmy water velocity meter was used. Mean water column velocities were calculated using standard formulas.

Water depths were measured to the nearest 0.1 foot with a top-setting wading rod in areas less than 8 feet deep. For depths greater than 8 feet, a boat-mounted sounding reel system with a cable and 15-pound sounding weight was
Substrate composition and fish cover were assessed in each observation cell. An observation cell is defined as having a width equal to the horizontal distance between midpoints of adjacent vertical measuring points, a height equal to the depth of the water column, and a length upstream and downstream to a point representing the "transition" point to the next habitat type.

Substrate composition was described using a modified Brusven index system (Table II). An index was used for application of the PHABSIM model and is composed of a 6-digit substrate descriptor based on dominant and subdominant substrate types. It is coded as xXyY.%E (where xX = dominant substrate, yY = subdominant substrate, and %E = percent embeddedness).

Cover was described using a three-digit code. The first digit of the code defines the size of the largest object(s) seen within the observation cell. The second digit defines any overhead cover which provides protection from

Predators, sunlight, etc., within the observation cell. The third digit, which follows a decimal, describes the quality of the cover as poor, fair, good, or excellent. Cover codes and descriptions are listed in Table III. The cover index is coded as XY.Z (where X = object cover, Y = overhead cover, and Z = cover quality).

If no overhead cover was present in the observation cell, the linear distance to the nearest overhead cover was estimated to the nearest foot.

General information recorded for each field day included sampling date and time, study area and site, estimated stream discharge, air and water temperatures, name of observer and recorder, observation method, water clarity, weather conditions, total length of study site and equipment used.

**Data Analysis**

Field data gathered was initially transcribed from the field data forms into
microcomputer database files using dBASE II (Ashton-Tate, DBASE II, IBM PC-DOS, Version 2.43). These files were checked for errors and corrected where necessary. They then became the "raw" database files from which all subsequent data analyses were conducted. The edited dBASE files were then transcribed to LOTUS 1-2-3 spreadsheets (1-2-3, release 2.01, LOTUS Development Corp.) for further analysis, including mean column water velocity calculations and conversion of substrate and cover codes to appropriate index values. These data were then formatted to input data decks needed for the hydraulic simulation (IFG4) program by using FLOSORT, a program developed by Andrew Hamilton of the Service's Lewiston Suboffice, Lewiston, California. All files were checked for accuracy using the RCKI4 microcomputer program provided by the Service's National Ecology Research Center, Aquatic Systems Modeling Section.

Physical habitat simulation (PHABSIM) input data decks were built for each study site using the water surface elevation (stage), streamflow (discharge), and water velocity data collected during the field measurements at the three calibration flows. In order to accurately portray the entire study area described by study site, transect weighting factors were all set to 1 and reach lengths were adjusted so that the total percent area represented by habitat type was equal to that measured during the habitat mapping phase of this study. Table IV lists the habitat type, reach length, weighting factor, and percent area represented by each transect for each study site during the computer modelling phase of this study. The input data decks used in this evaluation are listed in Appendix B.

Water surface elevations for computation flows, ranging from 50 cfs to 1300 cfs, were calculated in the model using a rating curve defined by the stage-discharge relationship established by those measured in the calibration flows. Each input deck was run separately through the PHABSIM.
The PHABSIM analysis also requires, as separate input, suitability criteria for the target species being considered. Water depth, velocity, and substrate suitability criteria for chinook salmon adults, fry, and juveniles were determined through direct observation and field measurements of habitat use and availability within the Stanislaus River. These data were collected between November 4, 1986 and April 13, 1989 and have been reported previously.

*Although this transect was described as a shallow pool, it more closely represented a run, especially at high flows. Therefore, it was combined with the run transects in the PHABSIM.*
(Aceituno, 1990). Egg incubation criteria used are a composite of water velocity and depth suitability described by Bovee (1978) and substrate suitability determined for the spawning life stage during the investigations of 1986 through 1989. For convenience, the criteria used in this analysis are listed in Appendix C.

The product of the PHABSIM is an index of the habitat potential, called the weighted usable area (WUA). For each study site and each computation flow the WUA is equal to the suitability index for the combined characteristics measured (water velocity, water depth, and substrate or cover) and the total surface area represented by that study site. The WUA is unique to the streamflow, the study site, and the target species and life stage to which it applies. The term "weighted" refers to the influence of the habitat suitability criteria developed for each target species and life stage which is applied to the physical habitat simulation.

The fish habitat versus streamflow relationship determined through the physical habitat simulation model is expressed in terms of square feet of weighted usable area of habitat per 1,000 linear feet of stream. To provide an overall picture of the relationship between physical habitat availability and streamflow within the study reach, the PHABSIM results for each study site were combined. Since the four study sites represent study areas of different lengths on the Stanislaus River, a value of total weighted usable area was calculated by multiplying the PHABSIM results for each study site by the total distance represented by that site, divided by 1,000, and summing the totals. This gives an estimate of weighted usable habitat area for the entire study reach from Goodwin Dam to Riverbank, California (approximately 24 river miles).
RESULTS AND DISCUSSION

Measured river flows at the four study sites, along with the releases from Goodwin Dam recorded at the U.S. Geological Survey river gage near the dam, are provided in Table V.

The total weighted usable area of habitat versus streamflow relationships for chinook salmon spawning, incubation, fry, and juvenile life stages are illustrated in Figure 4. Predicted weighted usable area of habitat (per 1,000
linear feet) versus streamflow relationships for each life stage, by study site, are illustrated in Figures 5 through 8. The weighted usable habitat area estimates used to generate these graphs are provided in Tables VI through IX.

Figure 5. Weighted usable area of habitat (in square feet per 1,000 linear feet of stream) versus streamflow relationship for chinook salmon spawning at the four study sites on the Stanislaus River, California.

Figure 6. Weighted usable area of habitat (in square feet per 1,060 linear feet of stream) versus streamflow for chinook salmon egg incubation at the four study sites on the Stanislaus River, California.
Predictably, estimated weighted usable area of habitat for chinook salmon in the Stanislaus River varies considerably with streamflow below Goodwin Dam.

Typically, weighted usable habitat area increases as flows increase and then begins to decline as streamflow continues to increase beyond an optimal level.

Figure 7. Weighted usable area of habitat (in square feet per 1,000 linear feet of stream) versus streamflow relationship for chinook salmon fry at the four study sites on the Stanislaus River, California.

Figure 8. Weighted usable area of habitat (in square feet per 1,000 linear feet of stream) versus streamflow relationship for chinook salmon juveniles at the four study sites on the Stanislaus River, California.

The PHABSIM model developed in 1989 for the Stanislaus River considers only the relationship between physical habitat availability and streamflow for chinook salmon spawning, incubation, fry rearing and juvenile rearing life stages, within the river reach between Goodwin Dam and Riverbank (approximately 24 river miles). The results of the PHABSIM model indicate that a streamflow of

300 cubic feet per second provides the greatest amount of usable habitat for chinook salmon spawning. Available habitat for egg incubation is maximized at 150 cfs. Fry habitat appears to be generally limited and does not increase or decrease appreciably as streamflow changes. This is most likely due to the

The fact that salmon fry are not well adapted to high velocity currents and spend most of their time along the shallow stream margins in slower water. In our observations during the habitat preference criteria development phase of this investigation, over 90 percent of all fry were found in areas of water velocity less than 0.5 foot per second and depths less than 2 feet (Aceituno, 1990). Chinook salmon juvenile weighted usable habitat area is highest at 200 cfs.

The Potential of Side-Channels

The potential of side-channel habitat areas for all chinook salmon life stages within the Stanislaus River should not be overlooked. For the fry and

juvenile life stages, significant habitat gains occur within the Honolulu Bar study site at streamflows above 450 cubic feet per second. This is because of the existence of a long side-channel at the site and the availability of more microhabitat in terms of low water velocities, shallower depths, and suitable substrate when this area becomes flooded.

Since side-channels are atypical of the lower Stanislaus River, representing less than 1 percent of the total habitat available, they are not included in the general habitat evaluation described in this report. Nonetheless, they could provide significant habitat enhancements beneficial to the dwindling chinook salmon population.

The Importance of Pulse Flows

This study did not directly provide information on flows needed for smolt emigration in the spring. Preliminary data from smolt survival studies being conducted by the Department of Fish and Game indicate that flows of 1,250 to 2,000 cfs would provide for a high level of smolt survival in the Stanislaus River. In testimony to the State Water Resources Control Board, the Department has recommended increasing streamflow between April 15 and May 15 each year. The flow increase is based on the results of studies documenting increased survival of salmon smolts to the Sacramento-San Joaquin River Delta. Detailed monitoring efforts are also recommended by the Department to further evaluate and document the benefits of the pulse flows and to determine the
duration required for smolt survival (CDFG, 1992).

**Yearling and Late Fall-Run Salmon Flow Needs**

Although river flows of 200 cfs provide maximum juvenile rearing habitat, higher flows may be necessary over the summer months. Not only is appropriate physical habitat needed for juvenile rearing (which is optimized at 200 cfs), but suitable water temperatures are also necessary during this period. In the past, flows released to meet water quality requirements have provided conjunctive benefits for fall-run yearling or late fall-run juvenile salmon rearing through the late spring and summer months. An exception has been when storage in New Melones Reservoir is severely depleted. The Bureau of Reclamation is developing a water temperature model for the Stanislaus River which will help determine the instream flow needs. In addition, studies are needed to determine the appropriate "carry over" storage to be maintained in upstream reservoirs, particularly New Melones, so that water temperatures in the river downstream can best be controlled for the benefit of juvenile salmon.

**Rainbow Trout and Steelhead Concerns**

Although an evaluation of the physical habitat versus streamflow relationship for other salmonid species was not originally a part of this study, staff from both the Bureau of Reclamation and the Department of Fish and Game have expressed an interest in seeing this relationship. Therefore, a PHABSIM analysis was conducted using habitat suitability criteria for resident rainbow trout and the anadromous steelhead rainbow trout. Table X lists the flows which would provide the maximum amount of habitat for each life stage of rainbow and steelhead trout in the Stanislaus River. The complete results of

this analysis are provided in Appendix D.

CONCLUSION

The results of this study show that microhabitat availability is highest for chinook salmon spawning at 300 cfs, egg incubation at 150 cfs, and for juvenile salmon at 200 cfs. Weighted usable area of habitat for chinook salmon fry is limited, restricted to shallow, low velocity areas along the stream margins. Table XI shows instream flows yielding the maximum weighted usable area of habitat for chinook salmon in the Stanislaus River. The incubation and fry life stages are combined since they overlap in occurrence. Considering such factors as possible redd dewatering, siltation, and the maintenance of suitable dissolved oxygen levels for development of incubating salmon eggs, the flow requirement for incubation is given priority.

Even though the PHABSIM model results indicate relatively little available fry habitat, overall, the potential exists to significantly increase its availability through the development of side-channels or other areas providing shallow, low velocity habitat.

While this report describes the water velocities, depths, and substrates suitable for chinook salmon life stages, a comprehensive instream flows regime...

which would protect and preserve the Stanislaus River salmon resource cannot be determined from that data alone. Other macrohabitat conditions, such as water quality and temperature, and the value of conveyance and attraction flows, have yet to be fully described for the Stanislaus River.

Consideration of other macrohabitat conditions before recommending instream flows is consistent with the Instream Flow Incremental Methodology, which integrates the multitude of components and associated habitat variables important to evaluating potential impacts to rivers. As noted earlier, the Bureau of Reclamation is developing a comprehensive water temperature model for the Stanislaus River. In addition, the Department of Fish and Game is continuing investigations into the benefits of spring "pulse" flows and fall attraction flows as part of the overall Stanislaus River Fishery Investigation. Once these studies are completed, the results can be combined with the results described in this report. Only after integrating a variety of habitat variables and competing species life stage needs can a comprehensive instream flow schedule for the Stanislaus River be developed which will protect and preserve the chinook salmon resource.

APPENDIX A

INSTREAM FLOW INCREMENTAL METHODOLOGY (IFIM) STUDY SITES, TRANSECT DESCRIPTIONS AND LOCATIONS FOR THE STANISLAUS RIVER INSTREAM FLOW STUDY, 1989
The Stanislaus River from Goodwin Dam to the confluence with the San Joaquin River was divided into three segments based on gross river morphology for the purposes of IFIM modeling. These three segments are: the 4 river miles between Goodwin Dam and Knights Ferry; the 20 river miles between Knights Ferry and the town of Riverbank; and, the 34 river miles from Riverbank to the confluence with the San Joaquin River. Within the upper two river segments one or more short sites were selected to represent the river segments, and to describe them via IFIM modelling procedures. Figure A-1 is a map showing the location of the IFIM study sites.

Each habitat type has variability between locations. For example a deep pool by our definition is any pool over 4 feet deep and with water velocity less than 1 foot per second. However, one pool may be 6 feet deep and another 20 feet deep. When the transects were established in the reaches they were placed to sample the variety of habitats within each study site and, by extrapolation, each segment.

The uppermost study segment, the 4 miles between Goodwin Dam and Knights Ferry, is defined by a steep walled bedrock gorge. The river channel has a moderate gradient (0.7%) and is made up of long pools interspersed with cascades. At a few locations large beds of gravel have gathered, forming gravel bars. Salmon spawning habitat on these gravel bars is excellent. The California Department of Fish and Game estimates that 10 percent of salmon spawning in the Stanislaus River occurs in these 4 miles of accessible river. One IFIM study site, Two Mile Bar, was established in this segment.

The second of the three river segments, the 20 miles between Knights Ferry and the town of Riverbank, is a low-gradient stream of 0.1 percent. Steep banks
of erodible soils are commonly present with bedrock outcrops occurring irregularly. The segment is comprised of typical pool-run-riffle habitats, but with considerable variance in length and occurrence of each habitat. Large, deep dredge pools add to the inconsistency of stream habitat types. Sand, gravel and cobble provide most of the substrate, with an occasional bedrock outcrop. Ninety percent of the chinook salmon spawning occurs in this middle river segment.

We have established three IFIM study sites to sample the diversity in this river segment. They are designated as Six Mile Bar, Honolulu Bar, and Valley Oak State Recreation Area.
Figure A-1. Location map of the instream flow study sites used to model the Stanislaus River, California.
TWO MILE BAR STUDY SITE

At Two Mile Bar, 10 transects were used to describe the reach.

Transect 1 crosses a moderately deep pool which is a common feature in this upper section.

Transect 2 crosses the head of a riffle. This riffle is heavily used for spawning.

Transect 3 is through a deep fast run.

Transect 4 crosses a shallow pool. Velocity is relatively slow and aquatic vegetation is thick.

Transect 5 crosses a spawning area at the lower end of the shallow pool where it drops off as a short riffle into the run below.

Transect 6 crosses the split channel with a fast shallow run on one side and a shallow pool on the other. During high flows riparian vegetation on the island and on the left side of the channel is inundated, creating excellent cover and forage areas for juvenile salmon (this transect proved to be extremely difficult to model, however, and was dropped from the final PHABSIM analysis).

Transect 7 crosses the bottom of the split channel where water is fast on both sides of the island. Here, as in transect 6, high flows inundate vegetation on the edges, expanding useful rearing habitat.
Transects 8 and 9 cross a fast run where the river narrows below the split channel.

Transect 10 crosses a deep pool, 15 feet in depth. The channel is still relatively narrow here.

The distribution of habitat types and the locations of transects at Two Mile Bar are illustrated in Figure A-2.
Figure A-2. Two Mile Bar Study Site and Instream Flow Study Transect Locations.
SIX MILE BAR STUDY SITE

The Six Mile Bar reach is a long reach with ten transects.

Transect 1 is across a spawning riffle at the bottom end of the study site.

Transects 2, 3, and 4 are all across a long run/glide. They are placed to sample the variability in the run/glide type habitat that occurs throughout the section.

Transect 5 is across a deep pool below where a side channel returns to the main channel.

Transects 6 and 7 are across a riffle heavily used by salmon for spawning.

Habitat distribution and transect locations are illustrated in Figure A-3.
Figure A-3. Six Mile Bar Study Site and Instream Flow Study Transect Locations.
HONOLULU BAR STUDY SITE

The second IFIM sampling site for the middle segment is at Honolulu Bar. Here there is a long side channel that is extensively used for both spawning and fry and juvenile rearing when adequate water flows through the channel. The main channel has seven transects. This reach differs from Six Mile Bar in generally having a narrower river channel and steeper swifter run/glides.

Transect 1 in the main channel crosses a deep pool.

Transect 2 crosses a spawning area.

Transect 3 crosses another deep pool.

Transects 4, 5, 6 and 7 are placed to model the variation in a long run/glide.

Transect 4 also includes a backwater area.

Because the side channel feature found here is atypical of the lower Stanislaus River as a whole, it was not modelled in this analysis.

Figure A-4 shows the habitat distribution and transect locations.
Figure A-4. Honolulu Bar Study Site and Instream Flow Study Transect Locations.
The third IFIM study site for the middle river segment is at Valley Oak State Recreation Area. In the lower part of the segment, the river slows down a bit and riffles become shorter. Still, salmon do spawn in this segment. Five of the seven transects at this site are categorized as run/glide.

Transects 1, 3, 4, 5 and 6 cross run/glide habitat and sample the variability of runs in this lower part of the middle section of river.

Transect 2 crosses a spawning area.

Transect 7 crosses a deep pool.

Figure A-5 shows the distribution of habitats and location of transects.
Figure A-5. Valley Oak SRA Study Site and Instream Flow Study Transect Locations.
The third segment of river is from Riverbank to the confluence of the Stanislaus with the San Joaquin River. It is 34 river miles long. The gradient of the river is low, 0.03% and the river actively meanders across its floodplain. The river is characterized by long sand bottomed run/glides, with some deep pools at the bends. No salmon spawn here.

No IFIM modeling sites were established within the segment. We determined that the site at Valley Oak State Recreation Area would adequately describe conditions found in the lower river segment as well.

APPENDIX C

HABITAT SUITABILITY CRITERIA USED IN THE STANISLAUS RIVER INSTREAM FLOW STUDY, 1989
STANISLAUS RIVER FISHERY INVESTIGATION, 1989.  
COMBINED FLOW VELOCITY DATA SET & WEIGHTED USING HABITAT MAPPING

CURVE SET DEFINITION DATA WAS OBTAINED FROM THE FISHFIL FILE WHOSE TITLE LINE IS - STANISLAUS RIVER FISHERY INVESTIGATION

VELOCITY WEIGHTING FOR CHINOOK SALMON (FALL RUN)
