Under the No Action Alternative, water temperatures in Clear Creek downstream of Whiskeytown Dam would be stress-inducing during September of critically dry years, suboptimal during September of all other year types, suboptimal during October of dry and critically dry years, optimal during October of all other year types, and optimal during November of all year types. Under the No Action Alternative, water temperatures would be optimal for rearing and outmigrating juvenile Spring-Run Chinook Salmon during all water years. Water temperatures would be optimal for migrating adult Spring-Run Chinook Salmon during all years, except during June of critically dry years when water temperatures would be in the suboptimal range.

Water temperatures during September of critically dry years would be only slightly above the suboptimal temperature range for Spring-Run Chinook Salmon eggs and fry (54°F to 58°F) under the No Action Alternative. Therefore, the No Action Alternative would likely have only a minimal adverse effect on Spring-Run Chinook Salmon.

Fall-Run Chinook Salmon

Modeling results show that water temperatures in Clear Creek would be suboptimal for Fall-Run eggs and emerging fry under the No Action Alternative during October of critically dry years; eggs and emerging fry would experience optimal temperatures in all other year types during their period of peak occurrence. Rearing and outmigrating juveniles as well as migrating adults would experience optimal temperatures during the entire period of their peak occurrence in all water year types. Overall, the No Action Alternative would have beneficial effects on Fall-Run Chinook Salmon, as modeled temperatures are within optimal ranges during the period of occurrence for all life stages except for eggs and emerging fry in October of critically dry years, in which temperatures would be suboptimal, and result in negligible adverse effects.

Central Valley Steelhead

Modeling results show that all life stages of California Central Valley Steelhead, except for migrating adults, experience temperatures under the No Action Alternative within the optimal range during their entire period of peak occurrence for all year types. Migrating Central Valley Steelhead adults experience suboptimal temperatures during the period of their peak occurrence during all year types. No life stages of Central Valley Steelhead experience stress inducing temperatures under the No Action Alternative. Overall, the No Action Alternative would have a slightly adverse effect on Central Valley Steelhead, as modeled temperatures are within optimal ranges during the period of occurrence for all life stages except for migrating adults, in which temperatures would be suboptimal, and result in negligible adverse effects.

Pacific Lamprey

Modeling results show that Pacific Lamprey would experience suitable temperature ranges in which spawning generally takes place during May of all water year types, and in April of critically dry water year types; temperatures are below the suitable temperature range for this life stage during all other water year types and months of peak occurrence. Modeled No Action Alternative temperatures do not exceed temperature ranges during the period of peak occurrence of ammocoetes and outmigrating adults during all water year types. Overall, the No Action Alternative is unlikely to adversely affect Pacific Lamprey in Clear Creek as suitable temperatures occur during part or all of the period of peak occurrence for all life stages.

O.3.2.3.3 Spring Creek Debris Dam

The Spring Creek Debris Dam (SCDD) was constructed to regulate runoff containing debris and acidic mine drainage in Spring Creek. This debris and acidic drainage originate at the Iron Mountain Mine (IMM) Superfund site near Redding, California. The IMM was mined from the 1860s through 1963 for copper, gold, pyrite, silver, and zinc (EPA 2018: i). Low pH runoff, laden with heavy metals, historically originated in tributaries (primarily Boulder Creek), then discharged to Spring Creek, and ultimately to the Spring Creek Arm of the Keswick Reservoir (a mainstem dam and reservoir on the Sacramento River). Acidic and heavy metal discharge also affects Keswick Reservoir. When Spring Creek water is buffered by the larger volume of water in the Keswick Reservoir, heavy metals precipitate from the water column, contaminating sediments.

The continuous release of metals from the IMM has resulted in historical fish kills and has contributed to a progressive decline in the fisheries population in the Sacramento River. Construction of the SCDD reduced the frequency and magnitude of fish kills; however, during extreme storm events, the SCDD has filled beyond capacity, spilling toxic levels of acid mine drainage into the Sacramento River on an average of every 2 to 3 years, causing episodes when emerging fry were killed (CVRWQCB 2002: 23). As a result, releases from the SCDD, Shasta Lake, and Whiskeytown Lake via the Spring Creek tunnel to Spring Creek Powerplant are coordinated under a Memorandum of Understanding (MOU) to remediate pH and acidic releases to Keswick Reservoir.

Releases from Whiskeytown Lake and other CVP reservoirs, along with other remedial actions, are coordinated by a 1980 MOU between Reclamation, CDFW, and SWRCB. This MOU was executed to implement actions that protect the Sacramento River system from heavy metal pollution from Spring Creek and adjacent watersheds. The MOU identifies agency actions and responsibilities and establishes release criteria based on allowable concentrations of total copper and zinc in the Sacramento River below Keswick Dam. Operations initially coordinated under the MOU have been subsequently modified by the 1992 Central Valley Project Operations Criteria and Plan, the 1993 Biological Opinion for the Operation of the Federal Central Valley Project and the California State Water Project, and the results of a 2002 Total Maximum Daily Load (TMDL) for Cadmium, Copper & Zinc in the Upper Sacramento River. Remedial actions at the IMM and in Keswick Reservoir are dictated by five records of decision (RODs) implemented between 1986 and 2004.

In order to minimize the build-up of metal concentrations in the Spring Creek arm of Keswick Reservoir, releases from the debris dam are coordinated with releases from Spring Creek Powerplant to keep the Spring Creek arm of Keswick Reservoir in circulation with the main water body of Keswick Lake.

The operation of SCDD is complicated during major heavy rainfall events. SCDD reservoir can fill to uncontrolled spill elevations in a relatively short time period, anywhere from days to weeks. Uncontrolled spills at SCDD can occur during major flood events on the upper Sacramento River and localized rainfall events in the Spring Creek watershed. During flood control events, Keswick releases may be reduced to meet flood control objectives at Bend Bridge when storage and inflow at Spring Creek Reservoir are high.

Because SCDD releases are maintained as a dilution ratio of Keswick releases to maintain the required dilution of copper and zinc, uncontrolled spills can and have occurred from SCDD. In this operational situation, high metal concentration loads during heavy rainfall are usually limited to areas immediately downstream of Keswick Dam because of the high runoff entering the Sacramento River, adding dilution flow. In the operational situation when Keswick releases are increased for flood control purposes, SCDD releases are also increased in an effort to reduce spill potential.

The 2002 TMDL for Cadmium, Copper & Zinc specifies numeric targets for dissolved cadmium, copper, and zinc. The primary mechanism for achieving those targets is on-going remediation and continued operations of the SCDD and related facilities in a reasonable and prudent manner in compliance with operations criteria set forth in the 1980 MOU, as well as the subsequent 1992 Central Valley Project Operations Criteria and Plan, and 1993 Biological Opinion for the Operation of the Federal Central Valley Project and the California State Water Project.

Both before and since the 2002 TMDL, remedial actions at the IMM site have greatly reduced the amount of metal contamination and increased the pH of waters entering the Spring Creek Reservoir. Numerous source control, water treatment, diversion, retention, and sediment remedial actions have significantly improved the water quality of discharges from SCDD. Current contaminant discharges from the Boulder Creek watershed (the primary contaminant source) are estimated to constitute less than 5% of the overall historical IMM discharges of copper and zinc (EPA 2018: i). Nonetheless, EPA expects exceedances of water quality standards downstream of Keswick Dam on the rare occasions when large early winter storms follow very dry summers.

No modifications to existing operations are proposed at the SCDD under the No Action Alternative. Discharges from the SCDD and Spring Creek Tunnel will continue to be managed for the benefit of fish species and other purposes downstream of Keswick Dam. Reclamation's water management actions remain key to providing for the safe release of the continuing IMM contaminant discharges.

Future operations of the SCDD are governed by an existing MOU and subsequent regulations outside of the proposed actions addressed in this EIS. Reclamation controls discharges from CVP facilities (including the SCDD and Spring Creek Tunnel) in accordance with the 1980 MOU and subsequent regulations to comply with the Basin Plan standards in the Sacramento River below Keswick Dam. The objectives laid out by the RODs include: achieving water quality criteria established under the Clean Water Act, reducing the mass discharge of toxic heavy metals through application of appropriate control technologies, minimizing the need to rely on special releases of California's valuable water resources to ensure compliance with water quality standards in the Sacramento River through special releases of waters to dilute toxic spills of IMM contaminants, protecting the Sacramento River ecosystem from releases of heavy metals from Spring Creek Arm by preventing the mobilization and redeposition of contaminated sediment into important fishery spawning habitats in the Sacramento River below Keswick Dam, and preventing adverse impacts on water quality and beneficial uses of the Sacramento River below Keswick Dam by reducing the metal loads and suspended solids associated with contaminated sediment discharges from Spring Creek Arm to the Sacramento River.

The most recent five-year review of the project found that there has been a significant decrease in total copper and total zinc measured at lower Spring Creek since the remedies have been implemented. Prior to the remedies being implemented, total copper concentrations often exceeded the Daily Maximum Discharge Standard of 300 μg/L, and total zinc concentrations frequently exceeded the Daily Maximum Discharge Standard of 1500 μg/L. Between 2012 and 2017, the range of total copper and zinc concentrations measured at lower Spring Creek decreased to approximately 50 μg/L to 150 μg/L and 90 μg/L to 800 μg/L, respectively. Water quality below Keswick Dam has likewise shown dramatic improvement. The prescribed remedies are effectively protecting the Sacramento River as a drinking water source and as an important fish habitat. There has been a 97% reduction in heavy metals downstream of Keswick Dam, eliminating fish kills and greatly improving water quality downstream (CVRWQCB 2002: 23).

Potential changes to aquatic resources due to Spring Creek Debris Dam operations

The current RODs covering remedial actions at the IMM and SCDD are to be implemented through 2030. Because they are expressly designed to improve water quality and habitat conditions, environmental conditions for all species of concern are expected to continue to improve under the No Action Alternative.

Under the No Action Alternative (and in the absence of future remedial actions or adaptive management to address potential negative environmental consequences), population growth, climate change, and basin development will potentially result in adverse effects. Higher temperatures and shifts in the timing or nature of precipitation (from snow to rain, for instance) due to climate change may have multiple effects including increased evapotranspiration, reducing the amount of water available for storage in SCDD reservoir. More intense storms or a shift in precipitation from snow to rain may increase the likelihood of uncontrolled spills over the SCDD. These shifts may require future modifications to the water management scenarios used to control heavy metal and acidic discharges from the SCDD.

The potential for a failure of SCDD before 2030, though unlikely, does exist under the No Action Alternative, and the release of toxic waste from IMM resulting from such a failure could be devastating to downstream fish species (Moyle et al. 2017: 106).

Winter-Run Chinook Salmon

Winter-Run Chinook Salmon abundance has declined substantially from a population of approximately 200,000 spawning adults in the 1960s to approximately 3,500 adults in 2015 (Good et al. 2005: 145; NMFS 2016f: 3). Efforts of the Livingston Stone National Fish Hatchery since 1998, when Winter-Run Chinook populations reached historically low levels of fewer than 1,000 spawning adults, have likely resulted in a small increase in recent population levels (Brown and Nichols 2003: 18), but the population reached a high point of only 18,000 adults in 2006 before again declining to current levels (NMFS 2016f: 3). The primary factors currently affecting Winter-Run Chinook abundance include loss of habitat following the construction of Shasta and Keswick Dams, warm water releases from Shasta Dam, fishery operations, heavy metal contamination from IMM, entrainment in water diversions, and loss of floodplain rearing habitat (NMFS 2016e: 19-23). While implementation of remedial actions at IMM and SCDD through 2030 under the No Action Alternative will slightly improve water quality and habitat conditions for Winter-Run Chinook, these operations are unlikely to overcome the other factors currently interacting to maintain Winter-Run Chinook populations at historically low levels.

The effects of climate change through 2030 on Winter-Run Chinook are difficult to quantify, but drought, low instream flow, and high water temperatures are known to exacerbate the degradation of Winter-Run Chinook habitat (NMFS 1997: III-2). Past droughts have even corresponded with episodes of extreme Winter-Run Chinook mortality, particularly when the droughts occurred in successive years (NMFS 1997: III-97; NMFS 2016e: 20).

In the unlikely event of SCDD failing before 2030, the resulting heavy metal contamination of Winter-Run Chinook habitat could eliminate much of the existing population (Moyle et al. 2017: 106).

Spring-Run Chinook Salmon

Spring-Run Chinook Salmon abundance has decreased from a historical high of 600,000 adults to an average of approximately 30,000 spawning adults in the 1970s to annual totals as low as 3,000 adults within the past decade (CDFW 1998: 1; NMFS 2016c: 15). The primary factors currently affecting Spring-Run Chinook abundance include loss of habitat and declines in water quality following dam construction and development along the Sacramento River, fishery operations, heavy metal contamination from IMM, entrainment in water diversions, and predation by nonnative species (Moyle et al. 2017: 86–91). While implementation of remedial actions at IMM and SCDD through 2030 under the No Action Alternative will slightly improve water quality and habitat conditions for Spring-Run Chinook, these operations are unlikely to overcome the other factors currently interacting to maintain Spring-Run Chinook at low levels.

The effects of climate change through 2030 on Spring-Run Chinook are difficult to quantify, but drought, low instream flow, and high water temperatures are known to exacerbate the degradation of Spring-Run Chinook habitat (Lindley et al. 2007: 11). Recent droughts have even corresponded with the lowest recorded Spring-Run Chinook abundance in the Sacramento Basin (NMFS 2016c: 17).

In the unlikely event of SCDD failing before 2030, the resulting downstream heavy metal contamination would be lethal for any Spring-Run Chinook individuals that encounter the plume of toxic water (Moyle et al. 2017: 89).

Fall-Run Chinook Salmon

Historical abundance of Fall-Run Chinook Salmon is not well-known but is estimated at around 1,000,000 spawning adults (Yoshiyama et al. 1998: 492). In recent years, abundance has changed from a somewhat consistent level around 250,000 spawning adults in the 1970s and 1980s to increasingly variable levels ranging between 850,000 adults in 2002 to fewer than 100,000 in 2009 (CDFW 2018a). Current populations of Fall-Run Chinook consist chiefly of hatchery-origin fish (Palmer-Zwahlen and Kormos 2015: 53). The primary factors affecting Fall-Run Chinook abundance include loss of habitat and declines in water quality following dam construction and development along the Sacramento River, fishery operations, heavy metal contamination from IMM, entrainment in water diversions, and predation by nonnative species (Moyle et al. 2017: 51–56). While implementation of remedial actions at IMM and SCDD through 2030 under the No Action Alternative will slightly improve water quality and habitat conditions for Fall-Run Chinook, these operations are unlikely to outweigh the other factors currently interacting to maintain Fall-Run Chinook population levels.

The effects of climate change through 2030 are difficult to quantify, but drought, low instream flow, and high water temperatures can result in suboptimal or lethal conditions for Fall-Run Chinook (Moyle et al. 2017: 58).

In the unlikely event of SCDD failing before 2030, the resulting downstream heavy metal contamination would be lethal for any Fall-Run Chinook individuals that encounter the plume of toxic water (Moyle et al. 2017: 54).

Central Valley Steelhead

Historical abundance of Central Valley Steelhead is not well-known but is estimated to be between 50,000 and 100,000 spawning adults (Moyle et al. 2017: 223). Estimated abundance declined from an average of approximately 6,500 adults between 1967 and 1991 to an average of approximately 1,300 between 1992 and 2006 (NMFS 2016b: 11–17). Steelhead abundance has since somewhat stabilized, with an estimated 4,600 spawning adults in 2016 (NMFS 2016b: 11–17). Current populations of Central Valley Steelhead consist chiefly of hatchery-origin fish (NMFS 2016b: 11–17). The primary factors affecting Steelhead abundance include loss of habitat and declines in water quality following dam construction and development along the Sacramento River, fishery operations, and predation by nonnative species (Moyle et al. 2017: 224–226). While implementation of remedial actions at IMM and SCDD through 2030 under the No Action Alternative will slightly improve water quality and habitat conditions for Central Valley Steelhead, these operations are unlikely to outweigh the other factors currently interacting to maintain Steelhead population levels.

The effects of climate change through 2030 on Central Valley Steelhead are difficult to quantify, but drought, low instream flow, and high water temperatures can result in additional degradation and loss of habitat (Moyle et al. 2017: 228). Recent historic drought years between 2012 and 2016 likely reduced survival of Central Valley Steelhead in the American River, so similar effects could be anticipated elsewhere during periods of extreme drought (NMFS 2016b: 36).

In the unlikely event of SCDD failing before 2030, the resulting downstream heavy metal contamination would be lethal for any Central Valley Steelhead individuals that encounter the plume of toxic water (Moyle et al. 2017: 54).

Green Sturgeon

Sufficient historical data do not exist to accurately identify Green Sturgeon population trends, but fish salvage data indicate an overall decline in juvenile abundance (NMFS 2018b: 4-6). Recent studies estimate a population of approximately 2,100 adults (Mora et al. 2018: 202). Despite the lack of knowledge of Green Sturgeon population trends, they are listed as threatened primarily due to loss of habitat, altered flow patterns, and declining habitat quality resulting from dam construction and development along the Sacramento River (NMFS 2018b: 14). While implementation of remedial actions at IMM and SCDD through 2030 under the No Action Alternative will slightly improve water quality and habitat conditions for Green Sturgeon, these operations are unlikely to outweigh the other factors currently interacting to affect Green Sturgeon population levels.

The effects of climate change through 2030 on Green Sturgeon are difficult to quantify, but drought, low instream flow, and high water temperatures can result in additional degradation and loss of habitat (NMFS 2018b: 28). Recent sampling efforts indicate a higher catch of larval Green Sturgeon in years with cooler water temperatures.

In the unlikely event of SCDD failing before 2030, the resulting downstream heavy metal contamination would be lethal for any Green Sturgeon individuals that encounter the plume of toxic water (Moyle et al. 2017: 54).

O.3.2.3.4 Clear Creek Restoration Program

Since the early 1980s, numerous studies have evaluated methods to rehabilitate and/or restore salmonid habitat along lower Clear Creek (Figure O.3-6). In the 1990s, additional studies were conducted following the adoption of CVPIA. The Western Shasta Resource Conservation District watershed management plan evaluated methods to achieve healthy fish populations, diverse biological habitats, recreational opportunities, clean and safe conditions for visitors, and protection of property rights developed by the Lower Clear Creek Coordinated Resource Management and Planning Group of local landowners, stakeholders, and agencies (WSRCD 1998). The plan's recommendations included:

- Remove the McCormick-Saeltzer Dam;
- Inject gravel downstream of Whiskeytown Dam and reconstruct gravel channels below McCormick-Saeltzer Dam to reduce stranding;
- Modify water release patterns from Whiskeytown Dam;
- Reduce exotic vegetation along Clear Creek; and
- Reduce sands in Clear Creek through erosion control programs in the lower watershed.

This and other studies led to the formation of the Lower Clear Creek Floodway Rehabilitation Project that was implemented under CVPIA. Initial actions under this project included gravel augmentation initiated in 1996, an increase in Whiskeytown Dam releases initiated in 2001, removal of the McCormick-Saeltzer Dam in 2001, reconstruction and revegetation of the floodway, and a reduction of watershed erosion.

According to BLM and NPS (2008), "the removal of Saeltzer Dam in 2000 opened nearly 12 miles of access to areas just downstream of Whiskeytown Dam for a total of 18 miles for Central Valley Spring-Run Chinook Salmon (and Central Valley Steelhead) habitat. Adult Central Valley Spring-Run Chinook Salmon migrate up-stream beginning early June in lower Clear Creek, throughout the project area, to the upper most reaches to spawn beginning early September and continue through early to mid-October. Since 2003, the USFWS has installed a temporary picket weir from late August through early November, to allow Spring-Run Chinook Salmon a spatial separation from Fall-Run Chinook Salmon, which otherwise have an overlap in spawning timing." Overlapping spawning timing could result in hybridization between spring and fall runs.

The goals of the Clear Creek Restoration Program are to (1) provide flows to allow sufficient spawning, incubation, rearing, and out-migration for Central Valley Chinook and Steelhead; (2) restore the stream channel and associated instream habitat; (3) operate the picket weir (segregation weir) to create reproductive isolation between Fall-Run (Fall-Run and Late Fall-Run) Chinook and Spring-Run Chinook; and (4) determine impacts of restoration actions on anadromous fish and geomorphology.

The program manages flows and temperatures through releases from Whiskeytown Dam on a year-round basis to improve survival and condition of Salmon and Steelhead in Clear Creek. The magnitude and timing of flows and water temperature are controlled to meet this goal. The 2009 NMFS BO RPA Action I.1.3 (Clear Creek Spawning Gravel Augmentation), implemented under the No Action Alternative, requires restoration on a two-mile section of Clear Creek floodplain and stream channel by annual gravel augmentation to recharge and maintain gravel supply (approximately 8,000 to 10,000 tons of gravel per year). The aim of the 2009 NMFS BO RPA Action I.1.3 is to create and maintain 347,288 square feet of usable spawning habitat in Clear Creek.

Under the No Action Alternative, the current goals of the Clear Creek Restoration Programs would continue to be pursued. Effects of flow and temperature are discussed under the Clear Creek Flows section of this EIS. This section analyzes effects of gravel augmentation and segregation weir operations of the Clear Creek Restoration Program on focal fish species under the No Action Alternative.

Potential changes in aquatic resources due to gravel augmentation and segregation weir operation

Spring-Run and Fall-Run Chinook Salmon

Whiskeytown Dam blocks coarse sediment supply to the lower portion of Clear Creek by trapping all coarse sediment, including gravel suitable for spawning, in the reservoir. A lack of spawning gravel delivery to lower Clear Creak has limited available salmonid spawning habitat, and this limitation has been further exacerbated by similar spawning timing of Spring-Run and Fall-Run Chinook leading to redd superimposition and some hybridization of the two runs. Mechanical gravel augmentation has helped to restore some gravel supply and increased available spawning habitat, which is particularly important as the amount of habitat present is less than the amount needed to support 7,920 adult Fall-Run Chinook Salmon (the target population level) in Clear Creek (USFWS 2015). Since 2003, the proportion of Spring-Run Chinook spawning in injected gravel has increased from approximately 15% to 60% in 2017 (Delta Stewardship Council 2018). There are no exact estimates on the use of injected gravel by Fall-Run Chinook. Continued gravel augmentation under the No Action Alternative would result in potential benefits to Fall-Run and Spring-Run Chinook by reducing redd superimposition and increasing available spawning habitat.

Operation of the segregation weir currently helps alleviate some of the hybridization which has occurred between Fall-Run and Spring-Run Chinook by preventing concurrent use of spawning habitat. While exact estimates of this benefit are not available, it is anticipated that further operation of the weir under the No Action Alternative would further isolate Fall-Run and Spring-Run Chinook, leading to population-level benefits compared to current conditions.

Central Valley Steelhead

Whiskeytown Dam blocks coarse sediment supply to the lower portion of Clear Creek by trapping all coarse sediment, including gravel suitable for spawning, in the reservoir. A lack of spawning gravel delivery to lower Clear Creak has limited available salmonid spawning habitat. Mechanical gravel augmentation has helped to restore some gravel supply and increased available spawning habitat. Since

2003, the proportion of Central Valley Steelhead spawning in injected gravel has increased from approximately 41% to 84% in 2018 (Delta Stewardship Council 2018). Continued gravel augmentation under the No Action Alternative would result in potential benefits to Central Valley Steelhead by increasing available spawning habitat.

Pacific Lamprey

Little data are available on Pacific Lamprey spawning in Clear Creek, but lamprey are assumed to occur throughout the accessible portion of Clear Creek downstream of Whiskeytown Dam. Like salmonids, lamprey numbers are presumably reduced from historical abundance due to the same factors that have affected anadromous salmonids (e.g., blocked passage and habitat alteration). Pacific Lamprey have similar life cycles to salmonids and require similar spawning conditions, which require substrate with gravel to create redds. It is anticipated that gravel augmentation in Clear Creek would benefit ocean returnees by providing higher quality substrates for spawning. While spawning trends and populations of Pacific Lamprey are not actively monitored in Clear Creek, salmonid data suggest that the spawning substrate habitat quality is likely to improve under the No Action Alternative compared to current conditions.

O.3.2.4 *Feather River*

O.3.2.4.1 FERC Project #2100-134

DWR releases water from their Oroville Complex Project (FERC Project No. 2100) into the lower Feather River to meet the requirements of FERC Project instream flow schedules and D-1641. Additionally, DWR balances its releases and the storage in Lake Oroville to meet flood control requirements, Sacramento–San Joaquin Delta export requirements, storage goals in the San Luis Reservoir, and water delivery objectives for contracted water agencies. Decisions on water-transfer timing from Lake Oroville on the Feather River to San Luis Reservoir in the southern Delta are based on different schedules and real-time factors, including current Delta conditions, reservoir storage volumes, storage targets, and environmental/regulatory requirements.

The Feather River contributes approximately 25% of the total flow to the Sacramento River, with a consistent pattern of higher flows in winter and spring and lower flows in summer and fall across all water year types (FERC 2007b). Prior to the completion of the Oroville Dam, the mean daily flow in the Feather River ranged from approximately 2,000 cfs in critically dry years to 18,000 cfs in wet years (Oroville gage 1906–1965). Following the completion of the Oroville Dam, the mean daily flow in the Feather River ranged from approximately 1,000 cfs during critically dry years to 12,000 cfs during wet years (Gridley gage 1969–2012) (Figures O.3-6 and O.3-7) (NMFS 2016a).

Under the No Action Alternative, minimum instream flows in the Feather River are set to 700 cfs to 800 cfs below the Thermalito Diversion Dam in the Low Flow Channel per the 2006 Settlement Agreement, and 750 cfs to 1,700 cfs below the Thermalito Afterbay outlet in the High Flow Channel (HFC) per the 1983 DWR-CDFG Agreement, with an additional CDFG/DWR operational objective of 2,800 cfs at the mouth of the Feather River from April through September (with options to vary flow depending on year types).

Potential changes to aquatic resources in the Feather River due to seasonal variation in flow

Climate change and increasing water demands may affect aquatic resources in the Feather River. Modeled scenarios suggest possible effects of climate change may include changes in precipitation patterns, reduced snowpack and runoff, and earlier snowmelt between now and 2030, which may affect future water supply in Lake Oroville and therefore releases into the Feather River (Reclamation 2015). It is also anticipated that climate change will result in more extreme dry-to-wet precipitation events, altered stream flow volume and timing, and lower late summer flows, which may increase challenges for migrating and spawning fish.

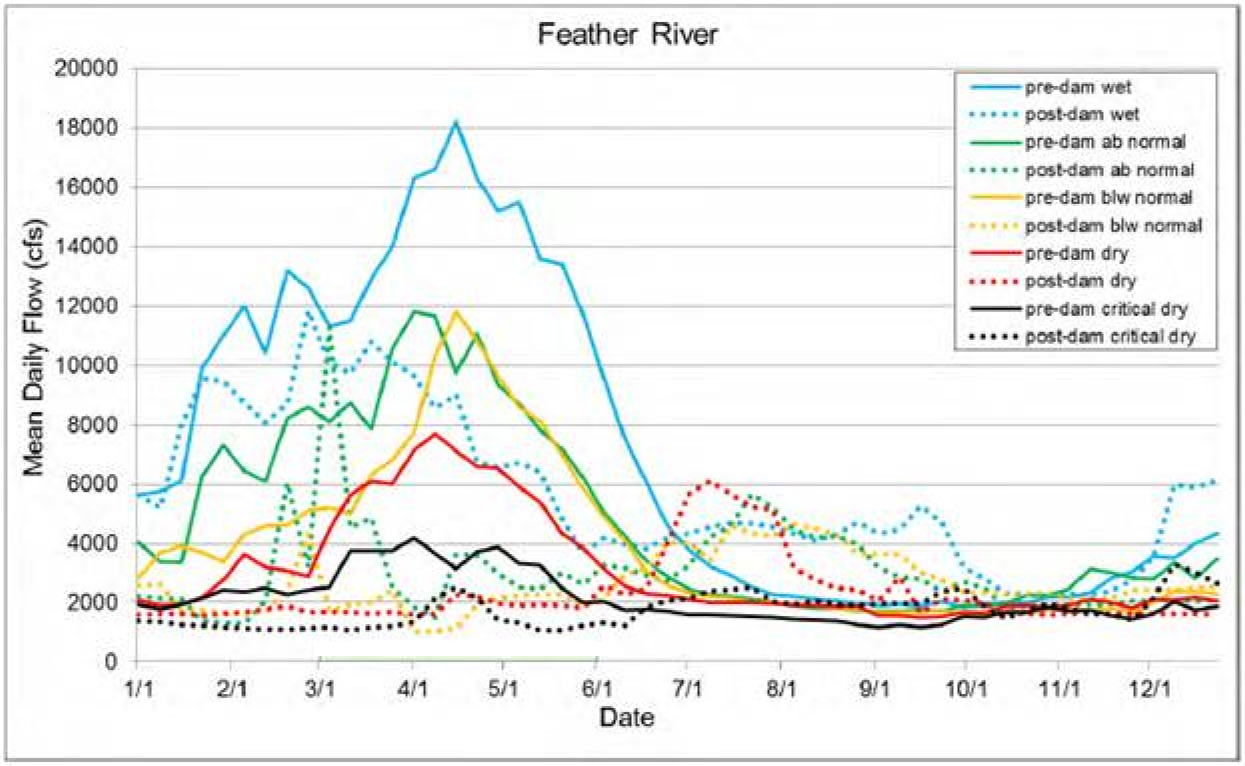

Figure O.3-6. Mean Daily Flow during All Water Year Types in the Feather River during Pre-Dam Years (Oroville Gage 1906–1965) and Post-Dam Years (Gridley Gage 1969–2012; NMFS 2016a).

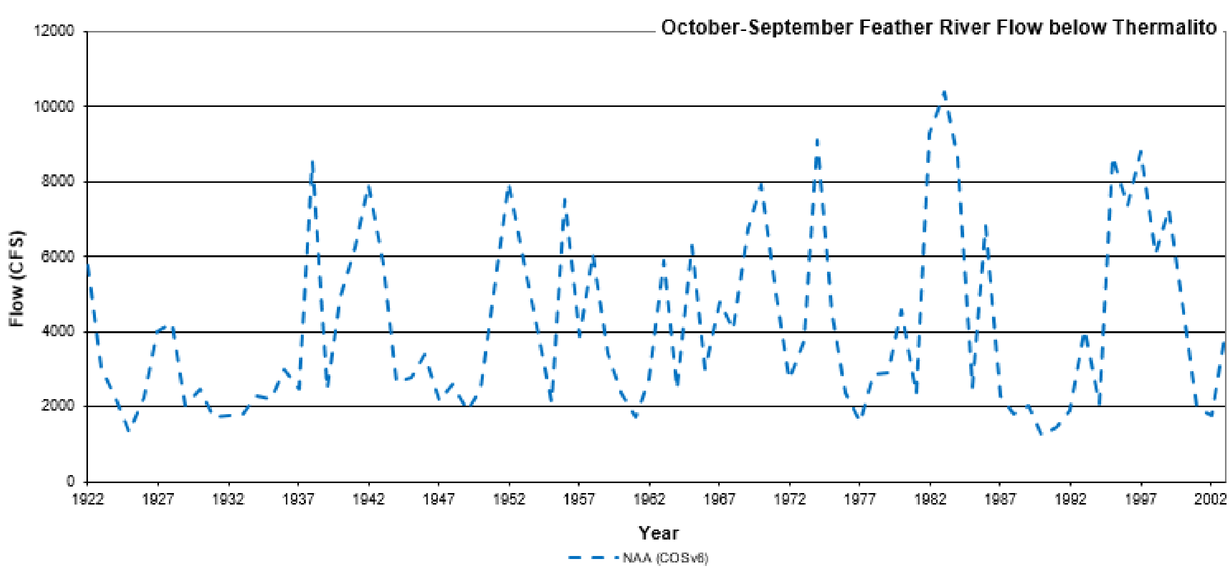

Figure O.3-7. CalSim Average Estimated Feather River Flow below Thermalito under the No Action Alternative.

Winter-Run Chinook Salmon

Winter-Run Chinook Salmon are not likely to be affected by the No Action Alternative compared to current conditions in the Feather River due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Spring-Run Chinook Salmon in the Feather River have declined in number and continue to face several challenges; following the construction of the Oroville Complex, the number of naturally spawning Spring-Run Chinook in the Feather River has been periodically estimated between 2,908 fish in 1964 and 2 fish in 1978 with the number of natural spawning fish in the stream remaining low. Additionally, hybridization between Spring-Run and Fall-Run Chinook has brought their genetic integrity into question, complicating population estimates of any remnant independent Spring-Run Chinook in the Feather River (Good et al. 2005). Existing challenges facing Spring-Run Chinook include the loss of access to historical spawning and rearing habitat and diminished adult holding conditions (Yoshiyama et al. 1996). Currently, the Feather River contains approximately 18% of the total spawning and rearing habitat for Central Valley Spring-Run Chinook; however, Spring-Run Chinook in the Feather River are nearly entirely limited to hatchery spawning. These conditions would likely continue into 2030 under the No Action Alternative.

Fall-Run Chinook Salmon

Fall-Run Chinook Salmon occur in the Feather River year-round. Adults begin their migration into the river in June with peak migration and spawning between October and March and complete their spawning by May. Fry and juveniles may occur in the river year-round, but peak out-migrating periods occur from January through April and August through November, and lesser migrations in May through July (NMFS 2016a; DWR and Reclamation 2016).

Existing challenges facing Chinook Salmon in the Feather River include upstream passage barriers, altered flow regime, high water temperature, habitat quality, entrainment in water diversions, and loss of riparian and floodplain habitat. Fall-Run Chinook Salmon downstream of the Thermalito Afterbay Outlet could be affected by altered stream flow volume and timing, lower late summer flows, and higher water temperatures leading up to 2030, when compared to current conditions, as a result of climate change.

Central Valley Steelhead

Steelhead in the Feather River primarily spawn within the Oroville Complex Boundary between the Fish Barrier Dam near the hatchery and the Thermalito Afterbay Outlet, although a small amount of spawning occurs downstream of the Thermalito Afterbay Outlet (FERC 2007b). Steelhead downstream of the Thermalito Afterbay Outlet could be affected by altered stream flow volume and timing, lower late summer flows, and higher water temperatures leading up to 2030, when compared to current conditions, as a result of climate change.

North American Green Sturgeon

North American Green Sturgeon are thought to have historically spawned in the Sacramento, Feather, and San Joaquin Rivers (Adams et al. 2007). While regular occurrence of Green Sturgeon has been verified in the Sacramento River, only intermittent observations have been reported in the lower Feather River at the

Thermalito Afterbay Outlet (Beamesderfer et al. 2007; Seesholtz and Manuel 2012). Green Sturgeon in the Feather River could face conditions under the No Action Alternative in 2030 that, when compared to current conditions, may have altered stream flow volume and timing, lower late summer flows, and a rise in water temperatures due to climate change.

Potential changes to aquatic resources in the Feather River due to changes in water temperature from differences in flow

Streamflow, combined with other environmental drivers, has the potential to affect aspects of water quality such as temperature. Water temperatures affect the condition and survival of fish species during all stages of their life cycle. Optimal water temperatures can facilitate physiological responses including improved growth rates and heightened immune systems, which lead to a higher likelihood of survival. In contrast, effects of suboptimal water temperatures include an inability to satisfy metabolic demand and acute to chronic physiological stress, potentially leading to mortality (Stillwater Sciences 2006; Martin et al. 2017).

Water temperatures in the Feather River follow a seasonal pattern, where on average, they peak around 72°F in July to August and reach a minimum of around 47°F in January (Figure O.3-8). Increased flow releases from the Oroville Complex facilities can influence water temperatures in summer and fall when air temperatures and solar radiation levels are at their highest. Minimum water temperatures in the Feather River are predicted to be similar across all water year types, but water temperatures can reach a maximum up to 4°F warmer (approximately 75°F) in critically dry years compared to wet years (approximately 71°F; Figure O.3-9). The effects of water temperature on fish in the Feather River vary among species and life stages; however, water temperatures under current conditions and the No Action Alternative surpass suboptimal levels for Chinook Salmon between 58°F and 75.2°F, for Steelhead between 55°F and 70°F, and for Green Sturgeon between 66°F and 70°F (Table O.3-3).

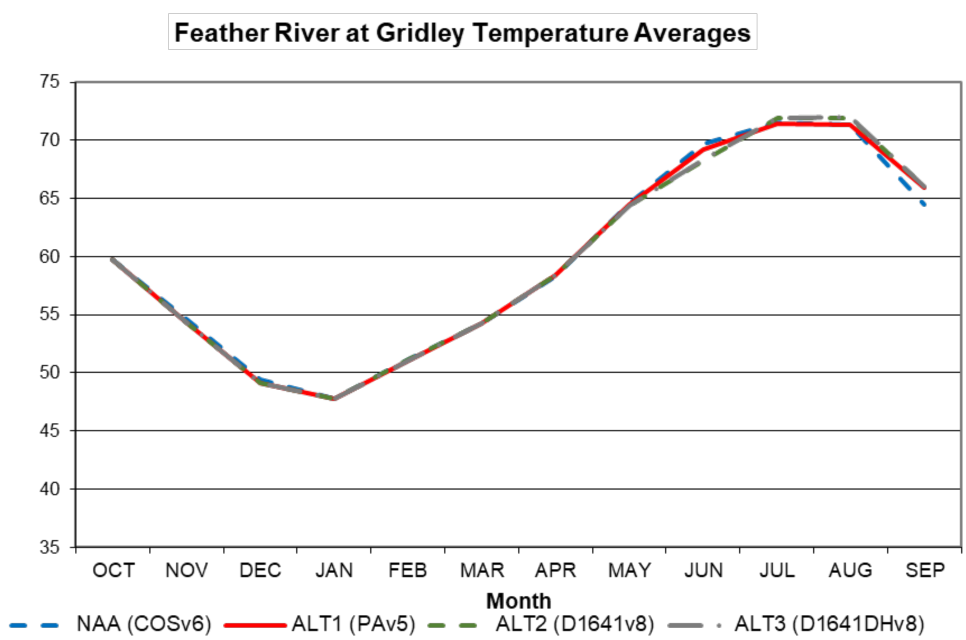

Figure O.3-8. RecTemp Average Feather River water Temperatures at Gridley Bridge under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 Scenarios.

Figure O.3-9. RecTemp average estimated Feather River water temperatures at Gridley Bridge in Wet, Above Normal, Below Normal, Dry, and Critically Dry Water Year Types under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 Scenarios

Table O.3-3. Water Temperatures Suitable for Spring- and Fall-Run Chinook, Central Valley Steelhead, and Green Sturgeon by Life Stage

Life Stage	Peak Occurrence	Optimal	Suboptimal	Stress-inducing
Spring-Run Chinook				
Eggs to fry	September to October	< 54°F	54°F to 58°F	> 58°F
Rearing to out-migrating	November to May	< 60°F	60°F to 65°F	> 65°F
Migrating adults	March to June	< 56°F	56°F to 65°F	> 65°F
Adult holding	May to August	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Fall-Run Chinook				
Eggs to fry	October to April	48.2°F to 55.4°F	55.4°F to 62.6°F	> 62.6°F
Rearing to out-migrating	April to June	55.4°F to 68°F	68°F to 75.2°F	> 75.2°F
Migrating adults	June to April	50°F to 68°F	68°F to 69.8°F	> 69.8°F
Central Valley Steelhead				
Eggs to fry	January	46°F to 52°F	52°F to 55°F	> 55°F
Rearing to out-migrating	January to May	< 65°F	65°F to 68°F	> 68°F
Migrating adults	September to October	< 52°F	52°F to 70°F	> 70°F
Adult holding	December to March	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Green Sturgeon				
Eggs to fry	May to July	53°F to 65°F	65°F to 66°F	> 66°F
Rearing to out-migrating	May to October	58°F to 66°F	66°F to 69°F	> 69°F
Migrating adults	March to May	53°F to 64°F	64°F to 66°F	> 66°F
Post-spawn adults	March to August	46°F to 68°F	68°F to 70°F	>70°F

Sources: NMFS 2016a; Stillwater Sciences 2006; CDFG 2012a, 2012b.

Additionally, although stream flows would remain the same under the No Action Alternative, mean air temperatures are predicted to increase by 4.5°F (2.5°C) by mid-century as a result of climate change, and could increase by 5.4°F (3°C), based on more extreme climate change predictions (Wang et al. 2018). Climate change is also predicted to result in overall increased precipitation of up to two inches, a higher frequency of short-duration high-rainfall events, fewer moderate-rainfall events with prolonged durations, less snowpack in winter and early spring months, altered stream flow volume and timing, and lower late summer flows by mid-century, although again, more extreme climate change predictions include decreased precipitation of up to 20 inches (Wang et al. 2018).

Because water temperatures under current conditions surpass suboptimal levels (greater than maximums of 55°F and 75.2°F) for several species and life stages in all water year types, and reach stress-inducing levels (greater than maximums of 58°F and 75.2°F) during some water year types (Table O.3-3; Figure O.3-9), there is potential for continued adverse temperature-related effects on Feather River Spring-Run Chinook Salmon, Fall-Run/Late Fall-Run Chinook Salmon, and Central Valley Steelhead under both current conditions and the No Action Alternative. and reach stress-inducing levels (greater than maximums of 58°F and 75.2°F) during some water year types (Table O.3-3; Figure O.3-9), there is potential for continued adverse temperature-related effects on Feather River Spring-Run Chinook Salmon, Fall-Run Chinook Salmon, and Central Valley Steelhead under both current conditions and the No Action

Alternative. Additionally, if climate change estimates are accurate, water temperatures in the Feather River would likely increase by 2030 under the No Action Alternative, further exasperating adverse temperature-related effects for these species, when compared to current conditions, discussed in more detail below.

Winter-Run Chinook Salmon

Winter-Run Chinook are not likely to be affected by changes in flow under the No Action Alternative compared to current conditions due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Effects of water temperature on Spring-Run Chinook have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance (Table O.3-3).

There is no difference in water temperature between the No Action Alternative and current conditions for Spring-Run Chinook; however, water temperatures under both scenarios would fall in the stress-inducing range for portions of all life stages present (Figure O.3-9and Table O.3-3). The average water temperatures currently, and under the No Action Alternative, fall in the stress-inducing range during the peak occurrence period of egg incubation and fry in all water year types. Similarly, average water temperatures are within the stress-inducing range during the peak occurrence period of rearing and out-migrating juveniles in May of above normal, below normal, dry, and critically dry water year types. Migrating adults would also encounter stress inducing temperatures toward the end of the migration season (i.e., May through June) and would continue to encounter these temperatures downstream of the Thermalito Afterbay outlet for the entirety of the holding period, across all water year types (Figure O.3-9 and Table O.3-3). Under the No Action Alternative, water temperatures in the Feather River would likely increase by 2030 due to climate change, further exasperating adverse temperature-related effects for each life stage of Spring-Run Chinook, when compared to current conditions. Therefore, the No Action Alternative has the potential for slightly adverse water temperature-related effects on all life stages of Spring-Run Chinook Salmon compared to current conditions.

Fall-Run Chinook Salmon

Effects of water temperature on Fall-Run Chinook have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-3).

There is no difference in water temperature between the No Action Alternative and current conditions for Fall-Run Chinook; however, water temperatures under both scenarios would fall in the stress-inducing range for incubating eggs and fry as well as migrating adults (Figure O.3-9 and Table O.3-3). The average water temperatures currently, and under the No Action Alternative, fall in the stress-inducing range during the peak occurrence period of egg incubation and fry in April of above normal, below normal, and dry water years, as well as in April and October of critically dry water years. Migrating adults would also encounter stress inducing temperatures before September in most water years (Figure O.3-9 and Table O.3-3). Under the No Action Alternative, water temperatures in the Feather River would likely increase by 2030 due to climate change, further exasperating adverse temperature-related effects for each life stage of Fall-Run Chinook, when compared to current conditions. Therefore, the No Action Alternative has the potential for slightly adverse water temperature-related effects on incubating eggs and fry and migrating adults Fall-Run Chinook Salmon compared to current conditions.

Central Valley Steelhead

Effects of water temperature on Central Valley Steelhead have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance (Table O.3-3). Central Valley Steelhead eggs, fry, and holding adults are present in the Feather River in winter and spring months; however, juveniles typically migrate to the ocean after spending 1 to 3 years in freshwater (CDFG 1996). Steelhead fry and fingerlings rear and migrate downstream during most months of the year, but the peak period of emigration is January through May (Table O.3-3).

There is no difference in water temperature between the No Action Alternative and current conditions for Central Valley Steelhead; however, water temperatures under both scenarios would fall in the stress-inducing range downstream of the Thermalito Afterbay outlet for rearing juveniles, given the potential to occur for up to 3 years in the stream (Figure O.3-9 and Table O.3-3). Under the No Action Alternative, water temperatures in the Feather River downstream of the Thermalito Afterbay outlet would likely increase by 2030 due to climate change, further exasperating adverse temperature-related effects for holding juvenile Steelhead when compared to current conditions. Given that current conditions limit rearing habitat to upstream of the Thermalito Afterbay outlet, there is likely only a negligible adverse water temperature-related effects on rearing juvenile Steelhead under the No Action Alternative compared to current conditions.

North American Green Sturgeon

Effects of water temperature on Green Sturgeon have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-3).

There is no difference in water temperature between the No Action Alternative and current conditions for Green Sturgeon; however, water temperatures under both scenarios would fall in the stress-inducing range for portions of all life stages present (Figure O.3-9 and Table O.3-3). The average water temperatures currently, and under the No Action Alternative, fall in the stress-inducing range during the peak occurrence period of egg incubation and fry in all water year types. Similarly, average water temperatures are within the stress-inducing range during the peak occurrence period of rearing and out-migrating juveniles in all water year types. Migrating adults would also encounter stress inducing temperatures toward the end of the migration season (i.e., May) of above normal, below normal, dry, and critically dry water year types (Figure O.3-9 and Table O.3-3). Under the No Action Alternative, water temperatures in the Feather River would likely increase by 2030 due to climate change, further exasperating adverse temperature-related effects for each life stage of Green Sturgeon, when compared to current conditions. Therefore, the No Action Alternative has the potential for slightly adverse water temperature-related effects on all life stages of Green Sturgeon compared to current conditions.

O.3.2.5 *American River*

Potential changes to aquatic resources in the American River from flood control

Flood Control for the American River at Folsom Dam would be the same under the No Action Alternative compared to the existing condition, since flood control follows the USACE Water Control Manual. The Water Control Manual has been updated over time, and a new Water Control Manual was developed that utilizes forecasted inflow as the criteria for determining flood control releases. The new manual looks ahead five days and considers the forecasted inflow volume for the total of those five days. If that volume exceeds a threshold, a flood control release is specified. The concept is to pre-emptively draw the reservoir down in anticipation of high inflows, thus providing space to store the rain event when it arrives. This will allow Reclamation to pass higher precipitation events with lower peak releases which relieves stress on the downstream levees and provides a higher level of flood protection to downstream areas.

Potential changes to aquatic resources from Folsom Reservoir operations in the American River to meet Delta salinity requirements

Folsom Reservoir operations to address Delta water quality requirements under D-1641 would not change under the No Action Alternative, compared to existing conditions. Folsom Reservoir flow requirements include releases to meet Delta standards under D-1641, as needed. Since Folsom Reservoir is the closest reservoir to the Delta, releases from Folsom can more quickly address Delta water quality requirements. Releases to address Delta water quality objectives would be conducted, as needed, in coordination with the American River stakeholders. Releases to address Delta water quality objectives would improve water quality conditions, and thus habitat conditions for fish and other aquatic species in the Delta when hydrologic conditions are negatively affecting salinity levels.

Potential changes to aquatic resources from flows in the American River

Flows in the American River below Nimbus Dam would be the same under the No Action Alternative compared to the existing condition, since flow management for the No Action Alternative is according to the American River 2006 Flow Management Standard, the same as under the existing condition. Under the No Action Alternative, flow releases follow the existing conditions and current flow operations in the lower American River were flows are managed according to the American River 2006 Water Forum Lower American Flow Management Standard (Water Forum 2006), with the objective of providing suitable conditions for Fall-Run Chinook Salmon and Steelhead. Under the Flow Management Standard, flows are managed according to the Minimum Flow Requirements (MFR), which establishes minimum flows, as measured by the total release at Nimbus Dam, which vary throughout the year in response to the hydrology of the Sacramento and American River basins. The October 1 through December 31 MFR range between 800 and 2,000 cfs. The January 1 through Labor Day MFR range between 800 and 1,750 cfs. The post Labor Day through September MFR range between 800 and 1,500 cfs. As a general rule, the MFR must equal or exceed 800 cfs year round. Narrowly defined exceptions to this rule allow Nimbus releases to drop below 800 cfs to avoid depletion of water storage in Folsom Reservoir when dry or critical hydrologic conditions are forecasted to occur. These narrowly defined exceptions to the MFR are an important component of the Flow Management Standard. Since the No Action Alternative follows the existing condition, implementation of the No Action Alternative would result in no change to flows in the lower American River.

Potential changes to aquatic resources in the American River due to changes in water temperature

Water temperatures in the American River at Watt Avenue would be the same under the No Action Alternative as under the existing conditions, since the temperature objectives for the No Action Alternative is according to the American River 2006 Flow Management Standard, the same as under the existing condition. Current objectives for water temperatures in the Lower American River address the needs for Steelhead incubation and rearing during the late spring and summer, and for Fall–Run Chinook Salmon spawning and incubation starting in late October or early November. However, only in wetter hydrologic conditions is the volume of cold water sufficient to meet the majority of the water temperature objectives.

Potential changes to aquatic resources in the American River from habitat restoration

Habitat restoration projects are not proposed under the No Action Alternative, therefore, there would be no changes to habitat in the lower American River.

O.3.2.6 *Stanislaus River*

Potential changes to aquatic resources in the Stanislaus River due to changes in flow

Reclamation operates the Stanislaus River separately from the other CVP reservoirs. While releases from New Melones Reservoir provide inflow to the Delta, Reclamation does not operate New Melones for Delta salinity, outflow, or export requirements. As described in Appendix C, *Facility Descriptions,* Reclamation is required to operate releases from the East Side Division reservoirs according to the New Melones year-type specific minimum flow schedules. Tables X1 through X5 in Appendix 1 indicate the specific minimum flow schedule that Reclamation currently operations for the East Side Division reservoir. However, the flow schedule does not preclude Reclamation from making higher releases for fishery benefits or other operational criteria[6]. Under the No Action Alternative, Reclamation would continue to meet the minimum flow schedule, to their best ability, as described in the 2009 NMFS BO RPA Action III.1.3. Reclamation currently manages flow (based on releases measured at Goodwin Dam) to provide habitat for all life history stages of Steelhead and to incorporate habitat maintaining geomorphic flows in a flow pattern that would provide migratory cues to smolts and facilitate out-migrant smolt movement.

Potential changes to aquatic resources in the Stanislaus River due to changes in water temperature

Cold water in the Stanislaus River is affected by the cold-water pool in New Melones Reservoir and air temperatures. Reclamation manages the cold-water supply and makes cold-water releases from New Melones Reservoir to provide suitable temperatures for Steelhead rearing, spawning, egg incubation smoltification, and adult migration in the Stanislaus River downstream of Goodwin Dam.

Under the No Action Alternative, water temperature Reclamation will continue, where feasible, to manage the cold water supply within New Melones as described in 2009 NMFS RPA Action III.1.2, with the objective of providing suitable temperatures for Central Valley Steelhead rearing, spawning, egg incubation, smoltification, and adult migration in the river downstream of Goodwin Dam. There are no temperature control devices at New Melones, Goodwin, or Tulloch Dams; thus, temperature management flexibility is limited to storage and flow management under certain conditions. Under the No Action Alternative, Central Valley Steelhead would continue to be vulnerable to elevated temperatures in dry and critically dry years, even if actions are taken to improve temperature management. The frequency of these occurrences is expected to increase with climate change-related temperature increases.

O.3.2.7 *San Joaquin River*

Potential changes to aquatic resources in the San Joaquin River due to changes in flow

The San Joaquin River is highly altered and as a result, flow within the River is a more complex issue. Currently, the San Joaquin River Restoration Program is working toward re-establishing contiguous in the river below Sack Dam. Progress is advancing toward this goal, but anadromous fish are currently collected at the San Joaquin River above the Merced River and moved to the upper reaches. Therefore

[6] https://www.westcoast.fisheries.noaa.gov/publications/Central_Valley/Water%20Operations/Operations,%20Criteria%20and%20Plan/040711_ocap_opinion_2011_amendments.pdf, February 18, 2019

flow between the upper San Joaquin and lower San Joaquin River (where many tributaries contribute) respond differently. Analyses of flow for the No Action Alternative and Alternatives 1 through 3 show that releases in the San Joaquin River below Millerton Reservoir will remain the same for all alternatives (Figure O.3-10). Therefore, no change is anticipated as a result in the upper San Joaquin River.

Flow at Vernalis in the San Joaquin River represents all contributions from the upper San Joaquin, Merced, Tuolumne, and Stanislaus Rivers combined. Flow contributions vary based on program alternatives in the tributaries; therefore, flow in the San Joaquin River changes as well (Figure O.3-11). Overall, there is not a substantial change between the No Action Alternative and Alternatives 1 through 3. Average flows follow the same general trend, rising early in the year to peak in spring and then generally decrease. The differences between annual average flow also is within 50 cfs of each alternative, representing no greater than 1.1% variation between all alternatives. Differences by water year type are again very similar, therefore substantial variation between all alternatives is not expected.

The San Joaquin River below the Merced confluence primarily represents a migration corridor. Salmonids and other potential species such as Sturgeon migrate between tributaries and the Delta through the San Joaquin River. Therefore the exposure to the lower San Joaquin River is temporary and generally during adult return or juvenile out-migration.

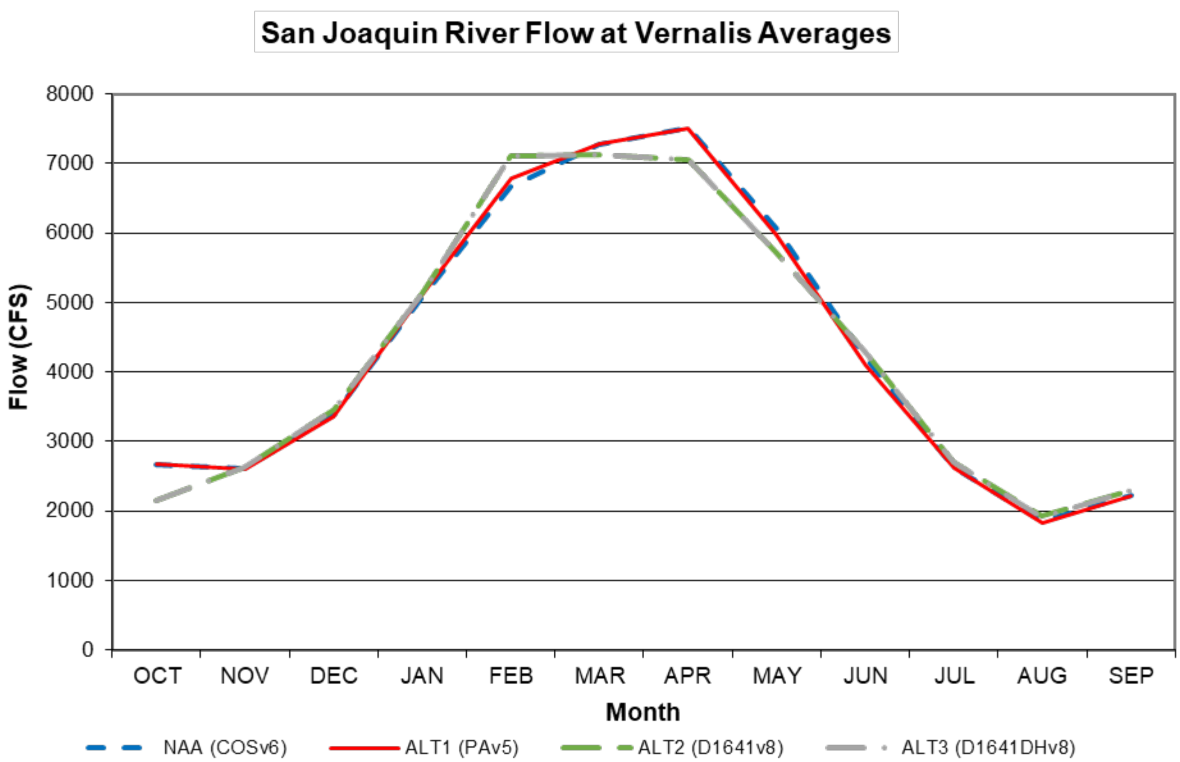

Figure O.3-10. Average Flow by Month at Vernalis on the San Joaquin River

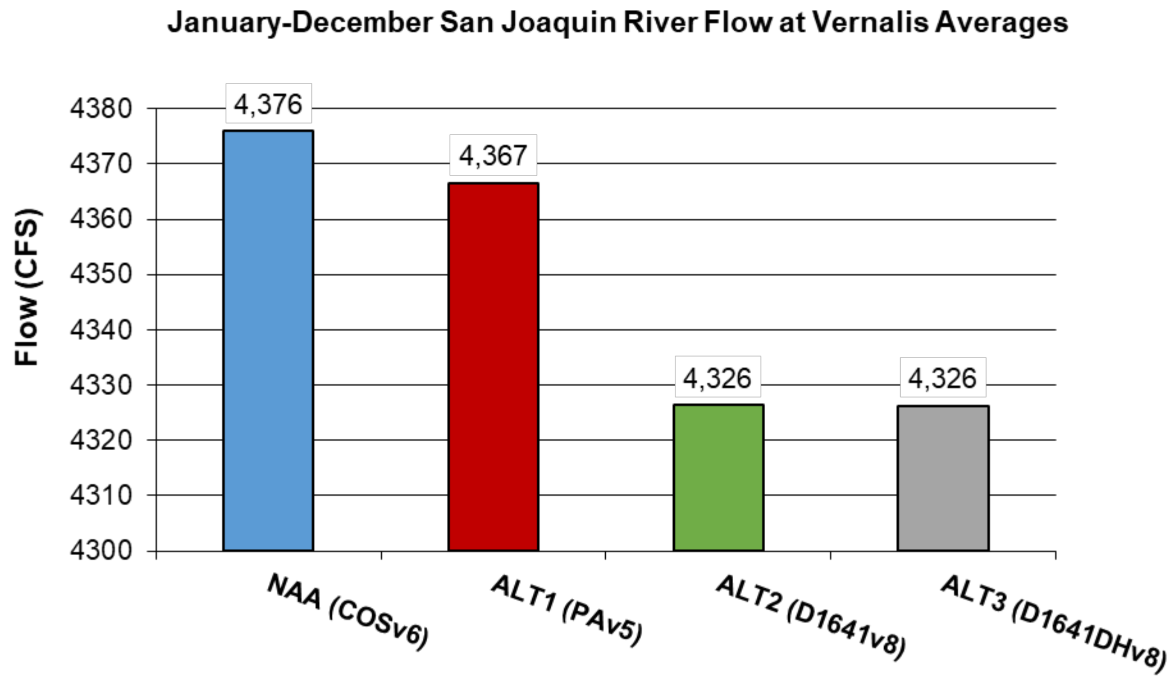

Figure O.3-11. Average Annual Flow Occurring at Vernalis on the San Joaquin River

Potential changes to aquatic resources in the San Joaquin River due to changes in water temperature

Variations in flow and reservoir storage both can result in direct changes to water temperature through the thermal buffering capacity of water based on volume of storage or discharge. There are no changes in outflow release from Friant Dam at Millerton Lake (Figure O.3-12). Therefore, no changes in temperature as a result of flow or storage are expected in the upper San Joaquin River.

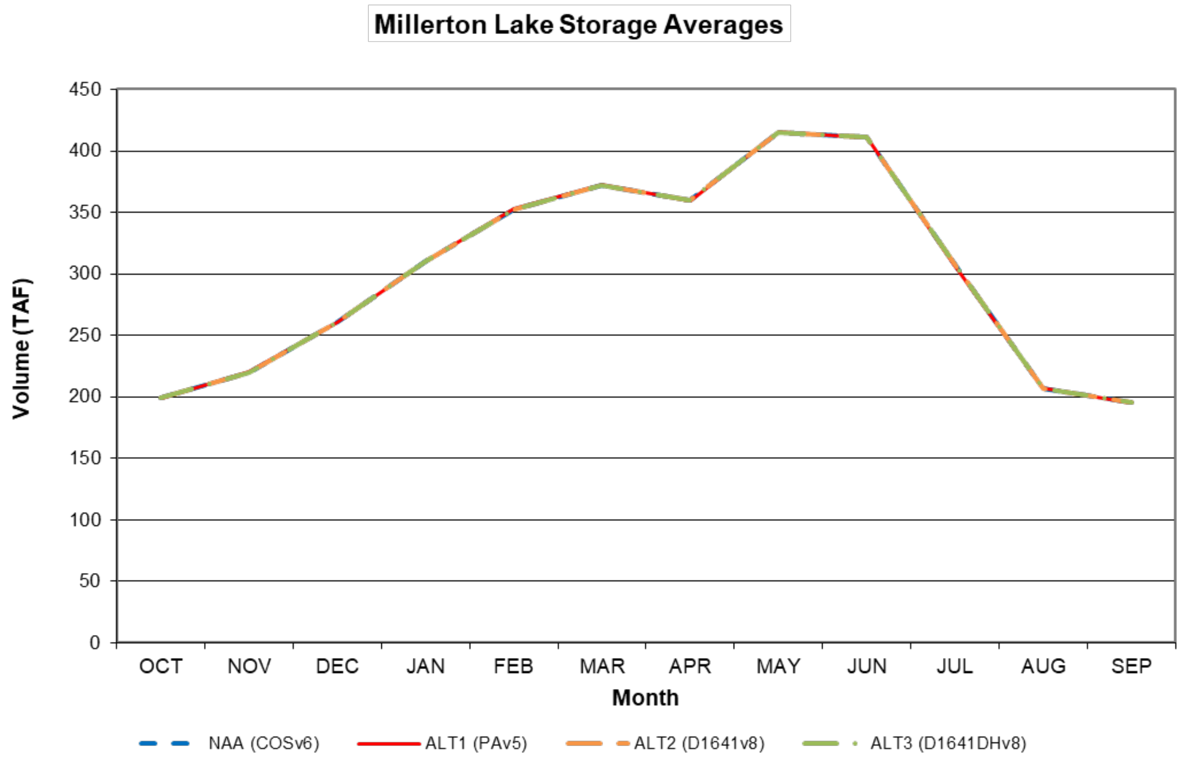

Figure O.3-12. Average Monthly Reservoir Volume at Millerton Lake on the San Joaquin River

In the lower San Joaquin River, changes in flow are expected to be relatively minimal as discussed above. Given the low variation in flow between program alternatives, little change in temperature is also anticipated. Figure O.3-13 shows the relatively similar average temperature modeled at Vernalis on the San Joaquin River. Average annual water temperature is expected to change by no more than 0.2°F between all project alternatives. Based on these results there does not appear to be any notable effect to water temperature.

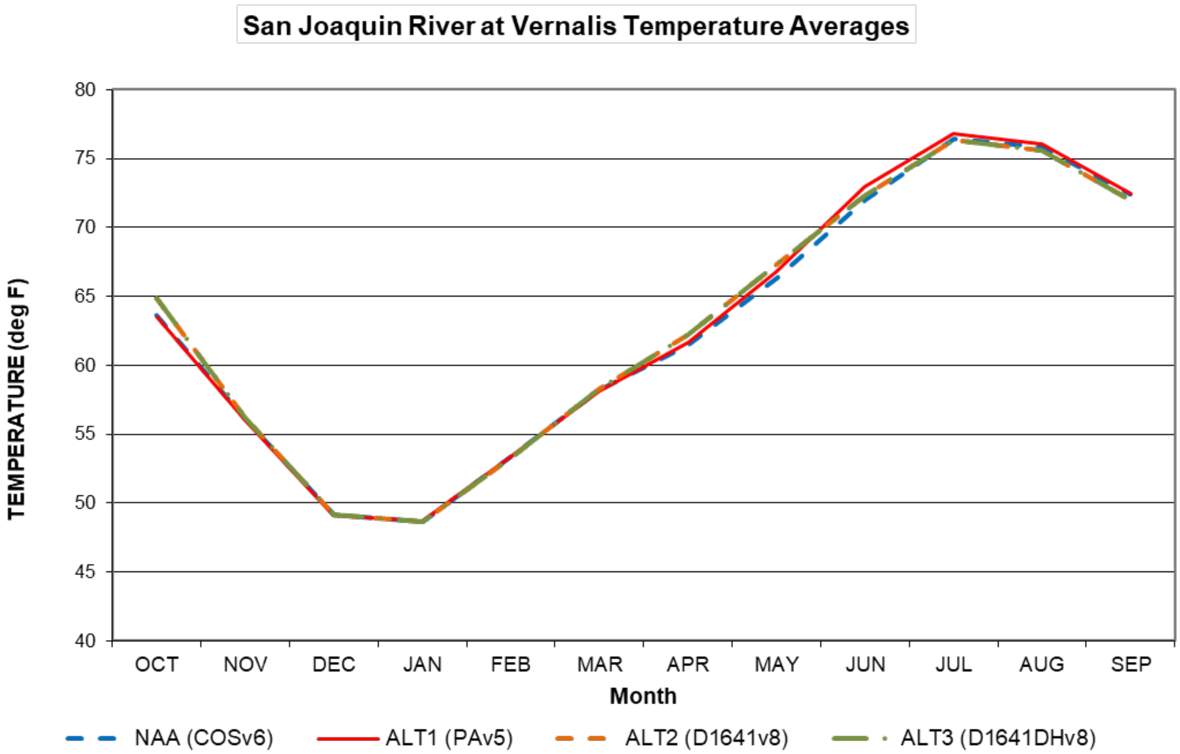

Figure O.3-13. Average Monthly Water Temperature at Vernalis by Project Alternative

Potential changes to aquatic resources in the San Joaquin River due to restoration activities

Proposed restoration activity in the San Joaquin River includes the San Joaquin River Restoration Program in the upper San Joaquin River and programmatic lower San Joaquin River Habitat restoration. Both of these activities may result in temporary disturbance to habitat and may expose nearby fish stressful conditions. Elevated turbidity, noise, and exclusion from habitat are all temporary potential effects as a result of restoration activity. Each of these potential issues will be mitigated for through regulatory review and established best management practices. The timing of activities will be focused on periods known for the least likely presence of protected species. The temporary nature of these activities will limit the potential for any lasting impact to the surrounding aquatic community. In addition, the benefit of the action will likely result in long-term improvements to the habitat and aquatic inhabitants.

O.3.2.8 *Bay Delta*

O.3.2.8.1 Delta Smelt

Potential changes to Delta Smelt due to seasonal operations

The No Action Alternative would include continuation of current seasonal operations, from which the primary potential effects to Delta Smelt include south Delta entrainment (limited by the OMR criteria from the USFWS [2008] BO), food web productivity entrainment (limited by the USFWS [2008] BO requirement to restore 8,000 acres of tidal habitat, which has the potential to reduce effects relative to current conditions, as described further below in *Potential changes to Delta Smelt from tidal habitat restoration* and effects to the extent of fall abiotic habitat (limited by the USFWS [2008] fall X2 requirement).

Potential changes to Delta Smelt due to changes in Delta Cross Channel operations

As noted in the Final Biological Assessment on the Reinitiation of Consultation on the Coordinated Long-Term Operation of the Central Valley Project and State Water Project (ROC LTO BA), it is unknown what if any direct impacts occur to Delta Smelt from opening or closing the DCC gates, and there is limited occurrence of Delta Smelt near the DCC (Reclamation 2019). Under the No Action Alternative, no changes are proposed to DCC operational criteria relative to current conditions, so any effects to Delta Smelt under the No Action Alternative would continue as currently occurring.

Potential changes in Delta Smelt survival related to the Temporary Barriers Project

Under the No Action Alternative, potential effects of the Temporary Barriers Project on Delta Smelt would be expected to be similar to the effects under current conditions (i.e., near-field predation and potential effects on transport of *P. forbesi* to the low salinity zone; see also ROC LTO BA. The spring HOR barrier has the potential to influence entrainment risk for larval/early juvenile Delta Smelt, but consistent with current practice the barrier would only be installed if Delta Smelt entrainment risk would not be affected.

Potential changes to Delta Smelt from Contra Costa Water District operations

Contra Costa Water District operations under the No Action Alternative would not change from current conditions and therefore would be expected to have similar effects to Delta Smelt, i.e., negligible entrainment and hydrodynamic effects (Reclamation 2019).

Potential changes to Delta Smelt from North Bay Aqueduct operations

North Bay Aqueduct Barker Slough Pumping Plant operations would not differ between the No Action Alternative and current conditions, so the effects to Delta Smelt would be expected to be similar under the No Action Alternative as currently occurring, i.e., potential entrainment, impingement, near-field predation, and entrainment of Delta Smelt food, which could have limited effects on Delta Smelt given low occurrence in the vicinity of the Barker Slough Pumping Plant (Reclamation 2019).

Potential changes to Delta Smelt from water transfers

Under the No Action Alternative, the water transfer window would remain the same as currently in place, i.e., July to September. This period avoids the occurrence of Delta Smelt in the south Delta (Reclamation 2019) and therefore limits entrainment and predation risk at the south Delta export facilities.

Potential changes to Delta Smelt from Clifton Court aquatic weed and algal bloom management

Continuation of the current aquatic weed removal program in Clifton Court Forebay under the No Action Alternative would be expected to have little to no effect on Delta Smelt as a result of the timing of the action avoiding the main period of Delta Smelt potential occurrence.

Potential changes to Delta Smelt due to changes from Tracy and Skinner fish facilities

Under the No Action Alternative, potential effects from the Tracy and Skinner fish facilities would continue as currently occurring. This includes Delta Smelt mortality from pre-screen loss, collection, handling, transport, and release, with only a very small fraction potentially surviving the salvage process (Reclamation 2019). The potential effects from the Tracy and Skinner fish salvage facilities under the No

Action Alternative would be limited by continued management based on the USFWS (2008) BO criteria for OMR management, as previously outlined in *Potential effects from seasonal operations*.

Potential changes to Delta Smelt due to changes from Suisun Marsh facilities

Under the No Action Alternative, the Suisun Marsh facilities would continue to be operated as currently occurs, with potential limited effects to Delta Smelt such as entrainment (Reclamation 2019).

Potential changes to Delta Smelt due to changes from tidal habitat restoration

Under the No Action Alternative, completion of the 8,000 acres of tidal habitat restoration required by the USFWS (2008) BO would add approximately 6,000 acres of tidal habitat relative to current conditions. This has the potential to provide positive effects on Delta Smelt as a result of increased food availability, thus offsetting potential food productivity negative effects described previously in *Potential changes to Delta Smelt due to seasonal operations*, as well potentially providing habitat for occupation by Delta Smelt depending on presence of suitable habitat features such as relatively high turbidity (Reclamation 2019). Potential negative effects from contaminants (e.g., methylmercury) would be addressed with minimization measures.

O.3.2.8.2 Longfin Smelt

Potential changes to Longfin Smelt due to seasonal operations

The No Action Alternative would include continuation of current seasonal operations, from which the primary potential effects to Longfin Smelt include south Delta entrainment (mitigated by the OMR criteria from the CDFG [2009] ITP requirements) and habitat quality (mitigated by the CDFG [2009] ITP requirement to restore 800 acres of intertidal and associated subtidal habitat in a mesohaline part of the estuary). Operations have the potential to influence population abundance through effects on winter-spring Delta outflow (Nobriga and Rosenfield 2016), although the extent to which interannual differences are operations- versus hydrology-related is uncertain (Maunder et al. 2015); any effects under the No Action Alternative would continue consistent with current conditions.

Potential changes to Longfin Smelt due to changes in Delta Cross Channel operations

Under the No Action Alternative, no changes are proposed to DCC operational criteria relative to current conditions, so any effects to Longfin Smelt under the No Action Alternative would continue as currently occurring.

Potential changes in Longfin Smelt survival related to the Temporary Barriers Project

Under the No Action Alternative, potential effects of the Temporary Barriers Project on Longfin Smelt would be expected to be similar in nature but less than the effects to Delta Smelt under current conditions (i.e., near-field predation for smelts occurring in the vicinity; see also ROC LTO BA, with less effect to Longfin Smelt than Delta Smelt because Longfin Smelt are generally further downstream than Delta Smelt (Merz et al. 2011; Merz et al. 2013; Kimmerer et al. 2013). When installed, the spring HOR barrier presumably has the potential to influence entrainment risk for juvenile Longfin Smelt as it does for Delta Smelt, although entrainment risk is managed such that hydrodynamic effects of the barrier would be reflected in OMR flows and therefore accounted for.

Potential changes to Longfin Smelt from Contra Costa Water District operations

Contra Costa Water District operations under the No Action Alternative would not change from current conditions and therefore would be expected to have similar effects to Longfin Smelt, i.e., negligible entrainment and hydrodynamic effects per analyses undertaken for Delta Smelt (Reclamation 2019).

Potential changes to Longfin Smelt from North Bay Aqueduct operations

North Bay Aqueduct Barker Slough Pumping Plant operations would not differ between the No Action Alternative and current conditions, so the effects to Longfin Smelt would be expected to be similar under the No Action Alternative as currently occurring, i.e., potential entrainment, impingement, near-field predation, and entrainment of Longfin Smelt food, as suggested for Delta Smelt (Reclamation 2019). Potential effects are limited under the CDFG (2009) ITP because DWR must operate Barker Slough Pumping Plant with a maximum 7-day average diversion rate that does not exceed 50 cfs from January 15 through March 31 of dry and critically dry water year types (per the current forecast based on D-1641) if larval Longfin Smelt are detected at Station 716 during the annual Smelt Larval Survey.

Potential changes to Longfin Smelt from water transfers

Under the No Action Alternative, the water transfer window would remain the same as currently in place, i.e., July to September. This period avoids the occurrence of Longfin Smelt in the south Delta (Merz et al. 2013) and therefore avoids entrainment and predation risk at the south Delta export facilities.

Potential changes to Longfin Smelt from Clifton Court aquatic weed removal

Continuation of the current aquatic weed removal program in Clifton Court Forebay under the No Action Alternative would be expected to have little to no effect on Longin Smelt as a result of the timing of the action avoiding the main period of Longfin Smelt potential occurrence (Grimaldo et al. 2009).

Potential changes to Longfin Smelt due to changes from Tracy and Skinner fish facilities

Under the No Action Alternative, potential effects from the Tracy and Skinner fish facilities would continue as currently occurring. This includes mortality from pre-screen loss, collection, handling, transport, and release, with only a very small fraction potentially surviving the salvage process (CDFG 2009a). The potential effects from the Tracy and Skinner fish salvage facilities under the No Action Alternative would be limited by continued management based on the CDFG (2009a) ITP criteria for OMR management, as previously outlined in *Potential changes to Longfin Smelt due to seasonal operations*.

Potential changes to Longfin Smelt due to changes from Suisun Marsh facilities

Under the No Action Alternative, the Suisun Marsh facilities would continue to be operated as currently occurs, with potential limited effects to Longfin Smelt such as entrainment (CDFG 2009a).

Potential changes to Longfin Smelt due to changes from tidal habitat restoration

Under the No Action Alternative, completion of the 8,000 acres of tidal habitat restoration required by the USFWS (2008) BO would add approximately 6,000 acres of tidal habitat relative to current conditions. This has the potential to provide positive effects to Longfin Smelt as a result of increased food availability to larvae, given relatively frequent occurrence in the north Delta (Merz et al. 2013), as well as potentially providing habitat for occupation by Longfin Smelt depending on presence of suitable habitat features. As previously described for Delta Smelt, potential negative effects from contaminants (e.g., methylmercury) would be addressed with mitigation measures such as MM-AQUA-9 (Appendix E, Mitigation Measures).

Potential positive and negative effects of completion of the 8,000 acres of tidal habitat restoration would be expected to be less than to Delta Smelt because Longfin Smelt generally occurs more downstream in the Bay-Delta than Delta Smelt (Merz et al. 2011; Merz et al. 2013; Kimmerer et al. 2013; Grimaldo et al. 2017).

O.3.2.8.3 Sacramento River Winter Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

The No Action Alternative would include continuation of current seasonal operations, from which the primary potential effects to Winter-Run Chinook include south Delta entrainment and reduced velocities within some migratory corridors. The BO requirement to restore 8,000 acres of tidal habitat has the potential to reduce effects relative to current conditions, as described further below in *Potential effects from Tidal Habitat Restoration (Complete 8,000 Acres from 2008 BO*).

Potential changes to aquatic resources due to Delta Cross Channel operations

Winter-Run Chinook salmon are vulnerable to entrainment into the Delta Cross Channel if they are present when the gates are open. Individuals entrained into the Delta Cross Channel enter the interior Delta where survival rates are lower relative to fish that remain in the main stem Sacramento River. Under the No Action Alternative, operation of the DCC, and resulting probabilities of entrainment would remain the same as the current condition.

Potential changes to aquatic resources due to the Temporary Barriers Project

Few if any Winter-Run Chinook Salmon would be expected to occur in the region of the Temporary Barriers during the period when they are installed. Any potential effect under the No Action Alternative would be similar to the existing condition.

Potential changes to aquatic resources due to Contra Costa Water District operations

Contra Costa Water District operations under the No Action Alternative would not change from current conditions and therefore would be expected to have similar effects on Winter-Run Chinook Salmon, i.e., negligible entrainment and hydrodynamic effects.

Potential changes to aquatic resources due to North Bay Aqueduct operations

North Bay Aqueduct Barker Slough Pumping Plant operations would not differ between the No Action Alternative and current conditions, so the effects to Winter Run would be expected to be similar under the No Action Alternative as currently occurring. Few juvenile salmonids are collected in monitoring efforts associated with the project and potential effects are negligible.

Potential changes to aquatic resources due to water transfers

Under the No Action Alternative, the water transfer window would remain the same as currently in place, i.e., July to September. This period is outside of the migration window for Winter Run Chinook Salmon in the Delta.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Continuation of the current aquatic weed removal program in Clifton Court Forebay under the No Action Alternative would be expected to have little to no effect on Winter-Run as a result of the timing of the action avoiding the main period of Winter-Run occurrence.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Under the No Action Alternative, potential effects from the Tracy and Skinner fish facilities would continue as currently occurring. This includes mortality from pre-screen loss, collection, handling, transport, and release. The potential effects from the Tracy and Skinner fish salvage facilities under the No Action Alternative would be limited by continued management based on the NMFS (2009) BO RPA.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Under the No Action Alternative, the Suisun Marsh facilities would continue to be operated as currently occurs, with potential limited effects to Winter-Run such as delay of adults migrating through Montezuma Slough and predation of juveniles around the salinity control gates.

Potential changes to aquatic resources due to tidal habitat restoration

Under the No Action Alternative, completion of the 8,000 acres of tidal habitat restoration required by the USFWS (2008) BO would add approximately 6,000 acres of tidal habitat relative to current conditions. This has the potential to provide positive effects on Winter-Run as a result of increased food availability, and rearing habitat. Potential negative effects from contaminants (e.g., methylmercury) would be addressed with minimization measures.

O.3.2.8.4 Central Valley Spring Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

The No Action Alternative would include continuation of current seasonal operations, from which the primary potential effects to Spring-Run Chinook include south Delta entrainment and reduced flow velocities within some migratory corridors. The BO requirement to restore 8,000 acres of tidal habitat has the potential to reduce effects relative to current conditions, as described further below in *Potential effects from Tidal Habitat Restoration (Complete 8,000 Acres from 2008 BO*).

Potential changes to aquatic resources due to Delta Cross Channel operations

Sacramento River-origin Spring-Run Chinook salmon are vulnerable to entrainment into the Delta Cross Channel if they are present when the gates are open. Individuals entrained into the Delta Cross Channel enter the interior Delta where survival rates are lower relative to fish that remain in the main stem Sacramento River. San Joaquin River-origin fish would not be exposed to the DCC. Under the No Action Alternative, operation of the DCC, and resulting probabilities of entrainment would remain the same as the current condition.

Potential changes to aquatic resources due to the Temporary Barriers Project

Few if any Sacramento River-origin Spring-Run Chinook Salmon would be expected to occur in the region of the Temporary Barriers during the period when they are installed. A greater fraction of San Joaquin River-origin Spring Run would be expected to be exposed to the barriers. Any potential effect under the No Action Alternative such as reduced survival would be similar to the existing condition.

Potential changes to aquatic resources due to Contra Costa Water District operations

Contra Costa Water District operations under the No Action Alternative would not change from current conditions and therefore would be expected to have similar effects on Spring-Run Chinook Salmon, i.e., negligible entrainment and hydrodynamic effects.

Potential changes to aquatic resources due to North Bay Aqueduct operations

North Bay Aqueduct Barker Slough Pumping Plant operations would not differ between the No Action Alternative and current conditions, so the effects to Spring Run would be expected to be similar under the No Action Alternative as currently occurring. Few juvenile salmonids are collected in monitoring efforts associated with the project and potential effects are negligible. San Joaquin River-origin Spring run would not be exposed to this facility.

Potential changes to aquatic resources due to water transfers

Under the No Action Alternative, the water transfer window would remain the same as currently in place, i.e., July to September. This period is outside of the migration window for Spring Run Chinook Salmon in the Delta.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Continuation of the current aquatic weed removal program in Clifton Court Forebay under the No Action Alternative would be expected to have little to no effect on Spring-Run as a result of the timing of the action avoiding the main period of Spring-Run occurrence.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Under the No Action Alternative, potential effects from the Tracy and Skinner fish facilities would continue as currently occurring. This includes mortality from pre-screen loss, collection, handling, transport, and release. The potential effects from the Tracy and Skinner fish salvage facilities under the No Action Alternative would be limited by continued management based on the NMFS (2009) BO RPA.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Under the No Action Alternative, the Suisun Marsh facilities would continue to be operated as currently occurs, with potential limited effects to Spring-Run such as delay of adults migrating through Montezuma Slough and predation on juveniles around the salinity control gates.

Potential changes to aquatic resources due to tidal habitat restoration

Under the No Action Alternative, completion of the 8,000 acres of tidal habitat restoration required by the USFWS (2008) BO would add approximately 6,000 acres of tidal habitat relative to current conditions. This has the potential to provide positive effects on Spring-Run as a result of increased food availability, and rearing habitat. Potential negative effects from contaminants (e.g., methylmercury) would be addressed with minimization measures.

O.3.2.8.5 Central Valley Fall Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

The No Action Alternative would include continuation of current seasonal operations, from which the primary potential effects to Fall-Run Chinook include south Delta entrainment and reduced flow velocities within some migratory corridors. The BO requirement to restore 8,000 acres of tidal habitat has the potential to reduce effects relative to current conditions, as described further below in *Potential effects from Tidal Habitat Restoration (Complete 8,000 Acres from 2008 BO*).

Potential changes to aquatic resources due to Delta Cross Channel operations

Sacramento River-origin Fall-Run Chinook salmon are vulnerable to entrainment into the Delta Cross Channel if they are present when the gates are open. Individuals entrained into the Delta Cross Channel enter the interior Delta where survival rates are lower relative to fish that remain in the main stem Sacramento River. San Joaquin River-origin fish would not be exposed to the DCC. Under the No Action Alternative, operation of the DCC, and resulting probabilities of entrainment would remain the same as the current condition.

Potential changes to aquatic resources due to the Temporary Barriers Project

Few if any Sacramento River-origin Fall-Run Chinook Salmon would be expected to occur in the region of the Temporary Barriers during the period when they are installed. A greater fraction of San Joaquin River-origin Fall Run would be expected to be exposed to the barriers. Any potential effect under the No Action Alternative such as reduced survival would be similar to the existing condition.

Potential changes to aquatic resources due to Contra Costa Water District operations

Contra Costa Water District operations under the No Action Alternative would not change from current conditions and therefore would be expected to have similar effects on Fall-Run Chinook Salmon, i.e., negligible entrainment and hydrodynamic effects.

Potential changes to aquatic resources due to North Bay Aqueduct operations

North Bay Aqueduct Barker Slough Pumping Plant operations would not differ between the No Action Alternative and current conditions, so the effects to Fall Run would be expected to be similar under the No Action Alternative as currently occurring. Few juvenile salmonids are collected in monitoring efforts associated with the project and potential effects are negligible. San Joaquin River-origin Fall run would not be exposed to this facility.

Potential changes to aquatic resources due to water transfers

Under the No Action Alternative, the water transfer window would remain the same as currently in place, i.e., July to September. This period is outside of the migration window for Fall Run Chinook Salmon in the Delta.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Continuation of the current aquatic weed removal program in Clifton Court Forebay under the No Action Alternative would be expected to have little to no effect on Fall-Run as a result of the timing of the action avoiding the main period of Fall-Run occurrence.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Under the No Action Alternative, potential effects from the Tracy and Skinner fish facilities would continue as currently occurring. This includes mortality from pre-screen loss, collection, handling, transport, and release. The potential effects from the Tracy and Skinner fish salvage facilities under the No Action Alternative would be limited by continued management based on the NMFS (2009) BO RPA.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Under the No Action Alternative, the Suisun Marsh facilities would continue to be operated as currently occurs, with potential limited effects to Fall-Run such as delay of adults migrating through Montezuma Slough and predation on juveniles around the salinity control gates.

Potential changes to aquatic resources due to tidal habitat restoration

Under the No Action Alternative, completion of the 8,000 acres of tidal habitat restoration required by the USFWS (2008) BO would add approximately 6,000 acres of tidal habitat relative to current conditions. This has the potential to provide positive effects on Fall-Run as a result of increased food availability, and rearing habitat. Potential negative effects from contaminants (e.g., methylmercury) would be addressed with minimization measures.

O.3.2.8.6 California Central Valley Steelhead

Potential changes to aquatic resources due to seasonal operations

The No Action Alternative would include continuation of current seasonal operations, from which the primary potential effects to CCV steelhead include south Delta entrainment and reduced flow velocities within some migratory corridors. The BO requirement to restore 8,000 acres of tidal habitat has the potential to reduce effects relative to current conditions, as described further below in *Potential effects from Tidal Habitat Restoration (Complete 8,000 Acres from 2008 BO*).

Potential changes to aquatic resources due to Delta Cross Channel operations

Sacramento River-origin steelhead are vulnerable to entrainment into the Delta Cross Channel if they are present when the gates are open. Individuals entrained into the Delta Cross Channel enter the interior Delta where survival rates are lower relative to fish that remain in the main stem Sacramento River. San Joaquin River-origin fish would not be exposed to the DCC. Under the No Action Alternative, operation of the DCC, and resulting probabilities of entrainment would remain the same as the current condition.

Potential changes to aquatic resources due to the Temporary Barriers Project

Few if any Sacramento River-origin CCV steelhead would be expected to occur in the region of the Temporary Barriers during the period when they are installed. A greater fraction of San Joaquin River-origin CCV steelhead would be expected to be exposed to the barriers. Any potential effect under the No Action Alternative such as reduced survival would be similar to the existing condition.

Potential changes to aquatic resources due to Contra Costa Water District operations

Contra Costa Water District operations under the No Action Alternative would not change from current conditions and therefore would be expected to have similar effects on CCV steelhead, i.e., negligible entrainment and hydrodynamic effects.

Potential changes to aquatic resources due to North Bay Aqueduct operations

North Bay Aqueduct Barker Slough Pumping Plant operations would not differ between the No Action Alternative and current conditions, so the effects to CCV steelhead would be expected to be similar under the No Action Alternative as currently occurring. Few juvenile salmonids are collected in monitoring efforts associated with the project and potential effects are negligible. San Joaquin River-origin CCV steelhead would not be exposed to this facility.

Potential changes to aquatic resources due to water transfers

Under the No Action Alternative, the water transfer window would remain the same as currently in place, i.e., July to September. This period is outside of the migration window for CCV steelhead in the Delta.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Continuation of the current aquatic weed removal program in Clifton Court Forebay under the No Action Alternative would be expected to have little to no effect on CCV steelhead as a result of the timing of the action avoiding the main period of occurrence.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Under the No Action Alternative, potential effects from the Tracy and Skinner fish facilities would continue as currently occurring. This includes mortality from pre-screen loss, collection, handling, transport, and release. The potential effects from the Tracy and Skinner fish salvage facilities under the No Action Alternative would be limited by continued management based on the NMFS (2009) BO RPA.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Under the No Action Alternative, the Suisun Marsh facilities would continue to be operated as currently occurs, with potential limited effects to CCV steelhead such as delay of adults migrating through Montezuma Slough and predation on juveniles around the salinity control gates.

Potential changes to aquatic resources due to tidal habitat restoration

Under the No Action Alternative, completion of the 8,000 acres of tidal habitat restoration required by the USFWS (2008) BO would add approximately 6,000 acres of tidal habitat relative to current conditions. This has the potential to provide positive effects on CCV steelhead as a result of increased food availability, and rearing habitat. Potential negative effects from contaminants (e.g., methylmercury) would be addressed with minimization measures.

O.3.2.8.7 North American Green Sturgeon southern DPS

Potential changes to aquatic resources due to seasonal operations

The No Action Alternative would include continuation of current seasonal operations, from which the primary potential effects to Green Sturgeon include south Delta entrainment and reduced flow velocities within some migratory corridors. The BO requirement to restore 8,000 acres of tidal habitat has the potential to reduce effects relative to current conditions, as described further below in *Potential effects from Tidal Habitat Restoration (Complete 8,000 Acres from 2008 BO*).

Potential changes to aquatic resources due to Delta Cross Channel operations

Green Sturgeon are vulnerable to entrainment into the Delta Cross Channel if they are present when the gates are open. Individuals entrained into the Delta Cross Channel enter the interior Delta. It is not known if survival of Green Sturgeon is lower in the interior Delta as has been observed for Chinook Salmon. Under the No Action Alternative, operation of the DCC, and resulting probabilities of entrainment would remain the same as the current condition.

Potential changes to aquatic resources due to the Temporary Barriers Project

Few if any Green Sturgeon would be expected to occur in the region of the Temporary Barriers during the period when they are installed due to their expected preference for large channels in the western Delta. If juvenile Green Sturgeon experience effects similar to Chinook Salmon, there may be reduced survival and passage delays. Any potential effect under the No Action Alternative would be similar to the existing condition.

Potential changes to aquatic resources due to Contra Costa Water District operations

Contra Costa Water District operations under the No Action Alternative would not change from current conditions and therefore would be expected to have similar effects. Green Sturgeon are not expected to occur near the facility as no Green Sturgeon have been collected in CDFW monitoring efforts and the habitat present is not expected to be used by Green Sturgeon.

Potential changes to aquatic resources due to North Bay Aqueduct operations

North Bay Aqueduct Barker Slough Pumping Plant operations would not differ between the No Action Alternative and current conditions, so the effects to Green Sturgeon would be expected to be similar under the No Action Alternative as currently occurring. Green Sturgeon are expected to be fully screened at this facility.

Potential changes to aquatic resources due to water transfers

Under the No Action Alternative, the water transfer window would remain the same as currently in place, i.e., July to September. Green Sturgeon may benefit from increased flow velocities in Delta channels during the expanded transfer window and effects from entrainment at the south Delta facilities is limited due to the low occurrence of Green Sturgeon at the salvage facilities.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Continuation of the current aquatic weed removal program in Clifton Court Forebay under the No Action Alternative would be expected to have little effect on Green Sturgeon because the occur infrequently at the SWP.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Under the No Action Alternative, potential effects from the Tracy and Skinner fish facilities would continue as currently occurring. This includes mortality from pre-screen loss, collection, handling, transport, and release. The potential effects from the Tracy and Skinner fish salvage facilities under the No Action Alternative would be limited by continued management based on the NMFS (2009) BO RPA.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Under the No Action Alternative, the Suisun Marsh facilities would continue to be operated as currently occurs, with potential limited effects related to entrainment. However, monitoring near some facilities have no identified Green Sturgeon and the configuration of the diversions combined with the strong swimming ability of juvenile Green Sturgeon suggests only limited effects are likely.

Potential changes to aquatic resources due to tidal habitat restoration

Under the No Action Alternative, completion of the 8,000 acres of tidal habitat restoration required by the USFWS (2008) BO would add approximately 6,000 acres of tidal habitat relative to current conditions. This has the potential to provide positive effects on Green Sturgeon as a result of increased food availability, and rearing habitat. Potential negative effects from contaminants (e.g., methylmercury) would be addressed with minimization measures.

O.3.2.9 *Nearshore Pacific Ocean on the California Coast*

O.3.2.9.1 Southern Resident Killer Whale

Potential changes to Southern Resident Killer Whale from Chinook Salmon prey abundance

As summarized in the ROC LTO BA, potential effects to Southern Resident Killer Whale as a result of SWP/CVP operations could occur as a result of effects to Chinook Salmon prey abundance; Central Valley Chinook Salmon have generally medium priority among other stocks in the diet of Southern Resident Killer Whale, and hatchery influence appears to be large. The potential effects of the No Action Alternative on Chinook Salmon are described above in Section O.3.2.1, *Trinity River*; O.3.2.2, *Sacramento River*; O.3.2.3, *Clear Creek*; O.3.2.4, *Feather River*; O.3.2.5, *American River*; O.3.2.6, *Stanislaus River*; O.3.2.7, *San Joaquin River*; and O.3.2.8, *Bay Delta*. Under the No Action Alternative, such effects generally would continue similar to current conditions, which include water operations and other activities as a result of the NMFS (2009) BO that are not likely to result in local depletion of Southern Resident Killer Whale prey (NMFS 2009c: 718). Effects on Southern Resident Killer Whales are potentially limited by the medium importance of Central Valley Chinook Salmon stocks to Southern Resident Killer Whale diet and the relatively high representation of hatchery-origin juvenile Chinook Salmon, many of which are released downstream of the Delta (Reclamation 2019).

O.3.3 Alternative 1 – Project-Level Effects

O.3.3.1 *Trinity River*

O.3.3.1.1 Seasonal Operations

Under Alternative 1, seasonal operations in Trinity Reservoir would continue to be integrated with Shasta Reservoir operations, as described in the No Action Alternative.

Potential changes to aquatic resources from changes in reservoir storage

Model results predict that under Alternative 1, storage volume in Trinity Lake would remain the same as under the No Action Alternative in most water year types. However, in dry and critically dry water years (40-30-30 Index) storage volume would increase throughout the entire year compared to the No Action Alternative (Figure O.3-14). On average, storage is expected to increase by 63 TAF under Alternative 1 in dry and critically dry years.

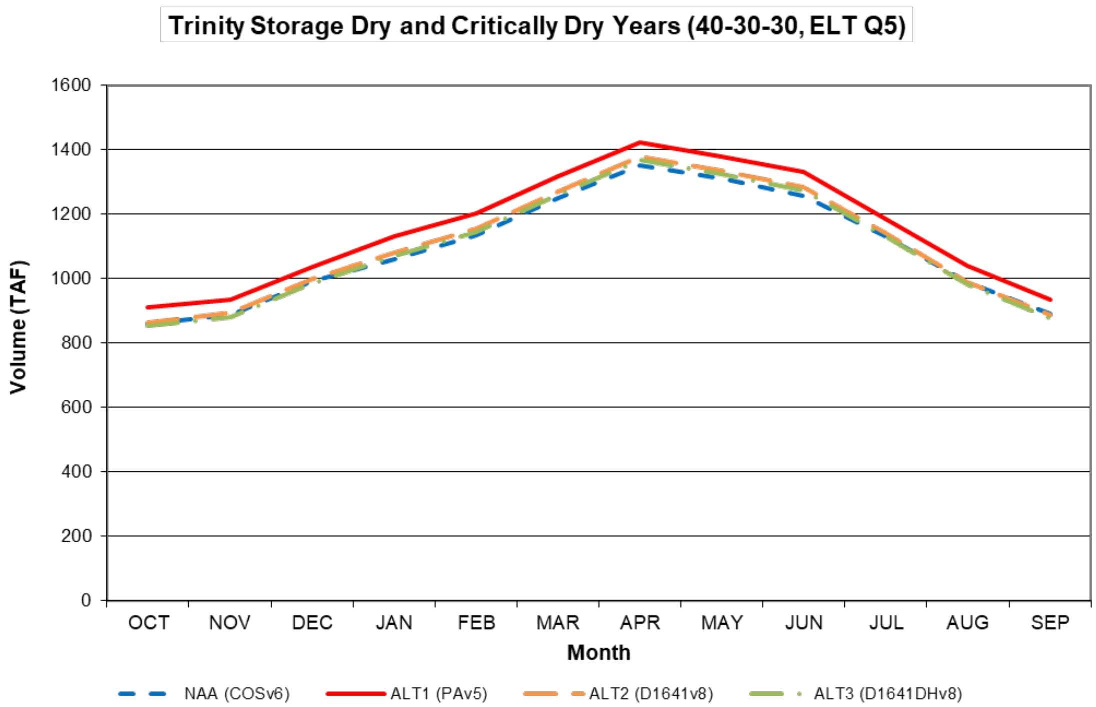

Figure O.3-14. Average Monthly Storage in Trinity Lake for the No Action Alternative and Alternatives 1, 2, and 3 in Dry and Critically Dry Water Year Types (40-30-30 Index)

The effects of changes in reservoir storage conditions as they relate to water temperature can be assessed by looking at temperatures in the Trinity River downstream of Trinity Dam. Average monthly water temperatures in the Trinity River downstream of Trinity Dam would remain similar under Alternative 1 compared to the No Action Alternative (Figure O.3-15). Maximum modeled water temperatures in the Trinity River downstream of Trinity Dam are generally similar under Alternative 1 compared to the No Action Alternative except in August when temperatures are approximately 4°F higher under Alternative 1 and in October when temperatures are approximately 4°F lower under Alternative 1 compared to the No Action Alternative.

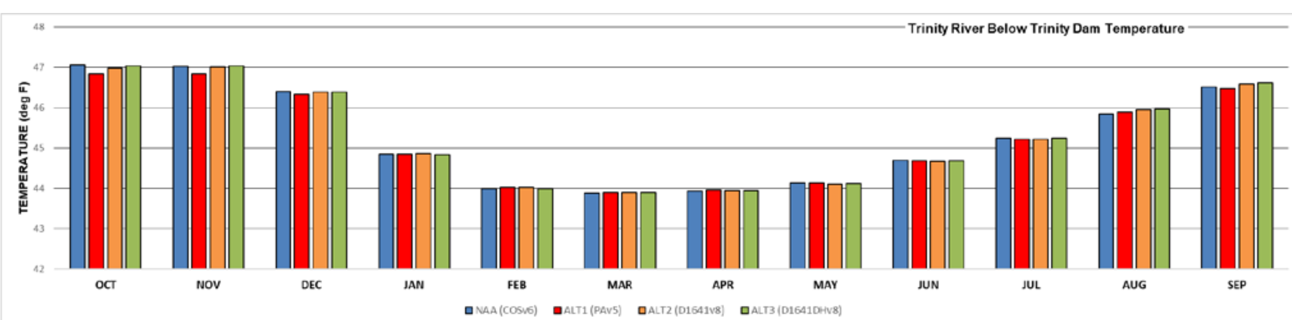

Figure O.3-15. Average Trinity River Water Temperatures below Trinity Dam for the period October to September, Average of All Water Year Types

No focal fish species occur in Trinity Lake or in the Trinity River downstream of Trinity Dam. Effects of Trinity Reservoir storage on fish in the Trinity River downstream of Lewiston Dam are described below.

Potential changes to aquatic resources from variation in flow

Under Alternative 1 flows in the Trinity River downstream of Lewiston Dam would be similar to flows under the No Action Alternative in most months and water year types. However, in wet years, flows would increase in December under Alternative 1 compared to the No Action Alternative (1,297 cfs versus 1,192 cfs). In above normal water years, flows under Alternative 1 would decrease in November compared to the No Action Alternative (625 cfs versus 678 cfs) and increase in February compared to the No Action Alternative (833 cfs versus 528 cfs). In critically dry years, flows under Alternative 1 would decrease compared to the No Action Alternative in September and October from 870 cfs to 818 cfs and from 342 cfs to 311 cfs, respectively. November flows would increase in critically dry years from 275 cfs to 300 cfs compared to the No Action Alternative.

Coho Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 1 compared to the No Action Alternative. Minor differences (<10%) in November and December of some water year types may affect spawning and juvenile rearing habitat for Coho Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), this difference in flow is not expected to result in a detectable effect on Coho Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in February of above normal water years would increase by approximately 58% under Alternative 1 (833 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Coho Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Spring-Run Chinook Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 1 compared to the No Action Alternative. Minor differences (<10%) in November of some water year types may affect spawning and juvenile rearing habitat for Spring-Run Chinook Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), this difference in flow is not expected to result in a detectable effect on Spring-Run Chinook Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in above normal water years in February would increase by approximately 58% under Alternative 1 (833 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Spring-Run Chinook Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Fall-Run Chinook Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 1 compared to the No Action Alternative. Minor differences (<10%) in November of some water year types may affect spawning habitat for Fall-Run Chinook Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), this difference in flow is not expected to result in a detectable effect on Fall-Run Chinook Salmon spawning habitat (USFWS 1999). Flows in February of above normal water years would increase by approximately 58% under Alternative 1 (833 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Fall-Run Chinook Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Steelhead (Winter- and Summer-Run)

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 1 compared to the No Action Alternative. Flow under Alternative 1in February of above normal water years would increase by approximately 58% (833 cfs) compared to the No Action Alternative (528 cfs). This increase in flow may reduce the amount of spawning habitat for Steelhead. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999: 123), increasing flows from 500 cfs to 800 cfs showed little change in the amount of spawning habitat for Steelhead in the Trinity River from downstream of Lewiston Dam to the confluence with Dutch Creek.

Green Sturgeon

Green Sturgeon occur within the lower 43 miles of the Trinity River, approximately 70 miles downstream of Lewiston Dam. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in flow under Alternative 1 would not affect Green Sturgeon.

White Sturgeon

White Sturgeon are not likely to be affected by changes in reservoir operations under Alternative 1 compared to the No Action Alternative due to their limited distribution in the lower Klamath River, primarily in the estuary.

Pacific Lamprey

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 1 compared to the No Action Alternative. However, minor differences (<10%) in flow would exist under Alternative 1 in November and December of some water year types and more significant increases in flow in February of above normal water years (833 cfs compared to 528 cfs under the No Action Alternative) are expected. Increased flows in February overlap with the Pacific Lamprey adult migration period but are not expected to affect migration because Pacific Lamprey migration spans multiple seasons and associated flows. Although previous flow habitat relationship studies in the Trinity River (USFWS 1999) did not focus on Pacific Lamprey, results for salmonids suggest that changes in flow under Alternative 1 would not result in a detectable effect on juvenile rearing or adult holding habitat for Pacific Lamprey compared to the No Action Alternative.

American Shad

American Shad are primarily found in the lower Klamath River but may occur in the lower sections of the Trinity River up to approximately RM 24 at the town of Willow Creek. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in flow under Alternative 1 would not affect American Shad.

Potential changes to aquatic resources due to variation in temperature

Modeling results indicate that monthly average water temperature in the Trinity River downstream of Lewiston Dam would be similar between the No Action Alternative and Alternative 1. Differences in monthly average temperature between Alternative 1 and the No Action Alternative are less than 0.5°F for all months of the year (Figure O.3-16). Modeled maximum temperatures in the Trinity River are lower under Alternative 1 compared to the No Action Alternative in July and October and higher in August, September, and December, with similar maximum temperatures in the remaining months (Figure O.3-17 and Table O.3-4).

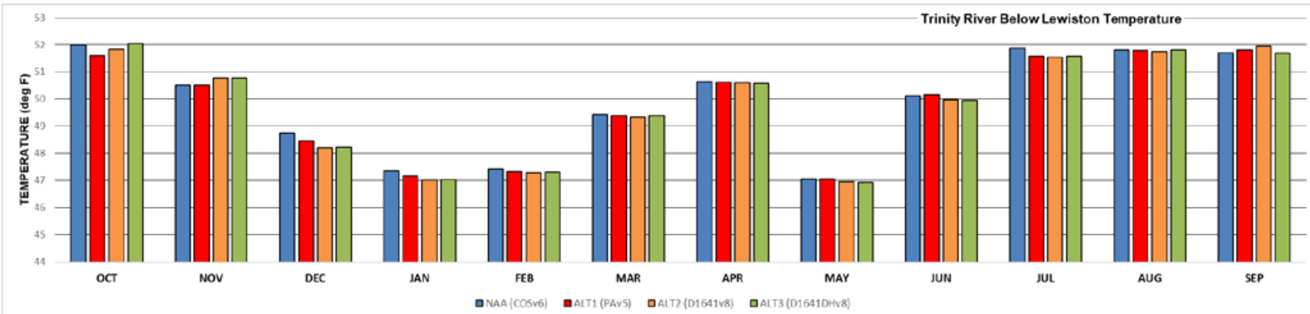

Figure O.3-16. Average Trinity River Water Temperatures below Lewiston Dam for the Period October to September, Average of All Water Year Types

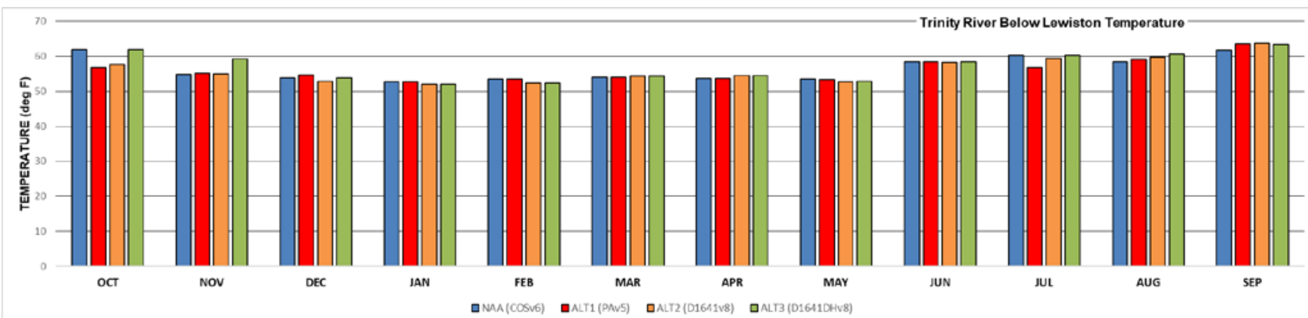

Figure O.3-17. Maximum Trinity River Water Temperatures below Lewiston Dam for the Period October to September, Average of All Water Year Types

Table O.3-4. Maximum Trinity River Water Temperatures below Trinity Dam for the Period October–September, Average of All Water Year Types (Differences >1°F Are Highlighted)

Alt	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
No Action Alternative	61.8	54.8	53.8	52.7	53.4	54.1	53.7	53.5	58.4	60.3	58.4	61.8
ALT 1	56.7	55.2	54.6	52.6	53.5	54.0	53.7	53.4	58.4	56.9	59.1	63.5
ALT 2	57.6	55.1	52.8	52.0	52.4	54.4	54.5	52.7	58.4	59.4	59.7	63.8
ALT 3	61.9	59.3	53.9	52.0	52.4	54.4	54.5	52.9	58.4	60.3	60.6	63.4

In a previous study that looked at flow and water temperatures in the Trinity River (USFWS 1999), results indicated that flows do not have a significant influence on water temperatures from mid-October through early April when cooler air temperatures help maintain cold water temperatures even when flow releases drop below 150 cfs. Once tributary influence begins to decrease and meteorological conditions warm from May to mid-July, flow releases become more influential on downstream temperatures, particularly during hot-dry conditions. Maintaining a flow of 450 cfs during the summer and early fall was found to meet the water temperature objectives for the Trinity River when water released from Lewiston Dam was 53°F or less (USFWS 1999: 203). Water temperatures are most influenced by flow releases from May through mid-October. Flows from May through October would be similar under Alternative 1 compared to the No Action Alternative in most water year types, with the exception of critically dry water years. In critically dry water years under Alternative 1, flows in September and October would decrease by approximately 6% to 9% compared to the No Action Alternative, from 870 cfs to 818 cfs and from 342 cfs to 311 cfs, respectively. Based on modeling results, changes in flow under Alternative 1 are not likely to have a detectable change in water temperature in the Trinity River downstream of Lewiston Dam in all but critically dry years.

Coho Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 1 compared to the No Action Alternative. Monthly average temperatures are slightly lower under Alternative 1 than under the No Action Alternative, with water temperatures up to 1°F lower under Alternative 1 in July, September, and October and less than 1°F higher from November to January (Figure O.3-16). Modeled maximum temperatures in the Trinity River are approximately 3°F to 5°F lower under Alternative 1 compared to the No Action Alternative in July and October and approximately 1°F to 2°F higher in August, September, and December with similar maximum temperatures in the remaining months. Maximum temperatures under Alternative 1 in August and September exceed the NCRWQCB (2018) objectives for the Trinity River. Under both the No Action Alternative and Alternative 1, water temperatures exceed the NCRWQCB objectives during this time; however, further increases in temperature that would occur under Alternative 1 may further reduce juvenile Coho Salmon rearing success. Conversely, the decreased maximum temperatures under Alternative 1 in July meet the NCRWQCB (2018) objectives for the Trinity River, and the cooler October water temperatures are likely to improve juvenile rearing conditions compared to the No Action Alternative.

Spring-Run Chinook Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 1 compared to the No Action Alternative. Monthly average temperatures would be slightly lower under Alternative 1 than under the No Action Alternative, with water temperatures up to 1°F lower under Alternative 1 in July, September, and October and less than 1°F higher from November to January (Figure O.3-16). Modeled maximum temperatures in the Trinity River would be approximately 3°F to 5°F lower under Alternative 1 compared to the No Action Alternative in July and October and approximately 1°F to 2°F higher in August, September, and December, with similar maximum temperatures in the remaining months. Spring-Run Chinook Salmon spawning usually peaks in October but typically ranges from the third week of September through November. Maximum August and September temperatures would exceed the NCRWQCB (2018) objectives for the Trinity River under both the No Action Alternative and Alternative 1. However, the further increases in temperature that would occur under Alternative 1 may reduce Spring-Run Chinook Salmon adult migration and spawning success. Conversely, the reduced maximum temperatures predicted under Alternative 1 in July meet the NCRWQCB (2018) objectives for the Trinity River and are likely to improve Spring-Run Chinook Salmon adult migration compared to conditions under the No Action Alternative, while decreased temperatures in October would improve spawning conditions compared to conditions under the No Action Alternative.

Fall-Run Chinook Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 1 compared to the No Action Alternative. Monthly average temperatures are slightly lower under Alternative 1 than under the No Action Alternative, with water temperatures up to 1°F lower under Alternative 1 in July, September, and October and less than 1°F higher from November to January (Figure O.3-16). Modeled maximum temperatures in the Trinity River are approximately 3°F to 5°F lower under Alternative 1 compared to the No Action Alternative in July and October and approximately 1°F to 2°F higher in August, September, and December, with similar maximum temperatures in the remaining months. Fall-Run Chinook Salmon spawning usually occurs between October and December, with peak spawning activity occurring in November. Maximum August and September temperatures would exceed the NCRWQCB (2018) objectives for the Trinity River under both the No Action Alternative and Alternative 1. However, the further increases in temperature that would occur under Alternative 1 may negatively affect Fall-Run Chinook Salmon adult migration compared to the No Action Alternative. Conversely, reduced October temperatures predicted under Alternative 1 would improve spawning conditions compared to conditions under the No Action Alternative.

Steelhead (Winter-Run and Summer-Run)

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 1 compared to the No Action Alternative. Monthly average temperatures would be slightly lower under Alternative 1 than under the No Action Alternative, with water temperatures up to 1°F lower under Alternative 1 in July, September, and October, and less than 1°F higher from November to January (Figure O.3-16). Modeled maximum temperatures in the Trinity River would be approximately 3°F to 5°F lower under Alternative 1 compared to the No Action Alternative in July and October, and approximately 1°F to 2°F higher in August, September, and December, with similar maximum temperatures in the remaining months. Maximum temperatures under Alternative 1 would increase in August and September, exceeding the NCRWQCB (2018) objectives for the Trinity River. Under both the No Action Alternative and Alternative 1, water temperatures would exceed the NCRWQCB objectives in this time. However, the larger increases in temperature that would occur under Alternative 1 may further reduce juvenile Steelhead rearing success. Conversely, the reduced maximum temperatures under Alternative 1 that would occur in July meet the NCRWQCB (2018) objectives for the Trinity River, and the cooler temperatures in October, would improve juvenile rearing conditions compared to the No Action Alternative.

Green Sturgeon

Green Sturgeon occur within the lower 43 miles of the Trinity River, approximately 70 miles downstream of Lewiston Dam. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Results of previous water temperature modeling for the Trinity River (USFWS 1999) predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43 with smaller temperature differences expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers. Therefore, changes in flow and water temperature under Alternative 1 would not affect Green Sturgeon.

White Sturgeon

White Sturgeon would not be affected by changes in reservoir operations under Alternative 1 compared to the No Action Alternative due to their limited distribution in the lower Klamath River, primarily in the estuary.

Pacific Lamprey

Model results predict that water temperatures in the Trinity River below Lewiston Dam would be similar under Alternative 1 compared to the No Action Alternative. Monthly average temperatures would be slightly lower under Alternative 1 than under the No Action Alternative, with water temperatures up to 1°F lower under Alternative 1 in July, September, and October, and less than 1°F higher from November to January (Figure O.3-16). Maximum temperatures in the Trinity River would be approximately 3°F to 5°F lower under Alternative 1 compared to the No Action Alternative in July and October, and approximately 1°F to 2°F higher in August, September, and December, with similar maximum temperatures in the remaining months. Maximum temperatures under Alternative 1 in August and September would exceed the NCRWQCB (2018) objectives for the Trinity River and may reduce Pacific Lamprey juvenile rearing success; however, decreased temperatures under Alternative 1 in July and October are likely to improve juvenile rearing conditions compared to the No Action Alternative.

American Shad

American Shad are primarily found in the lower Klamath River but may occur in the lower sections of the Trinity River up to approximately RM 24 at the town of Willow Creek. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Results of previous water temperature modeling for the Trinity River (USFWS 1999) predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 24 with smaller temperature differences expected downstream to the confluence of the Trinity and Klamath Rivers. Therefore, changes in water temperature under Alternative 1 would not affect American Shad.

O.3.3.1.2 Trinity River Record of Decision

The Trinity River ROD is being implemented under both Alternative 1 and the No Action Alternative. Therefore, implementation of the variable annual flow regime, restoration actions, and monitoring and adaptive management, per the Trinity River ROD under Alternative 1 would have similar effects as the No Action Alternative on Coho Salmon, Chinook Salmon (Spring- and Fall-Run), Steelhead (Winter- and Summer-Run), Green Sturgeon, White Sturgeon, Pacific Lamprey, and American Shad.

O.3.3.2 *Sacramento River*

Potential changes to aquatic resources in the Sacramento River from seasonal operations

Under all the Project alternatives, flows in the upper Sacramento River result from controlled releases from Shasta and Keswick reservoirs, as well as transfers from the Trinity River and natural accretions. The releases and transfers are determined by a suite of laws, regulations, contracts, and agreements to address demands of water users, requirements for water quality, and needs of fish populations throughout the river and the Delta. In particular, operations of all the alternatives are regulated by SWRCB's D-1641 decision, which requires flow releases to meet Delta standards, and their WRO 90-5 decision, which requires cold water releases to meet temperature targets at compliance points in the upper Sacramento River. Dry hydrologic conditions often lead to inadequate storage in Shasta for operators to provide suitable conditions for salmonids and other native species in the upper Sacramento River. In most cases, however, water temperature rather than flow is the limiting factor creating unsuitable conditions, as discussed below. The primary differences between the No Action Alternative and Alternative 1 for the Sacramento River upstream of the Delta with regard to seasonal operations is in operations of Shasta and Keswick reservoirs for coldwater pool management and the No Action Alternative requirement for Fall X2. The other proposed Alternative 1 components that are integral to seasonal operations include Shasta Cold Water Pool Management and Fall and Winter Refill and Redd Management. The effects of these components, especially with respect to water temperatures, are included in the following discussion of seasonal operations under Alternative 1.

CalSim II modeling indicates that average flow released at Keswick Dam under Alternative 1 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 1 flows would be substantially lower than the No Action Alternative flows (Table O.3-5). The higher September and November flows under the No Action Alternative result from Fall X2 releases, which are not included in Alternative 1. Table O.3-5 shows that the highest flows for both alternatives occur primarily during winter of wet and above normal water years and during summer of all water year types. Flow releases are high during summer to satisfy downstream demands of water users and Delta water quality, and to meet water temperature requirements of incubating Winter-Run Chinook Salmon eggs and alevins downstream of Keswick Dam. A minimum flow of 3,250 cfs is required from Keswick Dam to the RBDD during October through March (NCWA 2014).

Under the No Action Alternative and Alternative 1, the upper Sacramento River's water temperatures are controlled by selective withdrawal through the temperature control device (TCD) in Shasta Reservoir and by balancing releases between Lewiston (Trinity River) and Shasta reservoirs. The water temperature operations have three principal objectives: 1) provide enough cold water to optimize survival of the current year's Winter-Run Chinook Salmon eggs and alevins and those of other salmonids (Chinook Salmon and steelhead), 2) stabilize water levels through the fall to avoid dewatering redds and stranding juveniles of Winter-Run and other salmonids, and 3) conserve and rebuild Shasta storage in the fall and winter to provide the coldwater pool resources needed to optimize survival of the next year's Winter-Run eggs and alevins and those of other salmonids. Protection of other salmonids, especially Spring-Run Chinook Salmon and steelhead, is an important objective, but Winter-Run Chinook Salmon is the principal target of operations because it alone has no spawning habitat other than that in the upper Sacramento River (with some recent spawning in Battle Creek and Clear Creek). The seasonal operation of the TCD is generally as follows: during winter, early spring, and as long thereafter as possible, the highest elevation gates are utilized to draw water from the upper portions of the reservoir and conserve the deeper, colder water; during late spring and summer, the operators begin the seasonal progression of opening deeper gates as Shasta Reservoir surface elevation decreases, cold water is utilized, and downstream warming of the river accelerates; and during late summer and fall, the TCD side gates are opened to utilize the remaining coldwater pool as necessary. This year-round Shasta management program is expected to minimize frequency and duration of temperature-related egg mortality of Winter-Run and other salmonids in dry and critically dry years, thus reducing, though not eliminating, the population level stress of these temperature-related mortalities (NMFS 2011).

The main changes in water temperature management between the No Action Alternative and Alternative 1 would be in how the TCD would be operated to preserve sufficient coldwater pool through the summer and fall, the water temperature thresholds adopted for protection of Winter-Run and other salmonids, and the addition of real-time monitoring of Winter-Run behavior to support decision making. The water temperature threshold adopted for protection of salmonids under No Action Alternative operations is 56°F. However, high mortalities during recent extreme drought years and new analytical tools have demonstrated that a 56°F temperature limit does not sufficiently safeguard Winter-Run eggs and alevins (NMFS 2017a, Martin et al. 2017; Anderson 2018). Based on analyses using the new analytical tools, the Alternative 1 operations would use a water temperature threshold of 53.5°F.

Under the proposed Alternative 1 Shasta Cold Water Pool Management, operations during summer and fall would be based on the coldwater pool storage on May 1, combined with summer and fall predictions from water temperature modeling. In years with high May 1 coldwater pool storage (> 2.8 MAF), operators would manage temperature releases to maintain a water temperature of 53.5°F in the Sacramento River upstream of the Clear Creek confluence (CCR) beginning when real-time monitoring indicated that the Winter-Run population had begun spawning and ending October 31, or when fry had emerged from an estimated 95% of the Winter-Run redds, whichever was earlier. In years with an intermediate level of May 1 cold water storage, the coldwater pool is generally insufficient to maintain 53.5°F at CCR through October, so operations would target developmental-stage-specific requirements of Winter-Run eggs and alevins, maintaining the 53.5°F threshold only for the period when the most temperature-sensitive developmental stage would be present. This period would be estimated from modeling using the new analytical tools discussed above (Martin et al. 2017; Anderson 2018). The duration of the 53.5°F protection period would be adjusted in proportion to the available coldwater pool on May 1. In years with low May 1 coldwater pool storage (e.g., <2.3 MAF), the temperature maintained at CCR would be gradually increased up to 56°F as necessary to conserve remaining coldwater pool through the period of Winter-Run egg and alevin incubation. Operators would minimize adverse effects of the higher water temperatures to the greatest extent possible, as determined by the latest egg mortality models, real-time monitoring, and current and expected future water availability. Finally, if operators could no longer maintain 56°F at CCR, they would operate to a less than optimal duration and temperature target, which would be determined in real-time with technical assistance from NMFS and USFWS. A more complete description of the Alternative 1 proposed water temperature management operations is provided in Chapter 4, *Proposed Action*..

Reclamation would regularly evalute the performance of the coldwater pool management by monitoring egg to fry survival in the river and compare actual survival levels with those expected from modeling. If actual mortality was greater than expected, Reclamation would work with the SRTTG to develop alternative protective strategies and measures for the early life stages. The egg to fry survival monitoring and associated actions is discussed in detail in in Chapter 4, *Proposed Action*.

Different measures would be explored to mitigate effects of the adverse water temperature conditions, including intervention measures such as increasing hatchery intake and trap and haul, as described later. In the fall and winter, reductions in flow releases to conserve storage for the following year would be balanced by the efforts to maintain suitable water temperatures, minimize dewatering redds of Winter-Run and other salmonids, and avoid stranding rearing juveniles. These measures are more fully discussed later under *Potential changes to aquatic resources in the Sacramento River from fall and winter refill and redd* maintenance.

HEC-5Q modeling was used to compare water temperature effects of the No Action Alternative and Alternative 1. It is important to understand, however, that the modeling does not provide a complete characterization of water temperature effects associated with Alternative 1 because it relies on shutter (TCD) operations for Alternative 1 that are quite similar to those of the No Action Alternative, which does not accurately represent actual shutter operation under Alternative 1. Furthermore, the HEC-5Q modeling includes little of the effects expected from the water temperature management improvements proposed for Alternative 1. These include the risk based water temperature management approach described above, the proposed operations of an improved TCD (as previously described), and a number of the other proposed measures described later, all of which would facilitate increased cold water storage, resulting in greater availability of cold water for protection of salmonids, especially in the late summer and early fall.

An additional caution regarding the HEC-5Q water temperature modeling results, particularly with regard to meeting water temperature criteria (e.g., 53.5°F water temperature at CCR criterion), relates to the time step used in the modeling. HEC-5Q, like the CalSim II model on which it relies for flow data, has a monthly time step and provides estimates of monthly mean water temperatures. However, most of the regulatory requirements to meet water temperature criteria apply to daily mean (or shorter duration) water temperatures. Daily means tend to be much more variable than monthly means and, therefore, the monthly mean water temperature estimates provided by HEC-5Q are not directly comparable to these regulatory criteria. For example, even with constant flows, daily water temperatures would fluctuate around the mean in response to variation in solar radiation and other meteorological conditions within a given month. In view of this limitation, it is helpful to consider the comparisons of temperature effects among the alternatives as indicating the relative likelihoods of exceeding temperature criteria, rather than whether or not the criteria are actually met. These considerations apply to the CalSim II flow data as well, but are less important for flow because there are fewer regulatory criteria for flow and, except during storm events, flow tends to be less variable than water temperature.

During the summer and much of the fall, water released from Keswick Dam warms downstream, resulting in warmer water temperatures in more downstream habitats. Therefore, the effects of the alternatives on fish populations depend on the habitat distributions of the populations as well as the results of temperature management operations. Winter-Run mostly spawn from Keswick Dam to about 6 miles downstream of the Clear Creek temperature gage, Spring-Run from Keswick Dam to about Balls Ferry, fall-run from Keswick Dam to about RBDD, late fall-run spawning distribution is similar to that of Winter-Run, and Green Sturgeon spawn downstream of the Cow Creek confluence to the GCID oxbow near Hamilton City (NMFS 2018b). Steelhead spawning areas in the upper Sacramento River are poorly known.

Based on the HEC-5Q modeling, the mean monthly water temperatures at Keswick Dam are roughly equal under the No Action Alternative and Alternative 1, except for October of wet, above normal, and dry water years, which have 1.3 to 1.5°F lower mean water temperatures under Alternative 1 than under the No Action Alternative, and August of dry years, which has 1.0°F lower mean water temperature under Alternative 1 (Table O.3-6). Note that the October mean water temperatures under the No Action Alternative are just above the 53.5°F temperature threshold and those under Alternative 1 are just below the threshold (Table O.3-6). A more detailed examination of this difference shows that mean October water temperatures are predicted to be less than the temperature threshold in 20% of the years under the No Action Alternative, while under Alternative 1 they are predicted to be less than the threshold in two-thirds of the years (Figure O.3-18). For August, the mean water temperatures are predicted to be below the threshold in 75% of years under the No Action Alternative and 91% of years under Alternative 1 (Figure O.3-19). Therefore, although the differences in October and August water temperatures between the No Action Alternative and Alternative 1 are not large, they occurs over a critical range for salmonids eggs and alevins. The largest predicted increase in mean water temperature under Alternative 1 is 0.9°F for September of Above Normal water years (Table O.3-5). This increase occurs over a range well below the critical temperature threshold and is therefore less likely to have a large effect on the salmonids. The differences between the No Action Alternative and Alternative 1 in September water temperatures at Keswick Dam are small (Figure O.3-20) relative to those at more downstream locations, as described below.

Figure O.3-18. HEC-5Q Sacramento River Water Temperatures at Keswick Dam under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; October

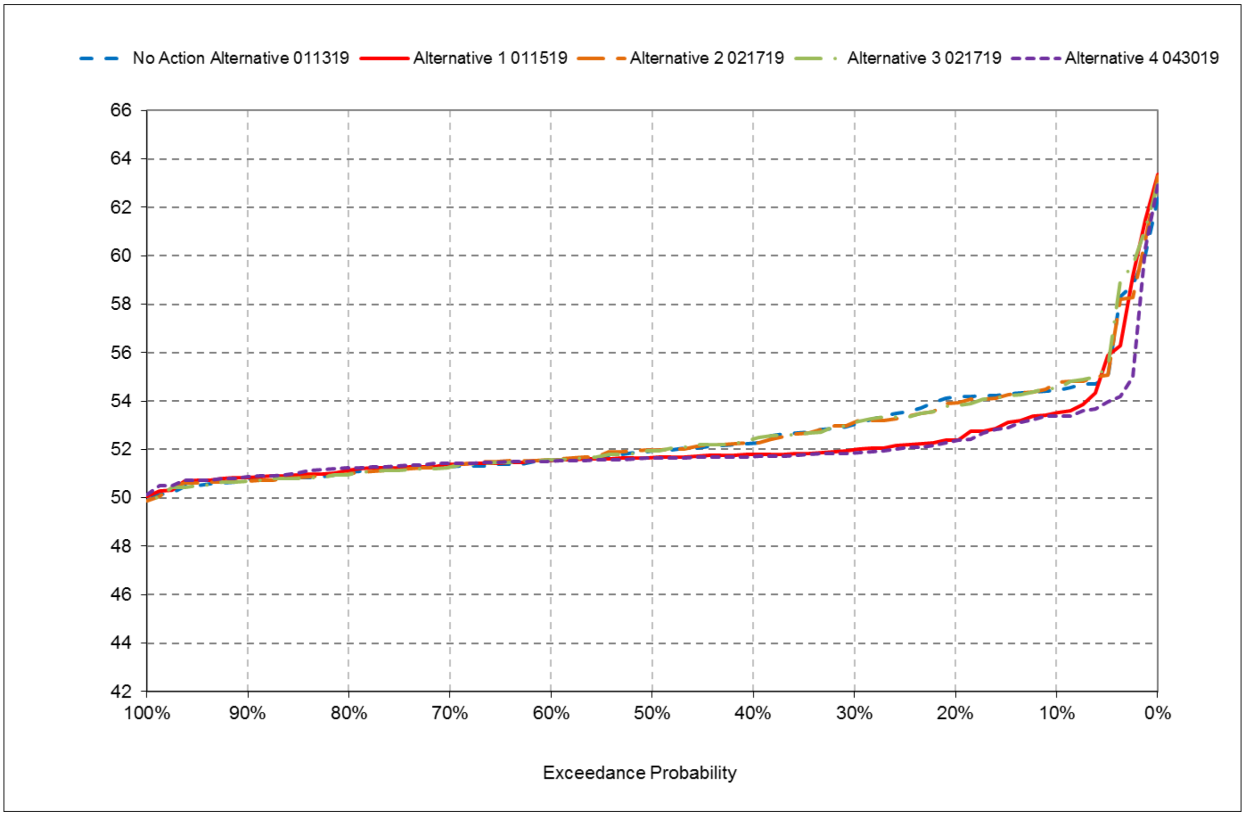

Figure O.3-19. HEC-5Q Sacramento River Water Temperatures at Keswick Dam under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; August

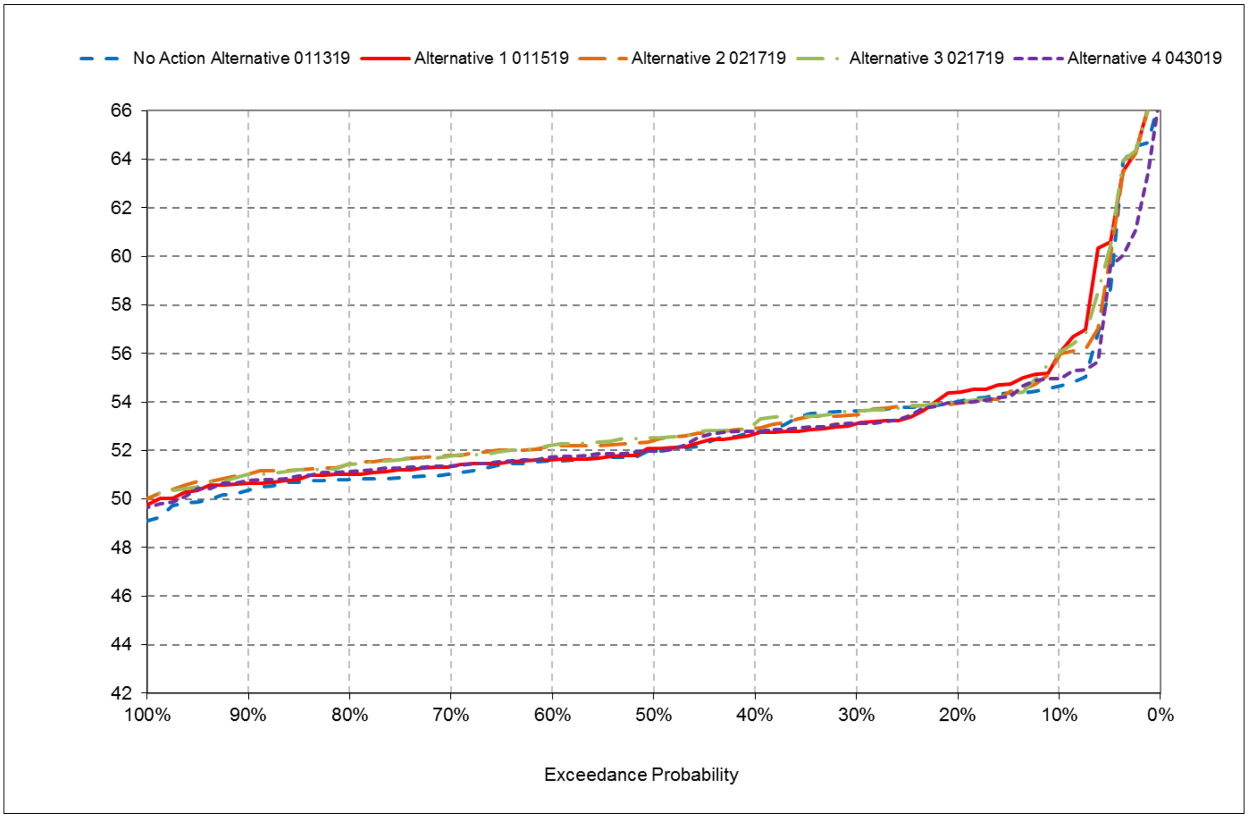

Figure O.3-20. HEC-5Q Sacramento River Water Temperatures at Keswick Dam under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; September

The HEC-5Q results indicate that late spring through early fall water temperatures in the Sacramento River at Clear Creek are slightly warmer than those at Keswick Dam, with larger increases in September water temperature between the No Action Alternative and Alternative 1 (Table O.3-7). At Balls Ferry, the temperatures are warmer still, and the October reductions in water temperature between the No Action Alternative and Alternative 1 are smaller, while the September increases are larger (Table O.3-8). Also, the October and August monthly mean water temperatures exceed the 53.5°F temperature threshold in all water year types under both alternatives (Table O.3-8) and, for the exceedance plots of annual mean October temperatures, the temperatures are below the threshold in only 20% of years under Alternative 1 and in no years under the No Action Alternative (Figure O.3-21). The Balls Ferry water temperature predictions for September are very different, with larger temperature increases from the No Action Alternative and Alternative 1 in wet and above normal water years than those noted for Keswick Dam, and mean water temperatures for these water year types exceeding the critical water temperature threshold under Alternative 1, but not under the No Action Alternative (Table O.3-8). October and November mean water temperatures are above (or equal to) the threshold under both alternatives. As discussed previously, the monthly mean water temperatures provide a rough estimate of the probability of mean daily water temperatures exceeding a temperature threshold. Therefore, when the monthly mean water temperature exceeds the temperature threshold, the probability or frequency of the daily mean temperature exceeding the threshold is greater than when the monthly mean water temperature is less than the threshold.

Figure O.3-21. HEC-5Q Sacramento River Water Temperatures at Balls Ferry under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; October

The downstream trends in water temperature conditions noted for Keswick Dam, Clear Creek and Balls Ferry continue to RBDD, with warmer late spring through early fall temperatures, smaller reductions in the October and August mean monthly temperatures between the No Action Alternative to Alternative 1, and larger increases in the September temperatures between the No Action Alternative and Alternative 1 (Table O.3-9). Under both the No Action Alternative and Alternative 1, the monthly mean water temperatures at RBDD for all water year types in April through October are above the critical water temperature threshold. The exceedance plots for the annual September mean temperatures shows that the temperature differences are largely limited to the cooler 50% of years (Figure O.3-22). These same patterns in water temperatures differences between the No Action Alternative and Alternative 1 continue downstream to Hamilton City and Knights Landing, where there is little difference between the No Action Alternative and Alternative 1 in monthly mean water temperatures in October and August, but relatively large differences (> 4°F) in wet and above normal Septembers (Table O.3-10 and O.3-11; Figures O.3-23 and O.3-24).

Figure O.3-24. HEC-5Q Sacramento River Water Temperatures at Knights Landing under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; September

The reduced downstream warming of the river in September of wet and above normal years under the No Action Alternative relative to the Alternative 1 is due, at least in part, to the much higher flow releases for Fall X2, as noted above (Table O.3-5 and O.3-12 through O.3-14). However, the reduced HEC-5Q mean August and October water temperatures under Alternative 1 (Figures O.3-18 and O.3-19) are likely due, at least in part, to the lower September and November flows under Alternative 1 relative to the No Action Alternative because the water thus conserved is used to reduce water temperature in October of the same year or is used to maintain the coldwater pool for a longer time in the following year. Note that November Fall X2 flow releases under the No Action Alternative do not result in lower downstream water temperatures relative to Alternative 1, because November air temperatures would, on average, be similar to or lower than the water temperatures.

The HEC-5Q temperature results, as previously cautioned, likely overestimate the Alternative 1 summer through early fall water temperatures because the HEC-5Q modeling does not include effects of several major operational and structural proposed water temperature management improvements included in Alternative 1. It is expected that with the proposed improvements included, Alternative 1 would provide cooler summer and fall water temperature releases than the No Action Alternative in all months in most years, with the possible exception of September, when water temperatures are warmer because the Alternative 1 would not include the Fall X2 flows that reduce downstream warming.

O.3.3.2.1 Sacramento River Winter-Run Chinook Salmon

O.3.3.2.2 Spawning and Egg/Alevin Incubation

Winter-Run Chinook Salmon adults spawn from May through August with peak spawning during June and July (Section O.2.4.2.1, *Winter-Run Chinook Salmon*). Fry emergence occurs up to 3 months after eggs are spawned, so effects of flow and water temperature on Winter-Run eggs and alevins may occur from May through November, but primarily occur during June through October.

As previously noted, CalSim II modeling indicates that mean monthly flow released at Keswick Dam under Alternative 1 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 1 flows would be substantially lower than the No Action Alternative flows (Table O.3-5). By September in most years, a large proportion of Winter-Run redds still contain incubating alevins. Assuming flows are stable enough to avoid dewatering the redds, which is generally true in September, the most important effect of flows on alevins is to transport dissolved oxygen to the developing alevins and to flush potentially toxic metabolites out of the redds. Although the mean September wet and above normal water year flows are substantially lower under Alternative 1 than under the No Action Alternative, the flows under Alternative 1 flows remain moderately high (>6,000 cfs) (Figure O.3-25). Flows at this level are expected to provide sufficient flow velocity to keep the redds clean and well oxygenated. With regard to redd dewatering, as described in the previous section, reductions in fall flow releases to conserve storage would be balanced by needs to maintain suitable water temperatures, minimize dewatering redds of Winter-Run and other salmonids, and avoid stranding rearing juveniles. Therefore, differences in flow between the No Action Alternative and Alternative 1 are expected to have little effect on Winter-Run Chinook Salmon spawning and incubation habitat.

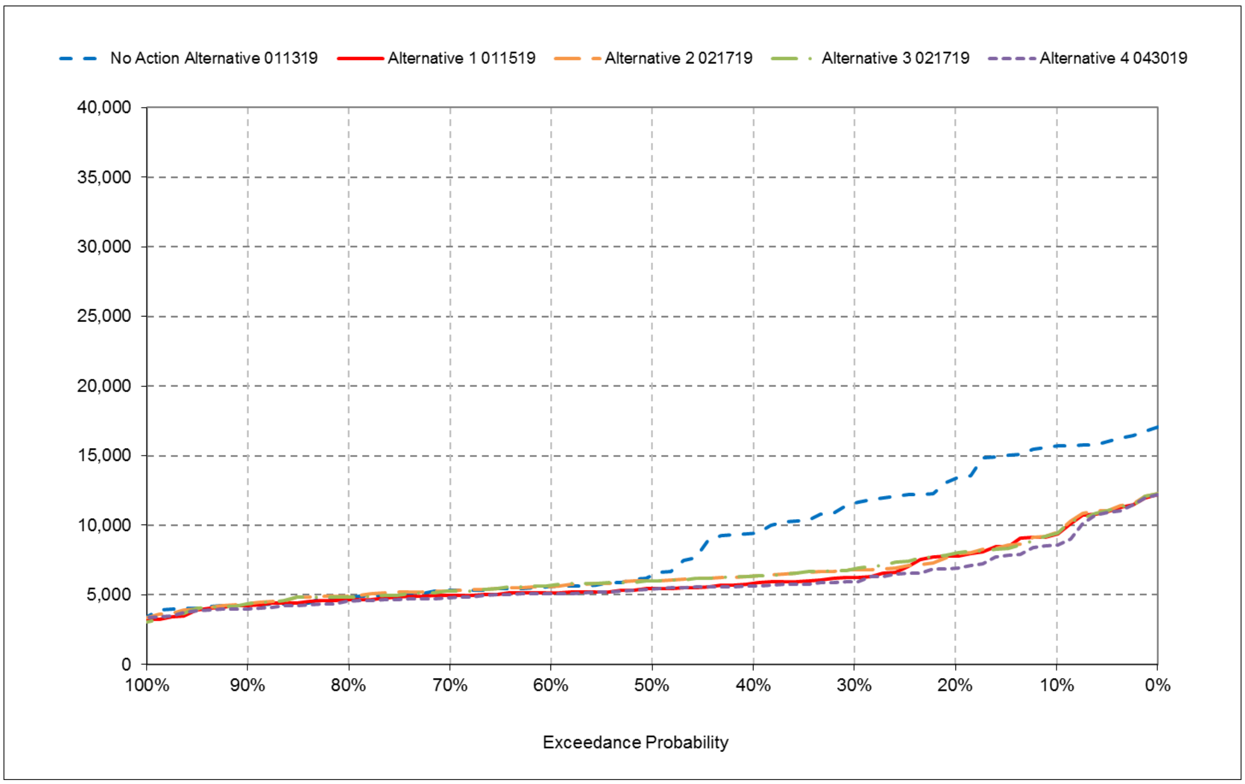

Figure O.3-25. CalSim II Sacramento River Flow at Keswick Dam under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; September

Differences between the No Action Alternative and Alternative 1 in water temperature during the Winter-Run spawning period may be important. As described in the previous section, HEC-5Q mean October water temperatures are predicted to be below the 53.5°F water temperature threshold in the majority of years under Alternative 1 and above the threshold in most years under the No Action Alternative (Figure O.3-18), and in August, the mean water temperatures are predicted to be above the threshold in about 25% of years under the No Action Alternative and 9% of years under Alternative 1 (Figure O.3-19).September water temperatures are expected to be higher under Alternative 1 than under the No Action

Alternative, but the increases are expected only for the most downstream portion of the Winter-Run spawning distribution and primarily for wet and above normal water years, for which the mean temperatures for both alternatives would mostly be below the water temperature threshold (Tables O.3-6 and O.3-7; Figure O.3-20).

The new analytical tools included in the proposed Alternative 1 water temperature management operations are primarily based on models developed from results of field studies during Winter-Run spawning in the upper Sacramento River by Martin et al. (2017) and Anderson (2018). These models, referred to hereinafter as the Matin and Anderson models, were used to compare water-temperature-related mortality of Winter-Run Chinook Salmon eggs and alevins under Alternative 1 and the No Action Alternative. The modeling was based on the HEC-5Q water temperature estimates for the years used in the HEC-5Q modeling (1922 to 2002). The results for all water year types combined indicate that egg/alevin mortality under Alternative 1 would be similar to or lower than that under the No Action Alternative, especially for the 30% to 5% of years with the highest mortality rates (Figure O.3-26). For many of those years, the annual mortality rate under Alternative 1 was almost 0.5 lower than that under the No Action Alternative for Anderson model and almost 0.3 lower for the Martin model. As discussed in the previous section, the proposed Alternative 1 water temperature management improvements are expected to result in significant October and August improvements in temperatures, driving the large reductions in temperature dependent mortality.

Figure O.3-26 combines results for all water year types, including wet years, when there is little temperature-related mortality. This obscures the modeling results for drier years, when egg/alevin mortalities are especially high. For critically dry years, the mortality modeling continues to show substantially lower mortality under Alternative 1 than under the No Action Alternative (Figure O.3-27).

The flow effects resulting from Alternative 1 would have a less-than-significant effect relative to the No Action Alternative on Winter-Run Chinook Salmon spawning and the egg and alevin life stages and the water temperature effects would be beneficial relative to the No Action Alternative.

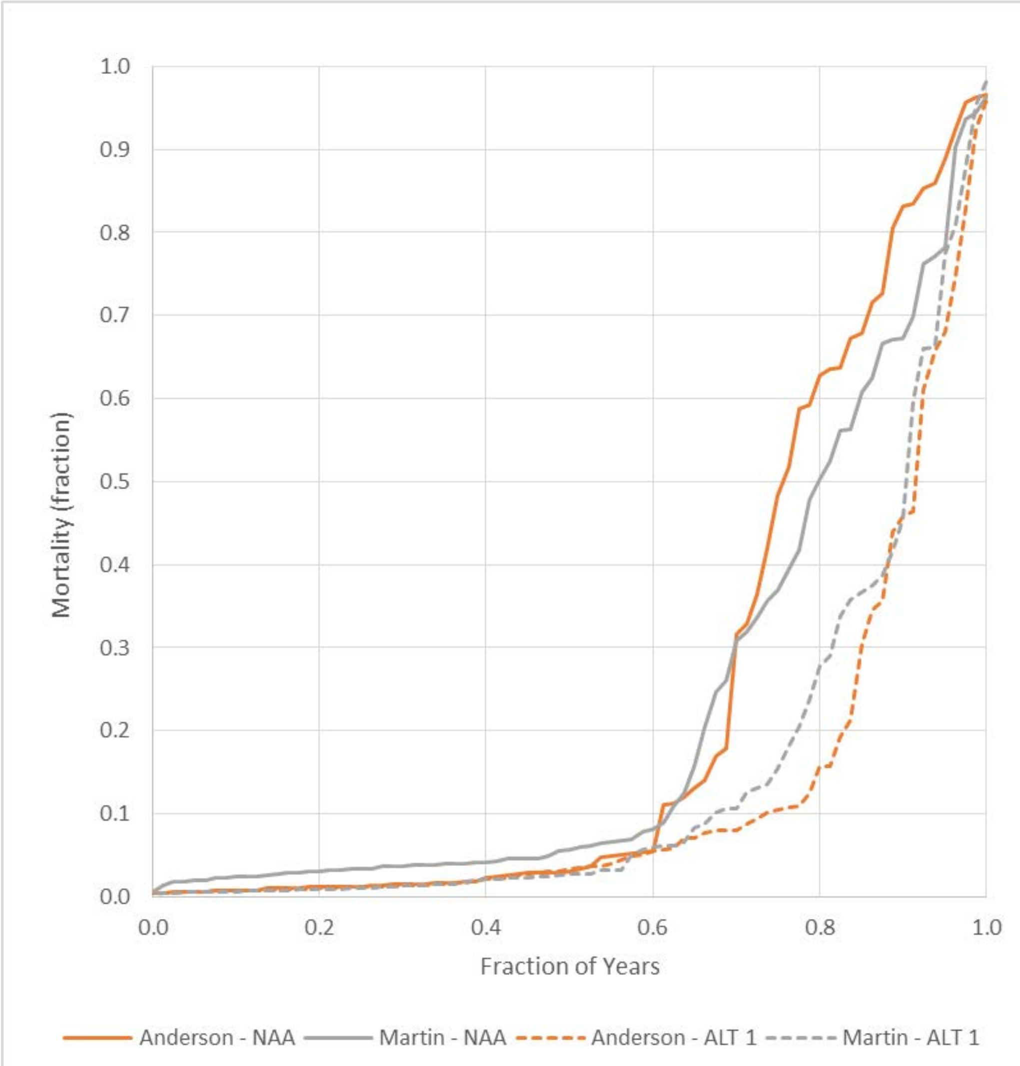

Figure O.3-26. Exceedances of Winter-Run Chinook Salmon Temperature-Dependent Egg Mortality, Alternative 1 vs. No Action Alternative; All Water Year Types.

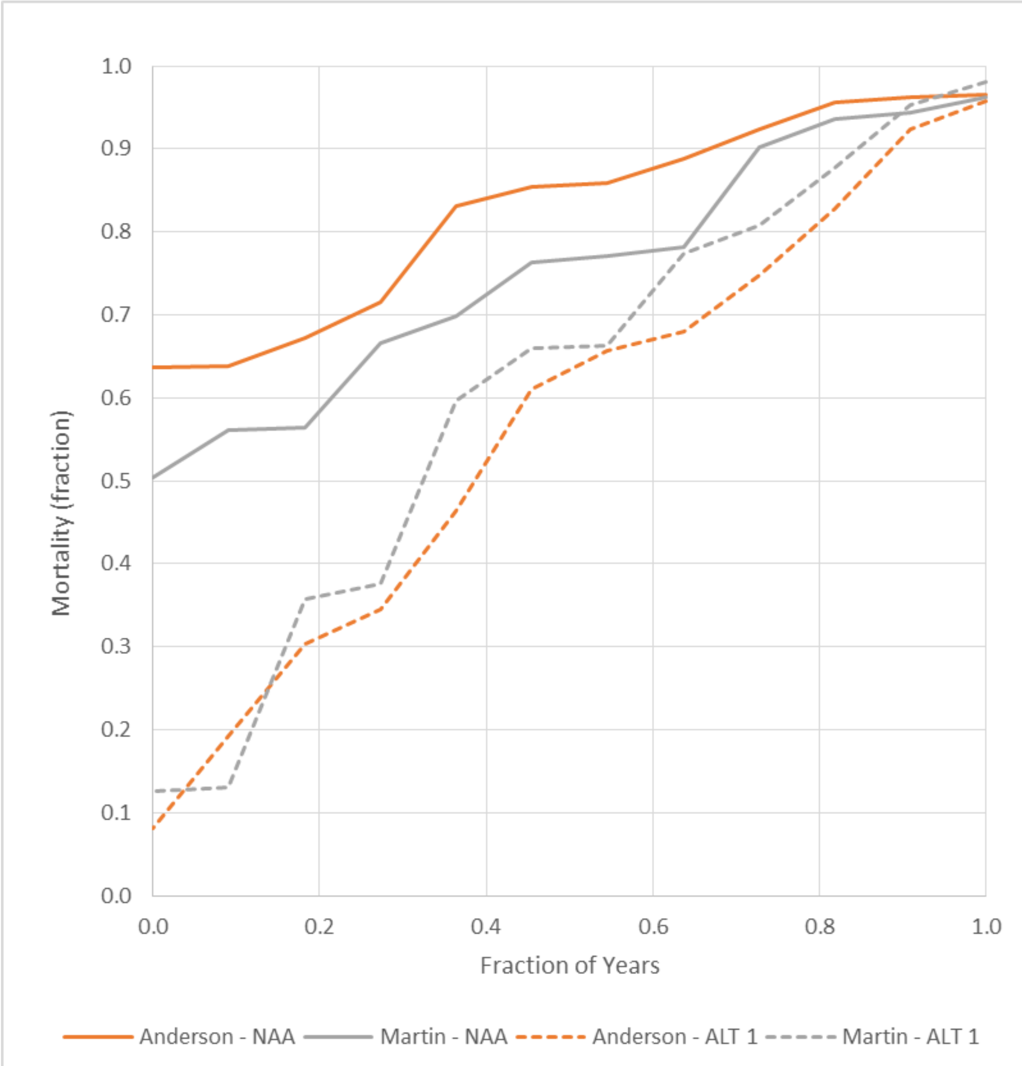

Figure O.3-27. Exceedances of Winter-Run Chinook Salmon Temperature-Dependent Egg Mortality, Alternative 1 vs. No Action Alternative; Critically Dry Water Years

Although the HEC 5Q results show little difference in water temperatures between the No Action Alternative and Alternative 1 in most months, the modeling for Alternative 1 does not include many of the actions of the new water temperature management operations and stuctures proposed for Alternative 1. It is expected that, througout the May through October period of operation, water temperatures under Alternative 1 would generally be more protective of Winter-Run Chinook Salmon spawning and egg/alevin incubation than the No Action Alternative.

Juvenile Rearing and Emigration

Winter-Run Chinook Salmon juveniles rear in the Sacramento River primarily from late summer to late winter, and emigrate from the river to the Delta beginning in November (see Section O.2.4.2.1, *Winter-Run Chinook Salmon*). The proportion of juveniles surviving to emigrate to the Delta depends largely on habitat conditions, including flow and water temperature. Inundated floodplain habitat has been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Sacramento River flow during the Winter-Run juvenile rearing and emigration period differs substantially between the No Action Alternative and Alternative 1 during some months, but the largest differences are generally limited to wetter water year types (Tables O.3-5, O.3-12 through O.3-14). The juveniles rear primarily in the upper and middle Sacramento River until about October, when they begin to appear in the lower river (e.g., Knights Landing) (del Rosario et al. 2013). As noted previously, because the No Action Alternative includes Fall X2 releases but not Alternative 1 does not, the mean monthly flows during September and November are much lower under Alternative 1 than under the No Action Alternative, which would potentially reduce suitable rearing habitat for juveniles (Tables O.3-5, O.3-12 through O.3-14; Figures O.3-25, O.3-28 and O.3-29).

Emigration of juvenile Winter-Run from the Sacramento River is triggered by pulse flows of about 14,000 cfs and above (at Wilkins Slough) (del Rosario et al. 2013). CalSim II September flows at Wilkins Slough exceed this threshold in about 18% of years under the No Action Alternative and never exceed it under Alternative 1, but September is too early for juvenile Winter-Run to emigrate to the Delta (del Rosario et al. 2013). For November, when Winter-Run juveniles are ready to emigrate, flow at Wilkins Slough is much higher under the No Action Alternative than under Alternative 1, but remains below the 14,000 cfs threshold for both alternatives, except for the highest 9% of flows (Figure O.3-29). There are no differences between the alternatives for these highest flows. An important limitation with this analysis is that the CalSim II flow estimates are monthly averages and Winter-Run emigration can be triggered by flow pulses that exceed 14,000 cfs for only a few days (del Rosario et al. 2013), so the flow differences in Figure O.3-29 incompletely represent the likelihood of triggering pulse flows occurring under the two alternatives.

Results from a more recent analysis suggest that the reduction in November flows from the No Action Alternative to Alternative 1 during wet and above normal water years could adversely affect Winter-Run juveniles emigrating at that time. The NMFS Southwest Fisheries Science Center ran statistical models using 2012-2017 tagging data from Spring-Run Chinook Salmon and Fall-Run Chinook Salmon and found a significant increase in smolt survival when Sacramento River flow at Wilkins Slough was above 9,100 cfs during the smolts out-migration period (Cordoleani et al. 2019). The CalSim II results for November at Wilkins Slough indicate that, under the No Action Alternative, 50% of years would have mean monthly flows that exceed the 9,100 cfs threshold, but that under Alternative 1 only 20% of years would exceed the threshold (Figure O.3-29). If these results apply to Winter-Run juveniles emigrating in November, they indicate a potential adverse effect of Alternative 1 on emigrating Winter-Run juveniles. The applicability of the results to Winter-Run are currently unknown, so the effect on Winter-Run is uncertain.

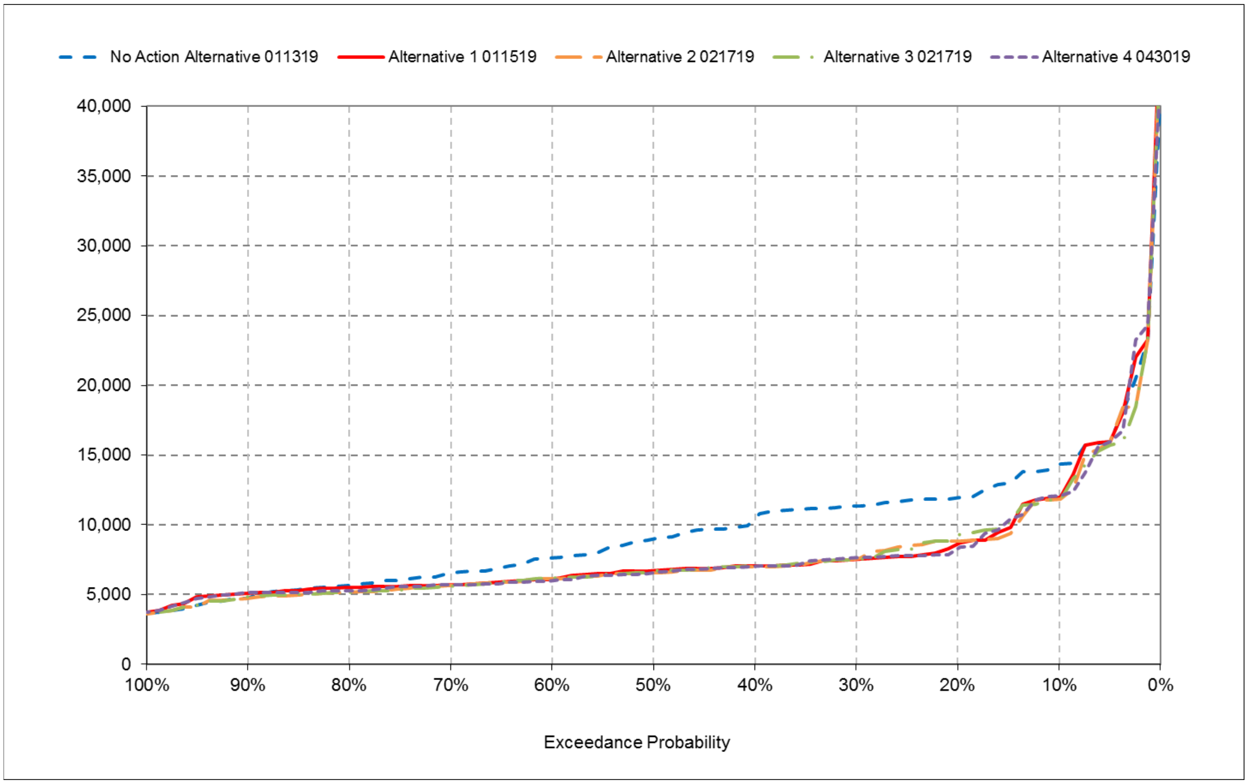

Figure O.3-28. CalSim II Sacramento River Flow at Hamilton City under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; November

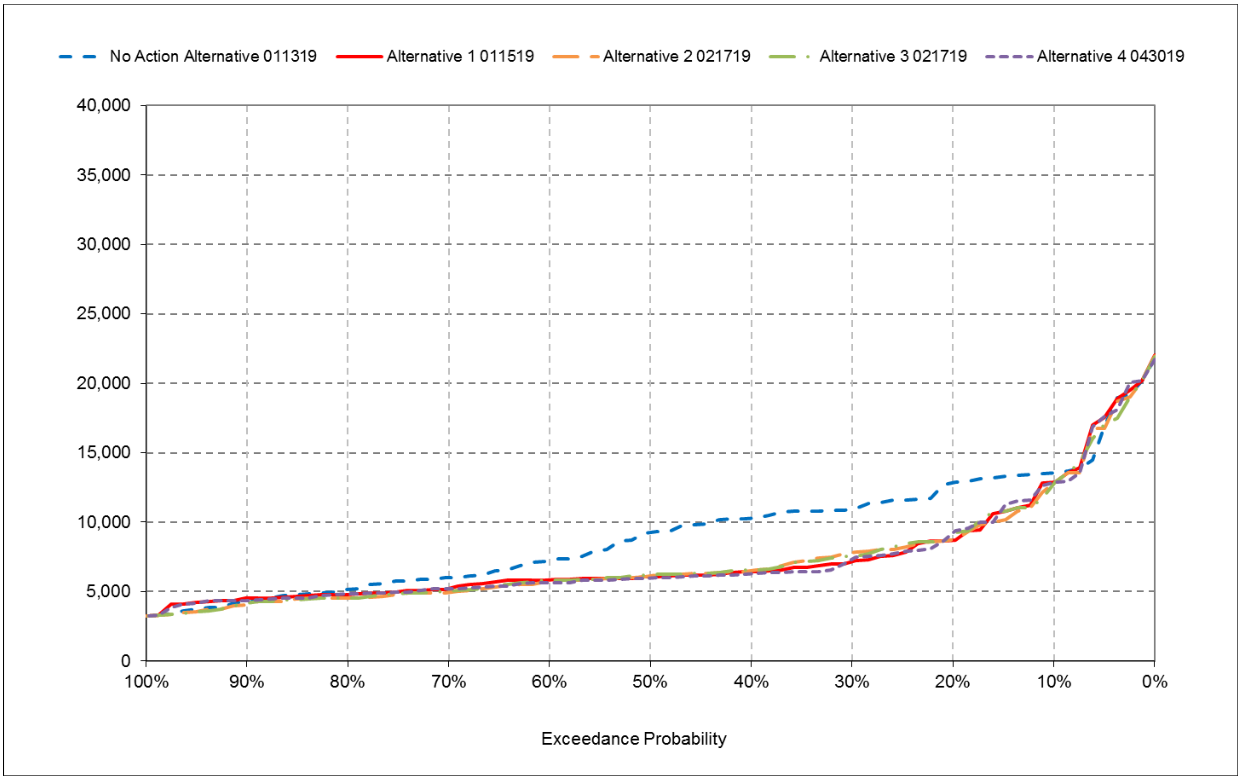

Figure O.3-29. CalSim II Sacramento River Flow at Wilkins Slough under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; November

The USEPA (2003) gives 61°F as the critical 7 day average daily maximum (7DADM) water temperature for Winter-Run Chinook Salmon juveniles rearing in the upper Sacramento River and 64°F (7DADM) for those rearing in the middle Sacramento River (Knights Landing). Under the No Action Alternative, NMFS currently requires Reclamation to maintain water temperature from May 15 through October 31 in the Sacramento River at no more than 56°F at compliance locations between Ball's Ferry and Red Bluff Diversion Dam (NMFS 2011; RPA 1.2.4). Alternative 1 proposes lowering this threshold in the future. Therefore, juveniles rearing in the upper Sacramento River are likely to be well protected from water temperature extremes through the end of October in all but the driest years.

Under the No Action Alternative and Alternative 1, mean monthly water temperatures at Keswick exceed the 61°F threshold in only about 5% of years in September and October, with no appreciable water temperatures differences between the alternatives for water temperatures greater than the 61°F threshold (Figures O.3-18 and O.3-20; Table O.3-6). The monthly average temperatures for these months should reasonably estimate daily mean temperatures because operations at Shasta and Keswick dams create relatively stable summer and fall flow and water temperature conditions in the upper Sacramento River. From November through March, by which month most juvenile Winter-Run have emigrated to the Delta, there are only minor differencs in mean water temperatures at all locations from Keswick Dam to Knights Landing (Tables O.3-6 through O.3-11).

The water temperature effects resulting from Alternative 1 on juvenile Winter-Run Chinook Salmon rearing in or emigrating from the Sacramento River would be less-than-significant relative to the No Action Alternative, but the flow effects would have a potentially significant impact on juvenile Winter-Run Chinook Salmon because the reductions in September flows in wet and above normal water years could reduce rearing habitat and the reductions November flows in wet and above normal water years could reduce smolt survival.

Adult Upstream Migration and Holding

Winter-Run Chinook Salmon adults enter the Sacramento River from the Delta and make their way to the upper Sacramento River, beginning as early as December. They hold in the upper River within 10 to 15 miles of Keswick Dam until they are ready to spawn, which may extend through August (Windell et al. 2017).

There are no flow or temperature requirements for the middle Sacramento River designed to protect fish. However, releases from Shasta Reservoir during November through early May may be reduced to conserve water for the May through October Winter-Run and Spring-Run spawning and incubation periods, resulting in reduced flow in the middle river (NMFS 2011: RPA I.2.2). Lower flow in the Sacramento River relative to flow from the lower Yolo and Sutter bypasses and agricultural drains may affect navigation cues and straying of Winter-Run adults into canals and behind weirs, increasing their stranding risk. Once the adults reach holding habitat in the upper Sacramento River, they are more directly affected by Shasta and Keswick reservoir operations designed to preserve cold water for the Winter-Run and Spring-Run spawning and incubation periods. During the December through August period of adult Winter-Run immigration and holding, the mean monthly flows under Alternative 1 at Keswick Dam, Hamilton City and Wilkins Slough would generally be similar to or greater than flows under the No Action Alternative, except during July of dry and critically dry water years at Hamilton City and Wilkins Slough (Tables O.3-5 and O.3-5 and O.3-6). However, the July flows at Hamilton City and Wilkins Slough under both alternatives would be high enough (>3,250 cfs) to allow upstream passage (Tables O.3-13 and O.3-14).

The USEPA (2003) gives 68°F as the critical 7DADM water temperature for Winter-Run Chinook Salmon adults migrating upstream in the Sacramento River and 61°F for adult Winter-Run holding in the upper river. There are few differences in HEC-5Q water temperature estimates between the No Action Alternative and Alternative 1 during any of the months that adult Winter-Run migrate upstream in the Sacramento River or hold in the upper river (Tables O.3-6 through O.3-11). However, the monthly mean water temperatures are moderately cooler under Alternative 1 at Hamilton City and Knights Landing sites during May, June and August in some of the water year types (Tables O.3-10 and O.3-11). Under both alternatives, the mean monthly water temperatures in the middle Sacramento River (Knights Landing) would be below the 68°F threshold for immigrating adults from December through April, but would exceed the threshold in May of critically dry water years and June through August of all water year types (Table O.3-11). Most Winter-Run adults have migrated upstream of RBDD by late May (see Section O.2.4.2.1, *Winter-Run Chinook Salmon*) and would therefore not be adversely affected by the elevated summer downstream water temperatures. In the upper Sacramento River from Keswick to Balls Ferry, the mean water temperatures would be well below the 61°F threshold for holding adults from December through August under both alternatives (Table O.3-6 through O.3-8).

Although the HEC 5Q results show little difference in water temperatures between the No Action Alternative and Alternative 1, the modeling for Alternative 1 does not include many of the actions of the new water temperature management operations and stuctures proposed for Alternative 1. It is expected that, during the May through October period of operation, water temperatures under Alternative 1 would in fact be more protective of Winter-Run Chinook Salmon adults than the No Action Alternative, particularly in the upper Sacramento River. Therefore, Alternative 1 is expected to have a beneficial effect on Winter-Run Chinook Salmon adult upstream migration and holding relative to the No Action Alternative.

O.3.3.2.3 Central Valley Spring-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Spring-Run Chinook Salmon adults spawn from August through October with peak spawning in September (see Section O.2.4.2.2, *Spring-Run Chinook Salmon*). Monitoring Spring-Run spawning in the mainstem Sacramento River is complicated due to lack of spatial/geographic segregation and temporal isolation from Fall-Run Chinook Salmon. Most spring-sun spawning occurs between the Keswick Dam and Ball Ferry Bridge (NMFS 2017b). Fry emergence occurs up to 3 months after eggs are spawned (Moyle 2002), so effects of flow in the upper Sacramento River on incubating Spring-Run eggs and alevins potentially occur from August through January, peaking in December.

As previously noted, CalSim II modeling indicates that mean monthly flow released at Keswick Dam under Alternative 1 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 1 flows would be substantially lower (up to 47% lower) than the No Action Alternative flows (Table O.3-5). Spawning and incubating eggs and alevins could be negatively or positively affected by the flow reductions. Assuming flows are stable enough to avoid dewatering the redds, which as noted previously is an important criterion for operators of Shasta and Keswick dams, the most important effect of flows on eggs and alevins is to transport dissolved oxygen to the developing eggs and alevins and to flush potentially toxic metabolites out of the redds. Although the mean September and November wet and above normal water year flows are substantially lower under Alternative 1 than under the No Action Alternative, the flows under Alternative 1 flows remain sufficiently high (>5,000 and >7,000 cfs for September and November, respectively) to provide the flow velocity needed to keep most redds clean and well oxygenated (Figure O.3-25). Therefore, differences in flow between the No Action Alternative and Alternative 1 are expected to have little effect on Spring-Run Chinook Salmon spawning and incubation habitat.

Differences in water temperature during the Spring-Run spawning period may be important. As described previously, HEC-5Q mean October water temperatures at Keswick Dam are predicted to be below the 53.5°F water temperature threshold in the majority of years under Alternative 1 and above the threshold in most years under the No Action Alternative (Figure O.3-18; Table O.3-6). Between the Clear Creek confluence and Balls Ferry, where more of the Spring-Run spawning occurs, more of the October mean monthly water temperatures under Alternative 1 exceed the threshold, especially in drier years, but most of them continue to be well below the No Action Alternative means (Tables O.3-7 and O.3-8). The same is true for August of drier water year types. September water temperatures in wet and above normal water years are expected to be higher under Alternative 1 than under the No Action Alternative, especially downstream of Keswick Dam (Tables O.3-7 through O.3-9), and the increases would result in more years with mean water temperatures exceeding the 53.5°F water temperature threshold, erspecially at Ball's Ferry (Figures O.3-30 and O.3-31). The critical temperature threshold for spawning adult Chinook Salmon in the Sacramento River is the same as that for eggs and alevins, 53.5°F (Martin et al. 2017) or 55.4°F (USEPA 2003).

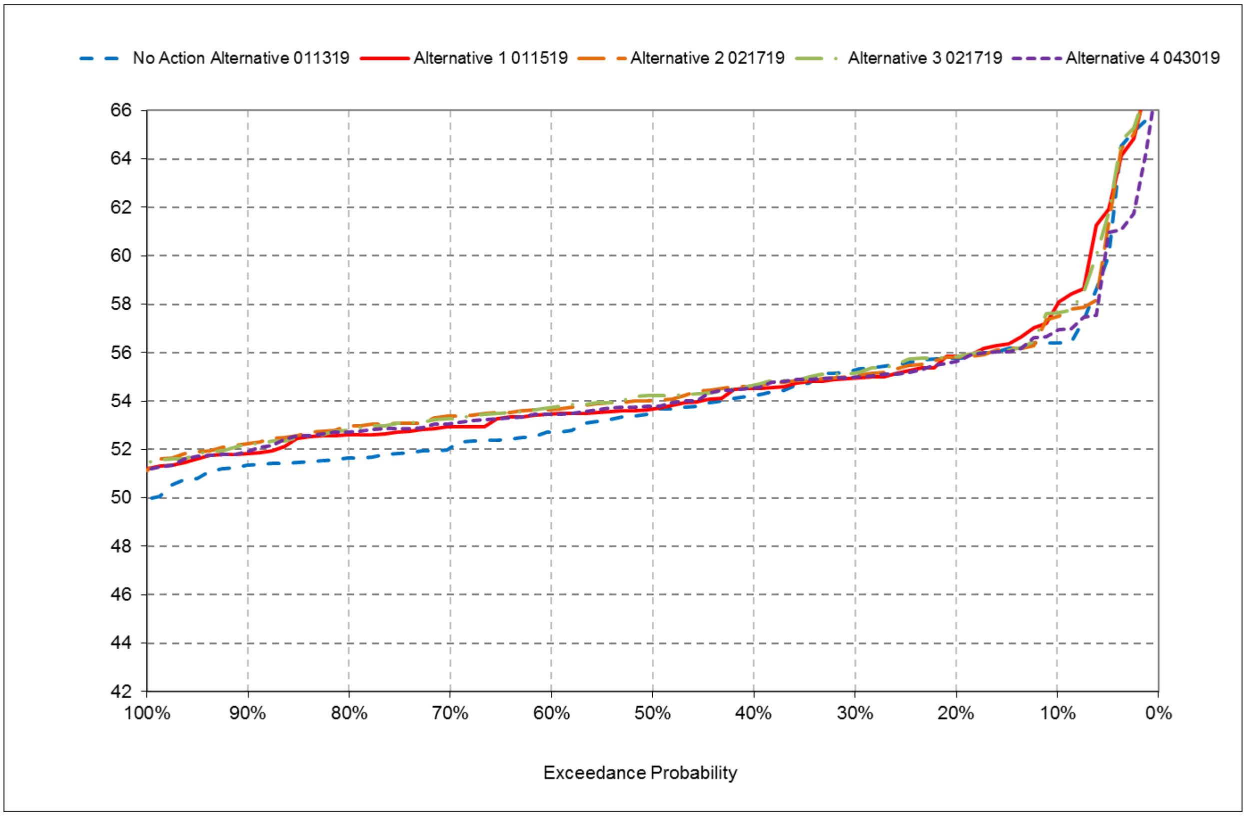

Figure O.3-30. HEC-5Q Sacramento River Water Temperatures at Clear Creek Confluence under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3; September

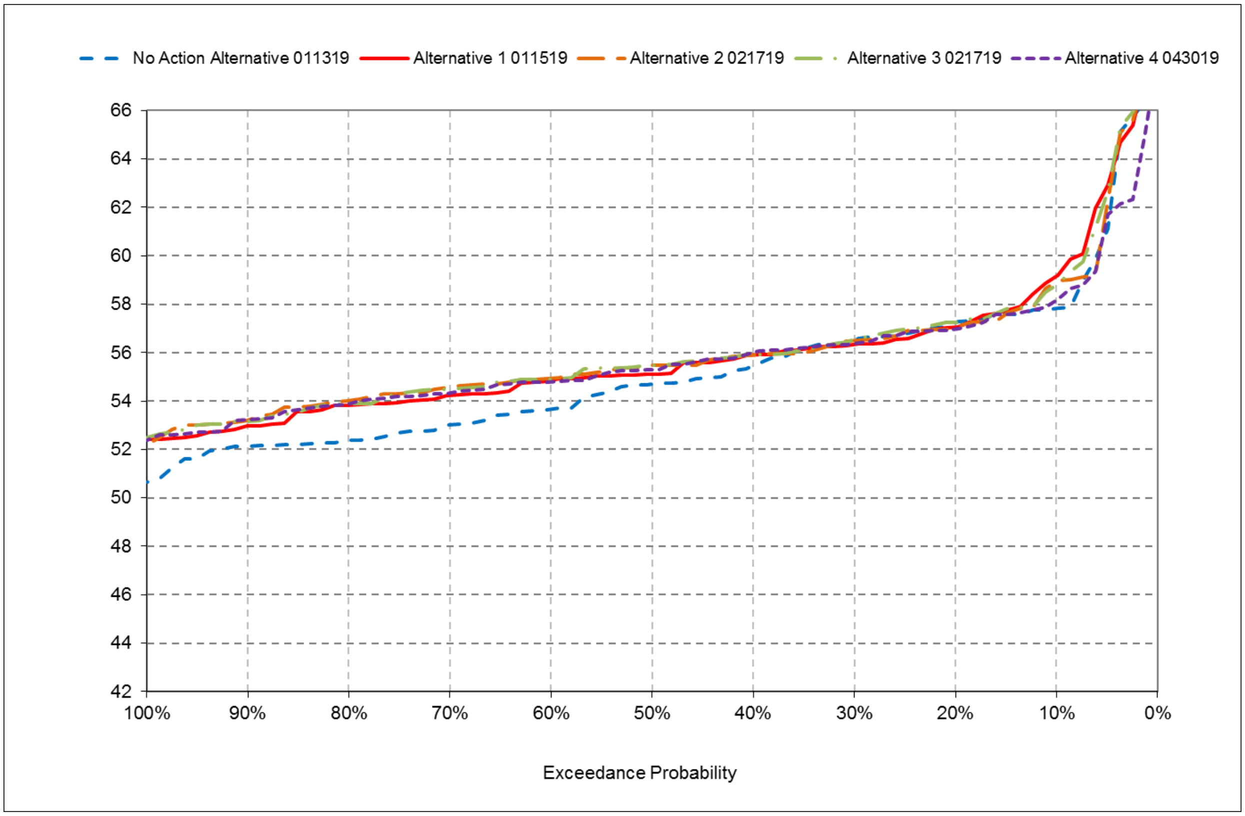

Figure O.3-31. HEC-5Q Sacramento River Water Temperatures at Balls Ferry under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3; September

The HEC-5Q modeling results, which show an increased exceedance of the 53.5°F water temperature threshold during September under Alternative 1 relative to the No Action Alternative suggest that Alternative 1 would have a significant adverse impact on Spring-Run spawning and egg and alevin incubation. However, as previously discussed, the HEC-5Q modeling results are believed to overestimate Alternative 1 water temperatures because the modeling relies on shutter (TCD) operations for Alternative 1 that are quite similar to those of the No Action Alternative, which does not accurately represent actual shutter operation under Alternative 1. Furthermore, the HEC-5Q modeling includes little of the effects expected from several of the major water temperature management improvements proposed for Alternative 1. These include the risk based water temperature management approach and the improved TCD described earlier, and a number of the other proposed measures, all of which would facilitate increased cold water storage, resulting in greater availability of cold water for protection of Spring-Run eggs and alevins.

It is concluded that Alternative 1 would have a less-than-significant impact on Spring-Run Chinook Salmon spawning and egg and alevin incubation with respect to flow and water temperature.

Juvenile Rearing and Emigration

Spring-Run Chinook Salmon juveniles rear in the Sacramento River primarily from November through early May and most emigrate to the Delta during December and again in March and April (see Section O.2.4.2.2, *Spring-Run Chinook Salmon*). Migratory cues, such as increased flow and/or turbidity from runoff, may spur emigration of juveniles from the upper Sacramento River basin when they have reached the appropriate stage of maturation (NMFS 2009). Inundated floodplain habitats have been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Based on the CalSim II modeling results, during most of the Spring-Run juvenile rearing and emigration period, Sacramento River flow would be higher under Alternative 1 than under the No Action Alternative at all locations and many of the increases would be greater than 5% (Tables O.3-5 and O.3-12 through O.3-14). However, the mean monthly flows for November of wet and above normal water years would be much lower under Alternative 1, because of the Fall X2 flows that are included in the No Action Alternative but not Alternative 1. Despite the reductions, the November flows under Alternative 1 remain relatively high (Tables O.3-5 and O.3-12 through O.3-14; Figures O.3-28 and O.3-29), so they are not expected to substantially affect rearing juveniles. Furthermore, as noted above, emigration occurs primarily in December and in the spring. Mean monthly flows would also be lower under Alternative 1 in January, February and April of critically dry water years, but all of these flows reductions are less than 5% (O.3-12 through O.3-14).

Results from a recent study suggest that for Spring-Run that do emigrate as early as November, the Alternative 1 flow reductions in November of wet and above normal water years would have a potentially adverse effect. The NMFS Southwest Fisheries Science Center ran statistical models using 2012-2017 tagging data from Spring-Run Chinook Salmon and Fall-Run Chinook Salmon and found a significant increase in smolt survival when Sacramento River flow at Wilkins Slough was above 9,100 cfs during the smolts emigration period (Cordoleani et al. 2019). The CalSim II results for November at Wilkins Slough indicate that 50% of years would have mean monthly flows that exceed the 9,100 cfs threshold under the No Action Alternative, and 20% of years would have flows that exceed the threshold under Alternative 1 (Figure (O.3-29). As shown by recent sampling at RBDD (Figure O.3-31-A) almost all Spring-Run juveniles emigrate from the upper Sacramento River after November, so the percentage of Spring-Run juveniles that would be affected by the expected reductions in November flows at Wilkins Slough would be small. Therefore changes in flow resulting from Alternative 1 are not expected to substantially affect rearing and emigrating juvenile Spring-Run Chinook Salmon.

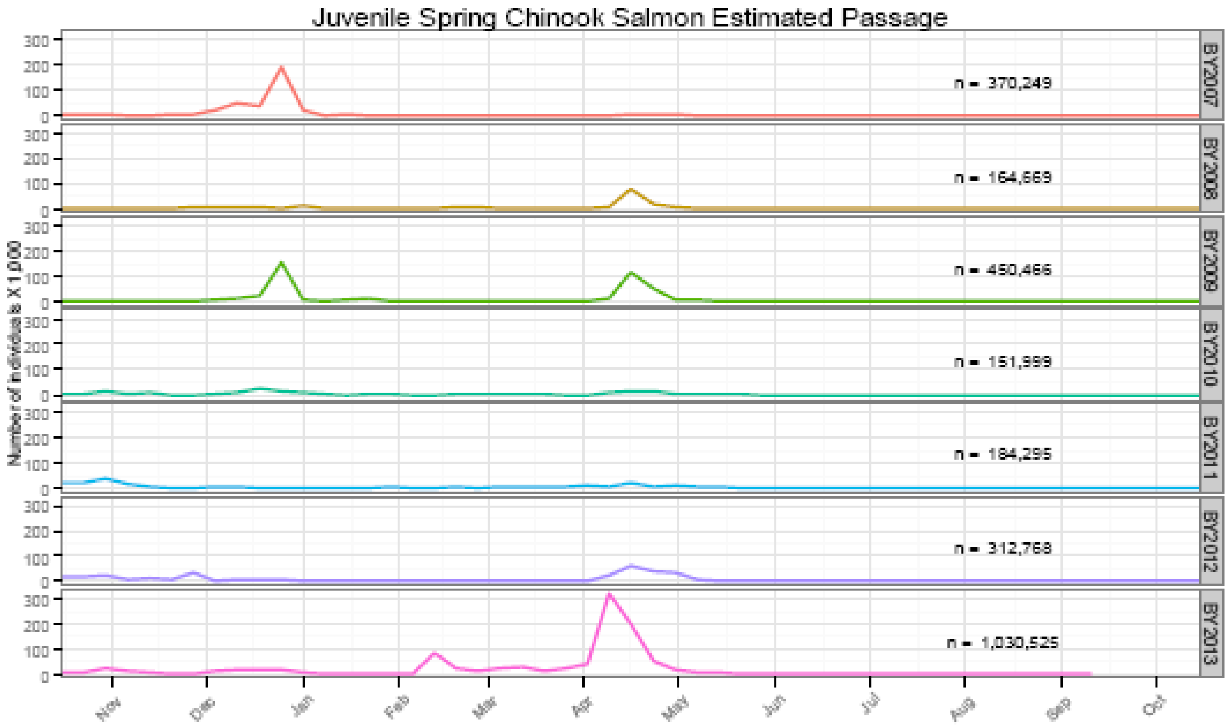

Figure O.3-31-A. Weekly Estimated Passage of Juvenile Spring-Run Chinook Salmon at Red Bluff Diversion Dam (RM244) by Brood Year (BY), Sampled using Rotary-Screw Trap.

The USEPA (2003) gives 61°F as the critical 7 day average daily maximum (7DADM) water temperature for Spring-Run Chinook Salmon juveniles rearing in the upper Sacramento River and 64°F (7DADM) for those rearing in the middle Sacramento River (Knights Landing). Under the No Action Alternative and Alternative 1, HEC-5Q estimates of mean monthly water temperatures from Keswick to RBDD do not exceed the 61°F threshold during any month and water year type during the November through May rearing period (Tables 0.3-6 through O.3-9). The mean monthly water temperatures for Hamilton City do not exceed the 64°F threshold for the middle Sacramento River during any of the months, but the mean monthly water temperatures for May exceed the middle river threshold at Knights Landing in all water year types under both alternatives. However, there are no meaningful differences between the Alternative 1 and No Action Alternative temperatures at Knights Landing (Table O.3-10). These results indicate that water temperature conditions would too warm for juvenile Spring-Run Chinook Salmon rearing and emigrating in the middle Sacramento River during May. It should be noted that May is the last month during spring or summer that Spring-Run Chinook Salmon juveniles are found in the middle river, and it is likely that when water temperatures are too high they emigrate to the ocean before May. It should be noted that early emigration could have other adverse effects.

The flow and water temperature effects resulting from Alternative 1 would have a less-than-significant effect relative to the No Action Alternative on juvenile Spring-Run Chinook Salmon in the Sacramento River.

Adult Upstream Migration and Holding

Spring-Run Chinook Salmon adults enter the Sacramento River from the Delta as early as January and make their way to the upper Sacramento River beginning in February, where they hold until ready to spawn in late summer and early fall (Windell et al. 2017). Adults may continue migrating upstream until

August, and holding continues until October when spawning is complete. There are no flow or temperature requirements for the middle Sacramento River designed to protect fish. Lower flow in the Sacramento River relative to flow from the lower Yolo and Sutter bypasses and agricultural drains may affect navigation cues and straying of Spring-Run adults into canals and behind weirs, increasing their stranding risk. Once the adults reach holding habitat in the upper Sacramento River, they are more directly affected by Shasta and Keswick reservoir operations designed to preserve cold water for the Winter-Run and Spring-Run spawning and incubation periods.

During the January through August period of adult Winter-Run immigration, the mean monthly CalSim II flows under Alternative 1 at Keswick, RBDD, Hamilton City, and Wilkins Slough would generally be similar to or greater than those under the No Action Alternative, except during July of dry and critically dry water years (Tables O.3-5 and O.3-12 through O.3-14). However, the mean July flows under both alternatives would remain high enough (>5,000 cfs) to allow upstream passage. During the holding period, September flow would be much lower under Alternative 1 than under the No Action Alternative (Tables O.3-5 and O.3-12; Figure O.3-25), but the mean September Alternative 1 flows at Keswick Dam would not fall below 6,000 cfs over the range of flows for which the alternatives have major flow differences (i.e., upper 50% in Figure O.3-25). A flow of 6,000 cfs would presumably be sufficient to maintain good water quality conditions in the Spring-Run holding habitats. Note that monthly mean flows for these months should reasonably estimate daily mean flows because operations at Shasta and Keswick dams create relatively stable summer and fall flow and water temperature conditions in the upper Sacramento River.

The USEPA (2003) gives 68°F as the critical 7DADM water temperature for Spring-Run Chinook Salmon adults migrating upstream in the Sacramento River and 61°F for adult Spring-Run holding in the upper river. Throughout the January through August period of Spring-Run upstream migration, HEC-5Q water temperatures for Alternative 1 are similar to or slightly lower than those for the No Action Alternative, including greater than 1°F reductions in mean monthly water temperature for June of below normal and dry water years at Knights Landing (Tables O.3-6 through O.3-11). Under both alternatives, the mean monthly water temperatures in the middle Sacramento River (Knights Landing) would be below the 68°F threshold for immigrating adults from December through April, but would exceed the threshold in May of critically dry water years and in June through August of all water year types (Table O.3-11). The high May through August water temperatures would be likely to adversely affect any Spring-Run adults that were migrating upstream in those months. High water temperatures were found to cause adult Spring-Run Chinook Salmon in Butte Creek to terminate their upstream migrations, which made them more susceptible to mortality from rising water temperatures (Mosser et al. 2012). The June temperature reductions under Alternative 1 occur in a range slightly above the 68°F threshold and, therefore, would likely have a beneficial effect on upstream migrating adults. In the upper Sacramento River at Keswick Dam to Balls Ferry, the mean water temperatures under both alternatives would be well below the 61°F threshold for holding adults from February through October (Tables O.3-6-2 through O.3-8). As previously noted, flow below Keswick Dam is relatively stable during the summer and fall months, so monthly mean flows and temperatures are likely to be fairly representative of daily means in those months.

As previously discussed, although the HEC 5Q results show little difference in water temperatures between the No Action Alternative and Alternative 1, the modeling for Alternative 1 does not include the new water temperature management operations and stuctures proposed for Alternative 1. It is expected that, during the May through October period of operation, water temperatures under Alternative 1 would in fact be more protective of Winter-Run Chinook Salmon adults than the No Action Alternative, particularly in the upper Sacramento River.

Therefore, with respect to flow, Alternative 1 is expected to have a less-than-significant effect relative to the No Action Alternative on Spring-Run Chinook Salmon adult migration and holding, and with respect to water temperature, Alternative 1 is expected to have a beneficial effect.

O.3.3.2.4 Central Valley Steelhead

Spawning and Egg Incubation

CV steelhead adults spawn from November through April with peak spawning from January through March. Based on the general timing of hatching and fry emergence, eggs and alevins may occur from November through May. Little is known about steelhead spawning locations in the Sacramento River, but it is generally assumed that spawning occurs primarily between Keswick Dam and RBDD.

CalSim II modeling indicates that mean monthly flows released at Keswick Dam under Alternative 1 would generally be higher than or similar to the flows under the No Action Alternative, except in September and November of above normal and wet years, when Alternative 1 flows would be substantially lower than the No Action Alternative flows (Table O.3-5). These reductions would average approximately 3,000 cfs and 3,500 cfs lower in November for above normal and wet years, respectively, when steelhead are assumed to initiate spawning. Based on PHABSIM results (flow versus weighted usable area [WUA]) developed by the USFWS (2003) for the Sacramento River between Keswick Dam and Battle Creek, lower flows under Alternative 1 would increase the amount of available spawning habitat (as measured by WUA) in above normal and wet years (Figure O.3-31-B). However, higher flows under Alternative 1 in subsequent months (averaging approximately 1,000 cfs to 2,000 cfs higher in December and January of above normal and wet years) would reduce the amount of available spawning habitat in these months relative to the No Action Alternative (Table O.3-5). For example, in wet years, the changes in flow under Alternative 1 would result in an 18% increase in spawning WUA in November, and 7% decrease in December, and a 14% decrease in January. Over all months, average WUA would increase by less than 1% under Alternative 1.

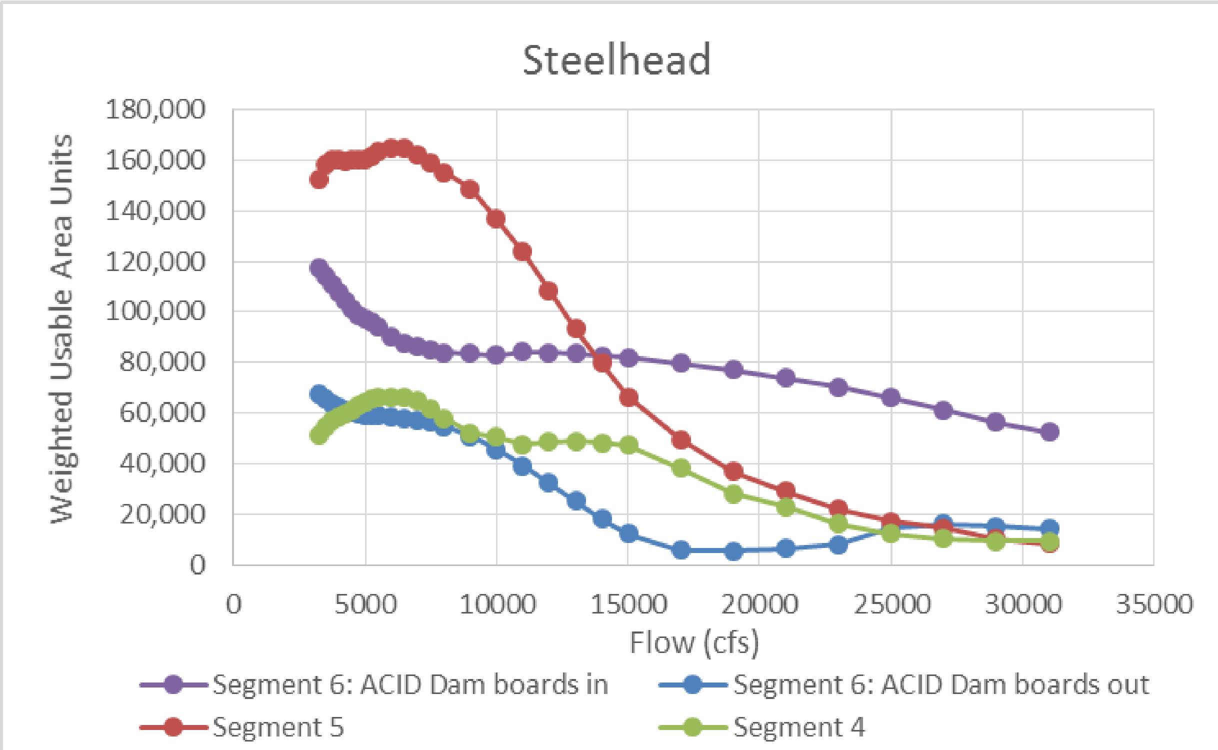

Figure O.3-31-B. Spawning WUA curves for CCV Steelhead in the Sacramento River. Segment 4: Battle Creek to Cow Creek; Segment 5: Cow Creek to the Anderson-Cottonwood Irrigation District (ACID) Dam; Segment 6: ACID to Keswick Dam

No water temperature requirements have been established for steelhead spawning and incubation in the Sacramento River. The USEPA-recommended 7DADM water temperatures is 55°F for salmon and trout spawning and incubation, although 53°F was selected for this analysis based on the review by McCullough et al. (2001); this was considered a more conservative criterion for evaluating the potential for adverse temperature effects based on monthly modeling results. HEC-5Q modeling indicates that the water temperatures in the upper Sacramento River during the steelhead spawning and incubation period (November through May) would be similar under the No Action Alternative and Alternative 1 (Tables O.3-6 through O.3-9). Under both alternatives, the exceedance plots for the upper Sacramento River generally indicate that suitable water temperatures for steelhead spawning and incubation would not occur until December and generally extend to March or April. Therefore, changes in Sacramento River flows and water temperatures under Alternative 1 would have a less-than-significant effect on spawning and incubating steelhead relative to the No Action Alternative.

Juvenile Rearing and Emigration

CV steelhead rear year-round in the Sacramento River, and use the river downstream from spawning areas as both a rearing and migration corridor. The timing of downstream migration is variable but generally peaks in the upper river at RBDD in spring and summer (March through June) and in the lower river at Knights Landing in winter and spring (January thorugh May) (NMFS 2009). The peak migration of yearling and older juveniles through the Delta occurs in March and April (NMFS 2009).

Flow-habitat relationships are not available for steelhead rearing habitat in the Sacramento River. In other assessments (e.g., SacEFT model, ESSA 2011), the PHABSIM results for juvenile Late Fall-Run Chinook Salmon (USFWS 2005) have been used to characterize potential flow effects on steelhead rearing habitat in the upper Sacramento River. Although similarities exist in their early life history and general habitat requirements, the validity of applying the PHABSIM results for Late Fall-Run Chinook Salmon to steelhead is uncertain. As described previously, CalSim II modeling indicates that the largest differences in Sacramento River flows under the No Action Alternative and Alternative 1 would occur in September and November of above normal and wet years, when Alternative 1 flows would be substantially lower than the No Action Alternative flows (Table O.3-5). These reductions would average approximately 4,700 cfs and 5,700 cfs in September and 3,000 cfs and 3,500 cfs in November in above normal and wet years, respectively, increasing the amount of available rearing habitat (as measured by WUA) in these months relative to the No Action Alternative (Figure O.3-40). However, higher flows under Alternative 1 in December (averaging approximately 1,000 cfs to 2,000 cfs higher in above normal and wet years) would reduce the amount of rearing habitat relative to the No Action Alternative (Table O.3-5). For example, in wet years, the changes in flows under Alternative 1 would result in a 30% increase in rearing WUA in September, a 2% increase in October, a 38% increase in November, a 17% decrease in December, and a 1% increase in January. Over all months, average WUA would increase be 11% under Alternative 1.

High summer water temperatures are recognized as a major stressor for Central Valley Steelhead (NMFS 2014a). However, current and proposed operations at Shasta and Keswick Dam to meet water temperature requirements for Winter-Run Chinook Salmon would be expected to maintain suitable rearing temperatures for juvenile steelhead in the upper Sacramento River throughout the summer. This assumption was evaluated for the No Action Alternative and Alternative 1 by comparing modeled summer water temperatures in the Sacramento River to general water temperature criteria for juvenile steelhead. The USEPA-recommended 7DADM water temperature for juvenile salmonids in core rearing areas (upper reaches of natal rivers) is 61°F. Although based on studies of steelhead in the Pacific Northwest, this criterion was considered a reasonable threshold for evaluating the potential for adverse temperature effects based on monthly modeling results. Under both alternatives, HEC-5Q modeling indicates that average water temperatures in the Sacramento River between Keswick Dam and RBDD would be maintained at or below 61°F in all water years except in the summer (July through September) of critical water years (Table O.3-9). However, no major differences would occur in the frequency and magnitude of temperatures above this threshold under these alternatives.

Under the No Action Alternative and Alternative 1, no major differences would occur in the frequency and magnitude of Sacramento River water temperatures during the peak steelhead emigration season (January through May) (Tables O.3-5 through O.3-11). However, monitoring at RBDD indicates that downstream movements of juvenile steelhead (predominantly fry and parr) past RBDD can occur throughout the summer (May through September), extending the distribution of rearing juveniles to the middle Sacramento River. Downstream of RBDD, lower flows in September of above normal and wet years under Alternative 1 are expected to increase the frequency of water temperatures exceeding 61°F relative to the No Action Alternative; HEC-5Q modeling indicates that September water temperatures near Hamilton City would average 3.5°F higher in wet years and 4.6°F higher in above normal years relative to the No Action Alternative (Table O.3-10). Over all years, modeled water temperatures exceeded the 61°F threshold 83% of the time under Alternative 1 compared to 55% of the time under the No Action Alternative (Figure O.3-23). While this represents a potential adverse effect on rearing and emigrating steelhead in the Sacramento River below RBDD, the overall effect on the juvenile steelhead population would be ameliorated by the relatively low numbers of steelhead that emigrate in the lower river in September and the improved habitat conditions that would be expected in the Sacramento River as a result of the additional flow and water temperature management actions (e.g., Shasta Lake Cold Water Pool Management), and other nonflow habitat and facility improvements that are proposed under Alternative 1. Therefore, changes in Sacramento River flows and water temperatures resulting from

Alternative 1 would have a less-than-significant effect on rearing and emigrating steelhead in the Sacramento River relative to the No Action Alternative.

Adult Upstream Migration and Holding

Adult steelhead immigration into Central Valley streams potentially occurs during all months of the year but typically begins in August and continues through March or April (McEwan 2001; NMFS 2014a). In the Sacramento River, adults migrate upstream past RBDD during all months of the year, but primarily during September and October (NMFS 2009). Adults may hold until the spawning season which generally extends from November through April.

Flow thresholds for evaluating immigration and holding conditions for steelhead adults have not been determined for the Sacramento River. A threshold of 3,250 cfs is used in this analysis to evaluate the potential for adverse effects on migrating and holding adults. Flows in the Sacramento River rarely drop below this level, and adults have not been observed to experience passage delays, crowding, or other adverse effects at this flow. Therefore, it represents a reasonable threshold for evaluating the potential for adverse effects on migrating and holding adults. During the August through April immigration and holding period, Shasta and Keswick operations under Alternative 1 would result in lower mean flows in the Sacramento River in September and November of wet and above normal years relative to the No Action Alternative. These reductions would average approximately 4,700 to 5,800 cfs lower in September and 3,000 cfs to 3,500 cfs lower in November depending on the water year (Table O.3-5, O.3-13, and O.3-14). However, CalSim II modeling indicates that a minimum flow of 3,250 cfs would be maintained in September and November (Figures O.3-29 and O.3-32) and throughout the year under both the No Action Alternative and Alternative 1.

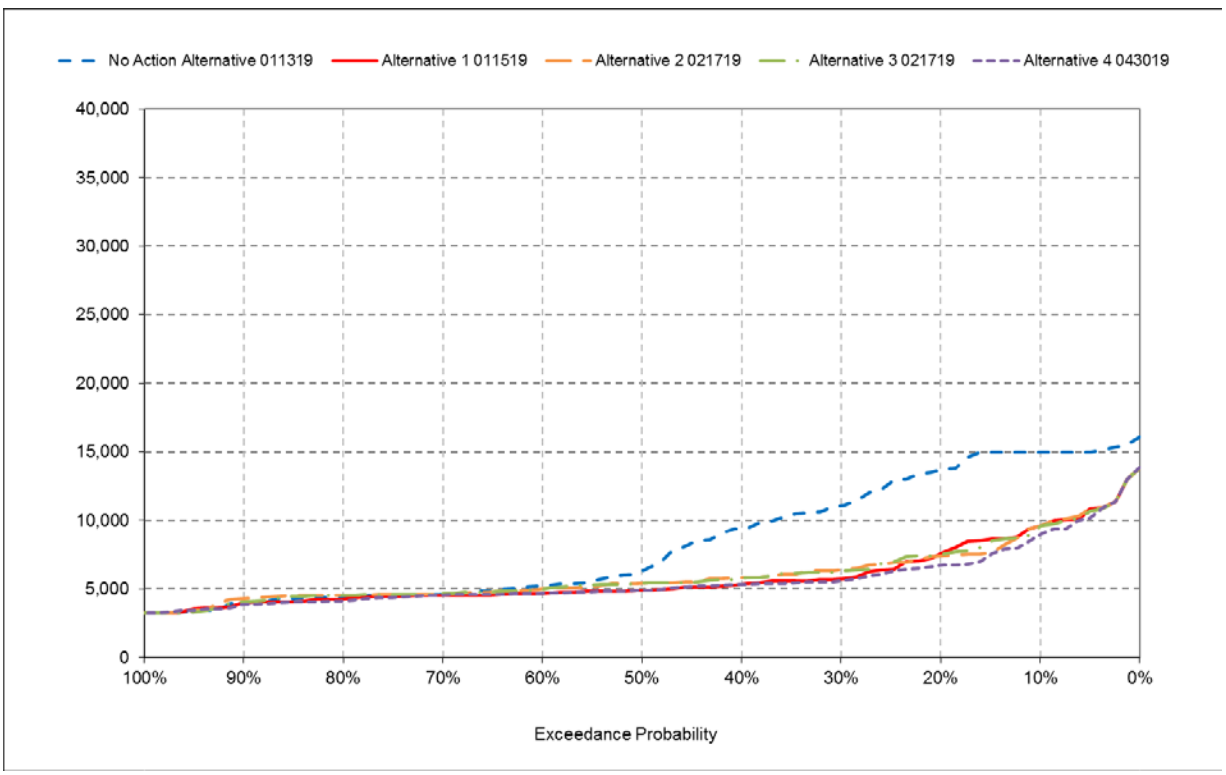

Figure O.3-32. CalSim II Sacramento River Flow at Wilkins Slough under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3, and Alternative 4; September

No water temperature requirements have been established for adult steelhead migration and holding in the Sacramento River (August through April). The USEPA-recommended 7DADM water temperatures is 68°F for migrating adult salmonids and 61°F for holding adults prior to spawning. Although based on studies of steelhead in the Pacific Northwest, this criterion was considered a reasonable threshold for evaluating the potential for adverse temperature effects on migrating and holding adults based on monthly modeling results. Under the No Action Alternative and Alternative 1, no major differences would be expected to occur in the frequency and magnitude of monthly water temperatures exceeding 68°F; for example, at Hamilton City, modeled water temperatures exceeding 68°F would occur in about 7% of the years (critical water years) under both the No Action Alternative and Alternative 1 (Figure O.3-23). Similarly, no major differences would be expected to occur in the exposure of holding adults to potentially stressful water temperatures; for example, at RBDD, modeled water temperatures exceeding 61°F would occur in about 27% of the years under both the No Action Alternative and Alternative 1 (Figure O.3-22). Therefore, changes in Sacramento River flows and water temperaturess associated with Alternative 1 would have a less-than-significant effect on migrating and holding adult steelhead in the Sacramento River relative to the No Action Alternative.

O.3.3.2.5 Southern DPS Green Sturgeon

Spawning and Egg Incubation

Green Sturgeon spawn in deep pools (averaging about 28 feet deep) (NMFS 2018b). Eggs from spawning Southern DPS Green Sturgeon have been found in the middle and upper Sacramento River from the GCID oxbow (River Mile [RM] 207) to Inks Creek (RM 265) and, based on adult sightings and presence of suitable habitat, spawning is believed to extend upstream to the confluence with Cow Creek (RM 277) (Heublein et al. 2017b).

Green Sturgeon spawn primarily from April through July, although they periodically spawn in late summer and fall (as late as October) (Heublein et al. 2009, 2017b, NMFS 2018b). Northern DPS Green Sturgeon eggs hatch about a week after fertilization (at 60ºF), and incubation time of southern DPS Green Sturgeon eggs is assumed to be similar (Heublein et al. 2017b). Because the incubation time for Green Sturgeon is so short, the effects analysis period for incubating eggs is considered to be the same as the spawning period, April through July, occasionally extending to October.

During the April through July Green Sturgeon spawning period, CalSim II estimates of mean monthly flows at RBDD (RM 244) under the No Action Alternative and Alternative 1 range from about 5,000 cfs for April of critically dry water years to about 14,300 cfs in July of Above Normal water years (Table O.3-12). Mean flows during most of this period are moderate (~8,000 cfs to ~12,000 cfs). These flow levels are likely to be suitable for Green Sturgeon spawning and egg incubation, and no adverse effects are expected to result. Differences in flows between Alternative 1 and the No Action Alternative are small in most months, but flows are moderately higher for Alternative 1 in May and June of below normal and dry water years (Table O.3-12). During the August through October period, when Green Sturgeon spawning occurs in occasional years, the flows under both alternatives tend to be lower than those in April through July, but the mean flows would be close to or above 5,000 cfs for all water year types in all three months. Large reductions in mean flows from the No Action Alternative to Alternative 1 are predicted for September of wet and above normal water years and, although the resulting Alternative 1 mean flows are close to or greater than 5,000 cfs, the flow reductions are so large (42 and 49%, respectively) that conditions for Green Sturgeon spawning and egg incubation are likely to be adversely affected (Table O.3-12). However, September spawning occurs only sporadically, so any effect on the Green Sturgeon population would be minor (NMFS 2018b). Therefore, the September flow reductions are expected to have a minor adverse impact on Green Sturgeon.

Critical water temperatures thresholds have been determined for Northern DPS Green Sturgeon but not for Southern DPS Green Sturgeon, but it is assumed that the temperature tolerances of the two distinct population segments are similar (Heublein et al. 2017b). Based on laboratory studies, Van Eenennaam et al. (2005, cited in Heublein et al. 2017) concluded that the optimal range for normal embryo development of Northern DPS Green Sturgeon is 53 to 64°F, and impaired fitness occurs below 52°F and above 71°F.

The spawning and egg incubation water temperature requirements for Green Sturgeon present a potential management conflict with temperature management for Winter-Run Chinook Salmon and other upper Sacramento River salmonid populations. When RBDD, which had prevented Green Sturgeon from spawning further upstream, was decommissioned in 2013, the sturgeon population was able to expand its spawning distribution upstream and, as noted above, their current upstream limit is about at the Cow Creek confluence, which is about 10 river miles downstream of the Clear Creek confluence and a few miles upstream of Balls Ferry. Based on the HEC-5Q modeling, mean water temperatures during the April through July primary spawning period of Green Sturgeon are frequently below the 53 and 52°F lower temperature thresholds for Green Sturgeon egg development at both locations (Tables O.3-7 and O.3-8). At Balls Ferry in July, which is the month of the Green Sturgeon spawning period most likely to be affected by the proposed water temperature management improvements of Alternative 1, the mean monthly water temperatures under the No Action Alternative are below 52 and 53°F in about 10% and 33% of years, respectively (Figure O.3-33). As discussed previously, daily water temperatures are likely to be more variable than monthly mean temperatures, so these percentages probably underestimate the frequency of years with July days falling below the 52°F and 53°F thresholds. These results suggest that further upstream movement of Green Sturgeon spawning may currently be limited by cold water temperatures and that further reductions in temperature to protect salmonids could force the upstream limit of Green Sturgeon spawning downstream.

The HEC-5Q modeling results show little difference in Clear Creek confluence and Balls Ferry mean water temperatures between Alternative 1 and the No Action Alternative during the April through July primary Green Sturgeon spawning and incubation period (Tables O.3-7 and O.3-8, Figure O.3-33). However, as has been discussed, the HEC 5Q modeling for Alternative 1 relies on shutter (TCD) operations quite similar to those of the No Action Alternative and does not include the proposed operational and structural water management improvements that are included in Alternative 1. Consequently, the HEC-5Q results for Alternative 1 may underestimate water temperatures for certain months, particularly in dry and critically dry water years, when the water temperature management improvements would be likely to have their greatest impact. Therefore, Alternative 1 is likely to cause a reduction in water temperatures relative to the No Action Alternative and thereby adversely affect Green Sturgeon spawning and egg incubation.

It should be noted that several factors other than the upstream water temperatures potentially affect the Green Sturgeon spawning distribution, and these complicate assessment of the effects of the reduced water temperatures under Alternative 1. For example, reducing the temperatures of Keswick Dam releases would potentially result in cooler water temperatures at the downstream limit of the Green Sturgeon spawning distribution, where summer/fall water temperatures under the No Action Alternative often exceed the 53°F to 64°F optimal range for Green Sturgeon eggs (Table O.3-11; Figure O.3-34). Cooler downstream temperatures, therefore, could result in a downstream expansion of the spawning distribution and no net loss of spawning habitat availability. Also, the spawning distribution of Green Sturgeon is affected by factors other than water temperature, including availability of spawning habitat elements such as suitable substrates and deep holes. Therefore, although Alternative 1 would potentially reduce availability of suitable spawning habitat for the Green Sturgeon relative to the No Action Alternative, confidence in this conclusion is low because of uncertainty about the effects of other potentially important effects on Green Sturgeon spawning distribution.

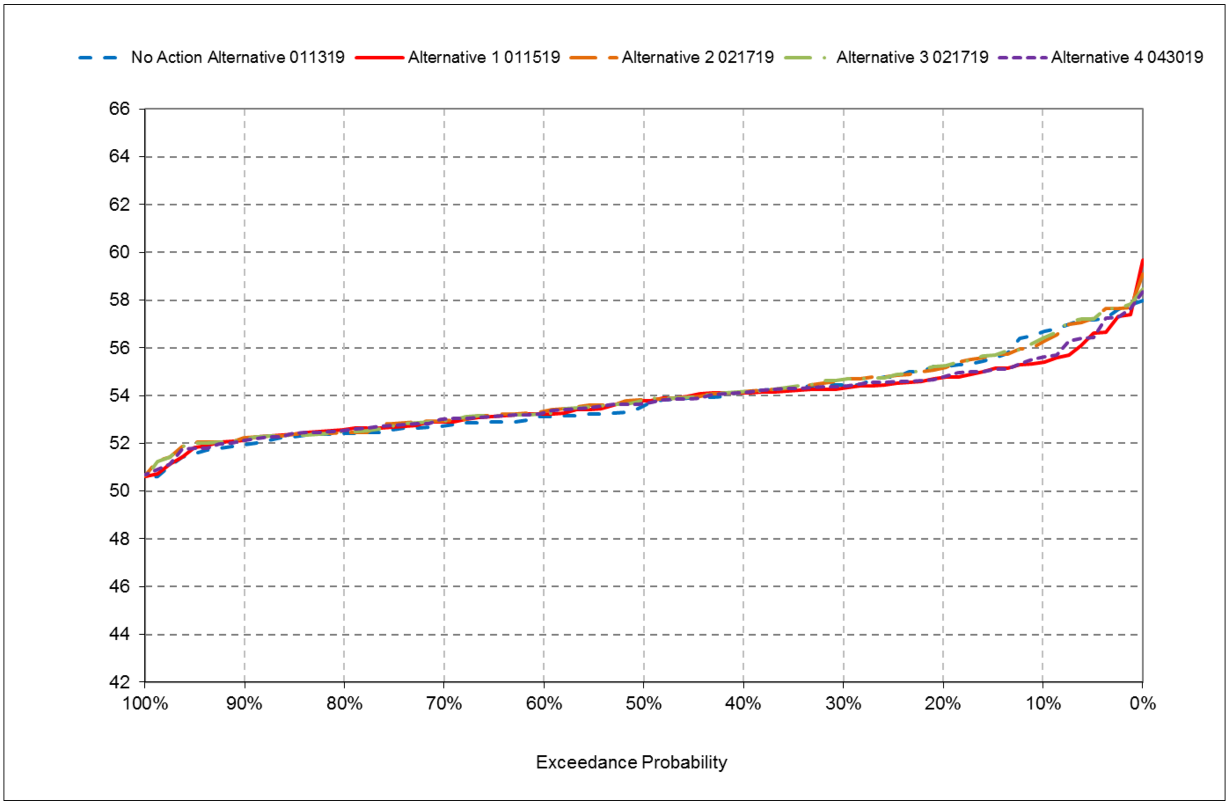

Figure O.3-33. HEC-5Q Sacramento River Water Temperatures at Balls Ferry under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; July

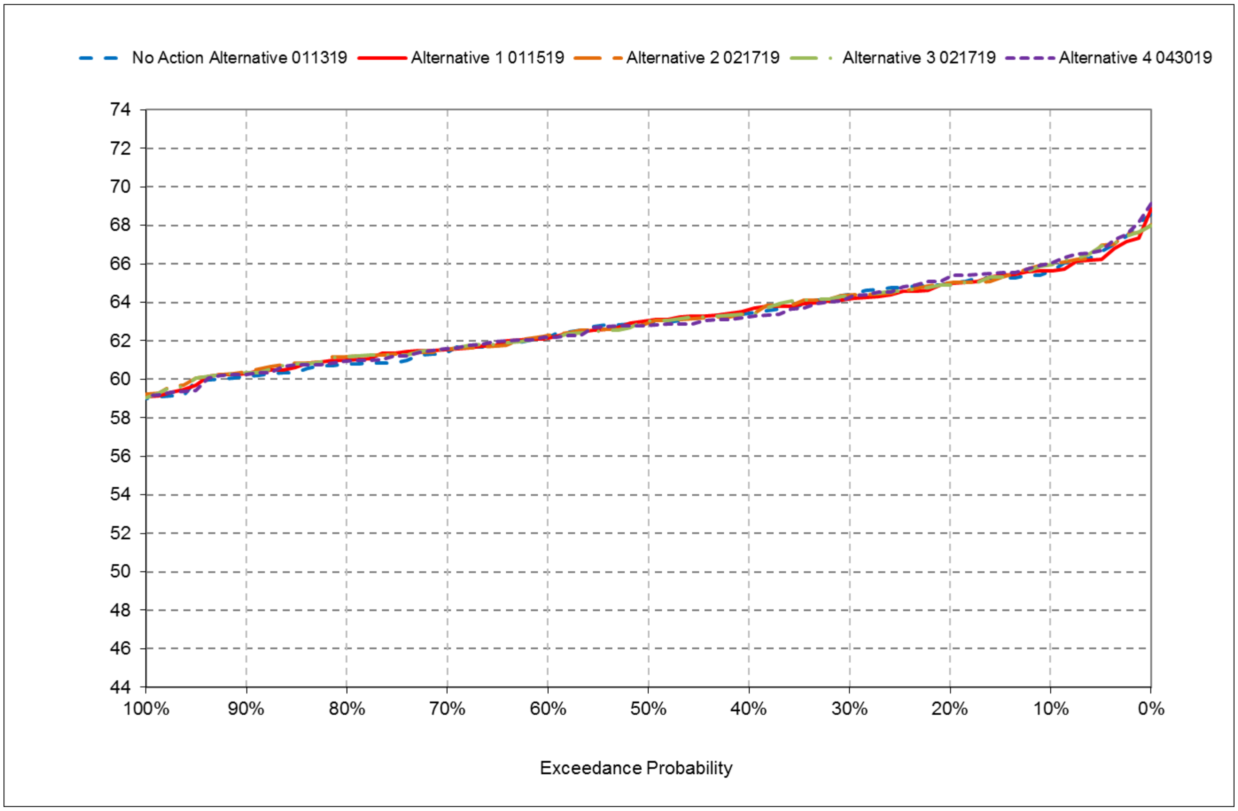

Figure O.3-34. HEC-5Q Sacramento River Water Temperatures at Hamilton CIty under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3, and Alternative 4; July

O.3.3.2.6 Larval and Juvenile Rearing and Emigration

According to field observations, Green Sturgeon larvae begin to disperse from hatching areas at 18 days post hatch (dph), and dispersion is complete at about 35 dph (Poytress et al. 2011, cited in Heublein et al. 2017b). They begin exogenous feeding at about 15 dph. The Green Sturgeon spawning period is from April through July, so the larval period is considered to be April through September. The downstream distribution of Green Sturgeon larvae in the Sacramento River is uncertain, but is estimated to extend to the Colusa area, at RM 157 (Heublein et al. 2017b). The upstream limit is the Cow Creek confluence.

The Green Sturgeon juvenile stage begins when metamorphosis of the larva is complete, typically at about 45 dph and about 75 mm in length (Heublein et al. 2017b). It is likely that juveniles rear near spawning habitat for a few months or more before migrating to the Delta (Heublein et al. 2017b). The juveniles rear in the Sacramento River from about May through December (NMFS 2017b, *Appendix B*). During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near the Cow Creek confluence to the Delta.

The effects of flow on Green Sturgeon larvae and juveniles are poorly understood. There appears to be a positive relationship between annual outflow and abundance in rotary screw traps at RBDD of Green Sturgeon larvae and juveniles (Heublein et al. 2017a *SAIL model*). Also, there is a positive correlation between mean daily freshwater outflow (April to July) and white sturgeon year class strength (CDFG 1992 and USFWS 1995, cited in NMFS 2018b). These relationships may result from flows transporting larvae to areas with greater food availability, dispersing larvae over a wider area, and/or enhancing nutrient availability to the Sacramento River and Delta/Estuary.

CalSim modeling for the Sacramento River at RBDD indicates that mean monthly flows during the April through September period of larval rearing are generally similar between the No Action Alternative and Alternative 1 except, as described previously, for moderately higher mean flows in May and June of the drier water year types under Alternative 1 and much higher flow during September of wet and above normal water years under the No Action Alternative (Table O.3-12). The September reductions in flow from the No Action Alternative to Alternative 1 would potentially affect Green Sturgeon larvae adversely because, as discussed above, there appears to be a positive relationship between annual outflow and abundance of Green Sturgeon larvae and juveniles, but this conclusion is highly uncertain.

CalSim modeling for the Sacramento River at Hamilton City indicates that mean monthly flows during the period of juvenile rearing and emigration, May through December, are generally similar between the No Action Alternative and Alternative 1 except, as described previously, for much higher flows under the No Action Alternative during September and November of wet and above normal water years, resulting from Fall X2 releases (Table O.3-13). These reductions in flow could adversely affect Green Sturgeon juveniles under Alternative 1 because, as discussed above, there appears to be a positive relationship between annual outflow and abundance of Green Sturgeon. There are moderate increases in mean flow from No Action Alternative to Alternative 1 in December, May and June, but these increases are much smaller than the reductions in September and November (Table O.3-13).

Critical water temperatures thresholds have been determined for Northern DPS Green Sturgeon but not for Southern DPS Green Sturgeon, but it is assumed that the temperature tolerances of the two distinct population segments are similar (Heublein et al. 2017b). Based on laboratory studies, Van Eenennaam et al. (2005 cited in Heublein et al. 2017b) concluded that 63°F to 68°F is optimal water temperature range for growth and survival of Green Sturgeon larvae. This temperature range exceeds the upper limit of optimal temperatures for Green Sturgeon eggs (63°F), so there is no overlap in optimal conditions for eggs and larvae. In another laboratory study, Mayfield and Cech (2004 cited in Heublein et al. 2017b) concluded that 59°F to 66°F is the optimal range of water temperatures for growth of juvenile sturgeon. This temperature range overlaps the optimal range temperature ranges for Green Sturgeon eggs (53°F to 63°F) and larvae (63°F to 68°F).

There are few notable differences in the HEC-5Q mean monthly water temperature estimates at RBDD or Hamilton City between the No Action Alternative and Alternative 1 during the Green Sturgeon larval and juvenile rearing and emigration period in any month, except for September (Tables O.3-9 and O.3-10). During over half of the years in September, the Alternative 1 water temperature at RBDD is greater than the No Action Alternative temperature, with a maximum difference of about 3°F (Figure O.3-22). Over the range of years for which there are temperature differences, the water temperatures of both the No Action Alternative and Alternative 1 are under the 63°F lower limit of the optimal range for larvae. However, the Alternative 1 water temperatures are closer to the optimal range and therefore would potentially provide more favorable conditions for larval growth and survival. For the juveniles at RBDD, the September water temperatures under the No Action Alternative are below the 59°F lower limit of the optimal temperature range in about half of the years, and under Alternative 1 they are below the optimal range in about a third of the years (Figure O.3-22). The September HEC-5Q temperature estimates for Hamilton City also fall within or are closer to the optimal ranges of Green Sturgeon larvae and juveniles in more years under the Alternative 1 than the No Action Alternative (Table O.3-10; Figure O.3-23).

The CalSim II flow results indicate that Alternative 1 would have a less-than-signficant impact on rearing larval and juvenile southern DPS Green Sturgeon relative to the No Action Alternative, and the HEC-5Q water temperature modeling results indicate that Alternative 1 would provide a minor potential benefit to rearing larval and juvenile Green Sturgeon relative to the No Action Alternative.

O.3.3.2.7 Adult Upstream Migration and Holding

Green Sturgeon adults enter the Sacramento River from the Delta as early as February and ultimately make their way upstream to spawn in deep pools from the GCID oxbow (near Hamilton City) to the Cow Creek confluence (Heublein et al. 2017b). Elevated flows during the late winter and early spring months may provide an important cue for spawning Green Sturgeon adults to initiate their upstream migrations (Heublein et al. 2009; NMFS 2018). Green Sturgeon spawn in most years from April through July, but spawn in occasional years as late as October. After spawning, the adults hold in the river for varying amounts of time, but typically emigrate back to the San Francisco Estuary and the ocean from about October through December (Heublein et al. 2017b).

Flows during the February through December period of Green Sturgeon immigration, spawning and holding would generally be similar between Alternative 1 and the No Action Alternative at RBDD, Hamilton City, and Wilkins Slough (Tables O.3-12 through O.3-14). Exceptions include moderately higher mean monthly flows under Alternative 1 at both locations during February, March, May, June, and December of various water year types and substantially lower flows under Alternative 1 during September and November. All of the more notable flow differences occur within a range of river flows (~5,000 cfs to 15,000 cfs) not expected to substantially affect upstream passage of migrating Green sturgeon, but the September and November flow reductions under Alternative 1 at Hamilton City and RBDD could result in reduced habitat quality in holding pool habitats, adversely affecting holding adults.

The USEPA (2003) gives 61°F as the critical 7DADM water temperature for Green Sturgeon adults holding in the Sacramento River. The water temperature upper limit for of spawning adults is assumed to be similar to that for incubating eggs, 63°F. In addition, assuming that adults are at least as tolerant to warm temperatures as juveniles, the upper limit for mean monthly water temperatures of migrating adults, whether immigrating or emigrating, is treated as 66°F.

There are few major differences in mean monthly water temperatures between the No Action Alternative and Alternative 1 in the Sacramento River at Knights Landing during the February through April period that most adult Green Sturgeon migrate upstream or during the later months (through December) when the sturgeon migrate downstream after spawning (Table O.3-11). However, large differences occur in September of wet and above normal water years, when monthly mean water temperatures under Alternative 1 are higher than those under the No Action Alternative by over 4°F. The means exceed the 66°F threshold for migrating Green Sturgeon adults in both water year types under Alternative 1 and in neither water year type under the No Action Alternative. The mean monthly water temperatures at Knights Landing also exceed the 66°F threshold under both alternatives during June through August of all water year types and May of all but wet years (Table O.3-11). Adults migrating downstream from May through September would potentially be adversely affected by the high water temperatures. However, adults migrating upstream would be less affected because most upstream immigration occurs before late spring (Heublein et al. 2009), when water temperatures are below the 66°F threshold.

During the May through December spawning and post-spawn holding period for Green Sturgeon, the HEC-5Q mean monthly water temperatures at Hamilton City, which is located in the most downstream, warmest section of the Green Sturgeon spawning reach, are generally similar between the No Action Alternative and Alternative 1, except for higher temperatures under Alternative 1 in September, as discussed above for Knights Landing (Table O.3-10). The mean monthly water temperatures during the hottest months of this period, July through September, range from 59°F to over 68°F (both in September). The temperatures frequently exceed the 63°F threshold for spawning adults and the 61°F threshold for holding adults during these months. During September, the mean water temperatures exceed the 63 and 61°F thresholds more often under Alternative 1 than under the No Action Alternative. Under Alternative

1, the temperatures exceeds the 63 and 61°F thresholds 66% and 82% of years, respectively, and under the No Action Alternative they exceed the thresholds 49% and 55% of years (Figure O.3-23). September water temperatures are cooler at RBDD and there is no difference at this location between Alternative 1 and the No Action Alternative in the frequency of the threshold exceedances (Figure O.3-22). During October through December, the mean monthly water temperatures stay well below both thresholds in every water year type, except in October of critically dry water years.

The CalSim II modeling results indicate that for adult southen DPS Green Sturgeon holding in September or November, reduced flows under Alternative 1 would have a potentially significant adverse impact on holding habitat relative to the No Action Alternative. However, it is more difficult to draw conclusiongs about the water temperature results. As previoulsy indicated, the HEC-5Q modeling for Alternative 1 does not include many of the proposed water temperature management improvements that would be included in Alternative 1 and, therefore, likely overestimates summer and fall water temperatures that would result from this alternative. Therefore, although the HEC-5Q modeling results indicate that the water temperatures for September of wet and above normal water years would more often exceed the 66, 63 and 61°F thresholds for migrating, spawning and holding adult Green Sturgeon under Alternative 1 than under the No Action Alternative, it is likely that this would not occur, or would occur less frequently, under full implementation of Alternative 1 with all of its operational and structural improvements for facilitating coldwater pool storage. In conclusion, although the HEC-5Q model results for adult Green Sturgeon migrating, spawning and holding during September near Hamilton City indicate that water temperatures under Alternative 1 would have a significant adverse impact relative to the No Action Alternative, the expected water temperature management improvements under Alternative 1, which are only partially represented in the HEC-5Q results, are expected to improve water temperatures for Green Sturgeon. The relative magnitude of the adverse effects indicated by the HEC-5Q modeling versus the expected benefits obtained from the water temperature management improvements is unknown, which makes any conclusion about the true effect of Alternative 1 highly uncertain.

O.3.3.2.8 Fall-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Fall-Run Chinook Salmon migrate upstream past RBDD on the Sacramento River between July and December, typically spawning in upstream reaches from October through January, with a peak in October and November. Eggs and alevins are present from October through April. The primary spawning area used by Fall-Run Chinook Salmon in the Sacramento River is the area from Keswick Dam downstream to RBDD. Spawning densities for all Chinook Salmon runs are highest in this reach, but the distribution of spawning fall-run generally extends farther downstream and includes spawning areas below RBDD (Gard 2013).

CalSim II modeling indicates that mean monthly flows released at Keswick Dam under Alternative 1 would generally be higher than or similar to the flows under the No Action Alternative, except in September and November of above normal and wet years, when Alternative 1 flows would be substantially lower than the No Action Alternative flows (Table O.3-5). These reductions would average approximately 3,000 cfs and 3,500 cfs lower in November for above normal and wet years, respectively, when Fall-Run Chinook Salmon are spawing and eggs and alevins are present. Based on PHABSIM results (flow-habitat relationships) developed by the USFWS (2003) for the Sacramento River between Keswick Dam and Battle Creek, lower flows under Alternative 1 would increase the amount of available spawning habitat (as measured by weighted usable area) in above normal and wet years (Figure O.3-35). However, higher flows under Alternative 1 in subsequent months (averaging approximately 1,000 cfs to 2,000 cfs higher in December and January of above normal and wet years) would reduce the amount of available spawning habitat in these months relative to the No Action Alternative (Table O.3-5). In wet years, for example, the changes in flow under Alternative 1 would result in an 80% increase in spawning WUA in November, a 26% decrease in December, and a 7% decrease in January. Consequently, changes in flows under Alternative 1 would have both positive and negative effects on the availability of spawning habitat relative to the No Action Alternative.

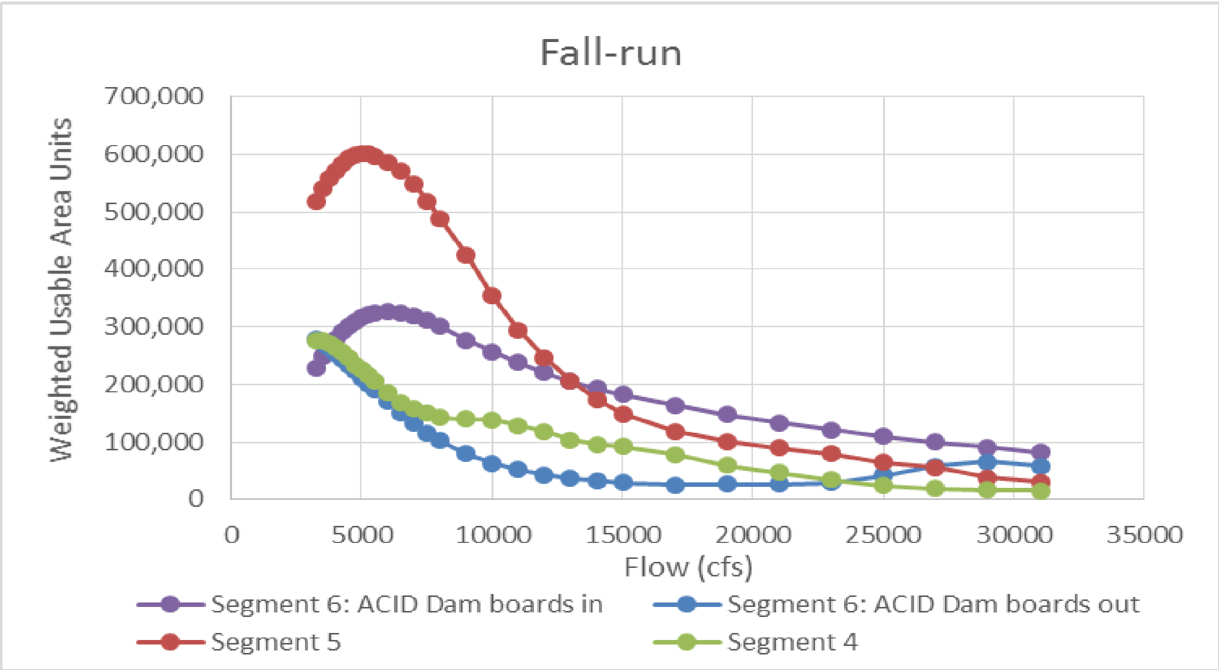

Figure O.3-35. Spawning WUA Curves for Fall-Run Chinook Salmon in the Sacramento River. Segment 4: Battle Creek to Cow Creek; Segment 5: Cow Creek to the Anderson-Cottonwood Irrigation District (ACID) Dam; Segment 6: ACID to Keswick Dam

HEC-5Q modeling indicates that Alternative 1 would improve water temperatures for Fall-Run Chinook Salmon spawning and incubation during the peak spawning months (October and November) relative to the No Action Alternative; for example, in October, modeled mean monthly temperatures at Keswick Dam are predicted to be below the 53.5°F threshold (Martin et al. 2017; Anderson 2018) in approximately 70% of years under Alternative 1 compared to less than 20% of the years under the No Action Alternative (Figure O.3-18; Table O.3-6). Under both alternatives, water temperatures in the upper Sacramento River during the remainder of the Fall-Run Chinook Salmon spawning and incubation period would be similar and within suitable ranges for spawning and incubation through March or April (Tables O.3-6 through O.3-9). Therefore, reductions in water temperatures in the upper Sacramento River under Alternative 1 in October and November would have beneficial effects on Fall-Run Chinook Salmon relative to the No Action Alternative. Other actions that would be expected to improve habitat conditions for spawning adults, eggs, and alevins include proposed operational and structural modifications at Shasta Dam as well as spawning habitat restoration actions (e.g., spawning gravel placement) that are currently proposed as part of Alternative 1. Spawning and rearing habitat restoration are proposed programmatic measures that are not certain to be included in Alternative 1. Overall, improved habitat conditions during the peak spawning months under Alternative 1 would be expected to substantially offset potential reductions in spawning habitat availability associated with higher flows later in the season. Therefore, changes in Sacramento River flows and water temperaturess resulting from Alternative 1 would have a less-than-significant effect on Fall-Run Chinook Salmon spawning and incubation in the Sacramento River relative to the No Action Alternative.

Juvenile Rearing and Emigration

Fall-Run Chinook Salmon juveniles rear in the Sacramento River primarily from December through May. Following emergence, juveniles rear for variable lengths of time in the Sacramento River before entering the Delta and estuary, and may emigate as fry, parr, or smolts. The timing of emigration is variable but generally peaks in the upper river from January through April and in the lower river from January thorugh May (NMFS 2009).

During the primary rearing period (December through May), CalSim II modeling indicates that Sacramento River flows under Alternative 1 would generally be higher than or similar to the flows under the No Action Alternative (Table O.3-5). Based on PHABSIM results (flow-habitat relationships) for fry (<60 mm) and juvenile (≥60 mm) Chinook Salmon developed by the USFWS (2005) for the Sacramento River between Keswick Dam and Battle Creek, higher flows under Alternative 1 would reduce the amount of available rearing habitat (as measured by weighted usable area). (Figures O.3-36 and O.3-37). The largest flow increases would occur in the winter of wet, above normal, and below normal water years, potentially affecting fry habitat (Table O.3-5). In wet years, for example, an increase in flow of approximately 2,100 cfs in December (on average) corresponds to a 7% decrease in available fry rearing habitat (as measured by WUA). In spring, the largest flow reductions would occur in above normal and below normal water years. In below normal water years, for example, an increase in flow of approximately 1,000 cfs in May (on average) corresponds to an 8% decrease in juvenile rearing WUA. While this represents a potential adverse effect on rearing habitat capacity.

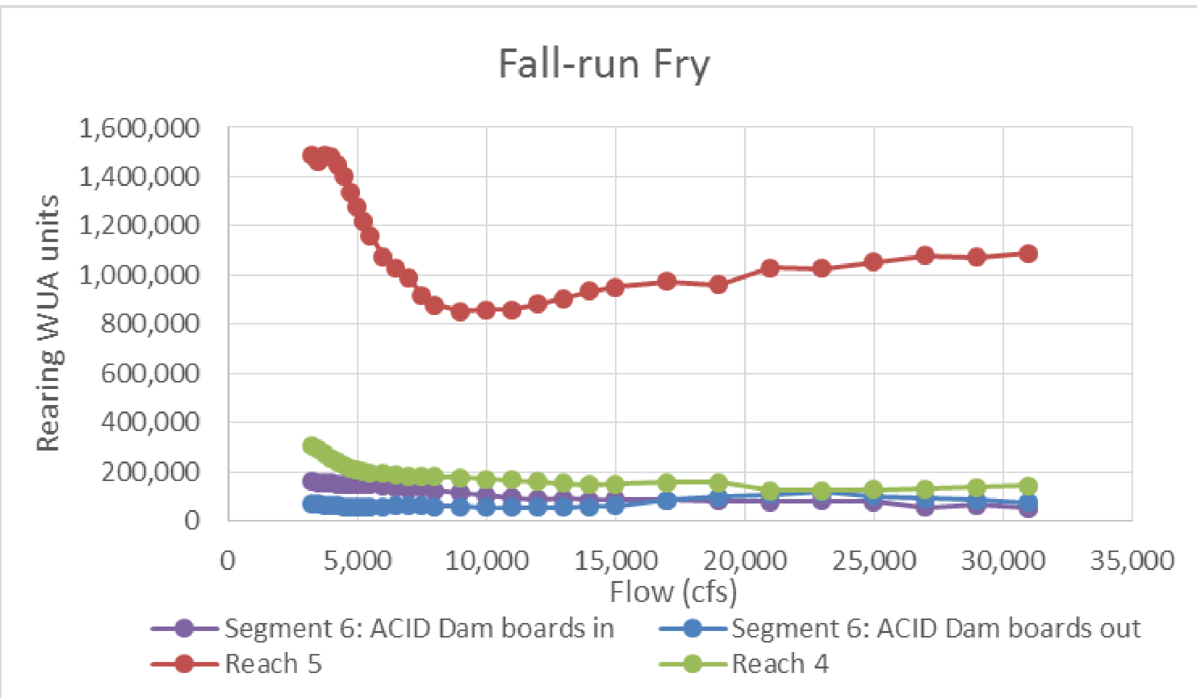

Figure O.3-36. Fry Rearing WUA Curves for Fall-Run Chinook Salmon in the Sacramento River. Segment 4: Battle Creek to Cow Creek; Segment 5: Cow Creek to the Anderson-Cottonwood Irrigation District (ACID) Dam; Segment 6: ACID to Keswick Dam

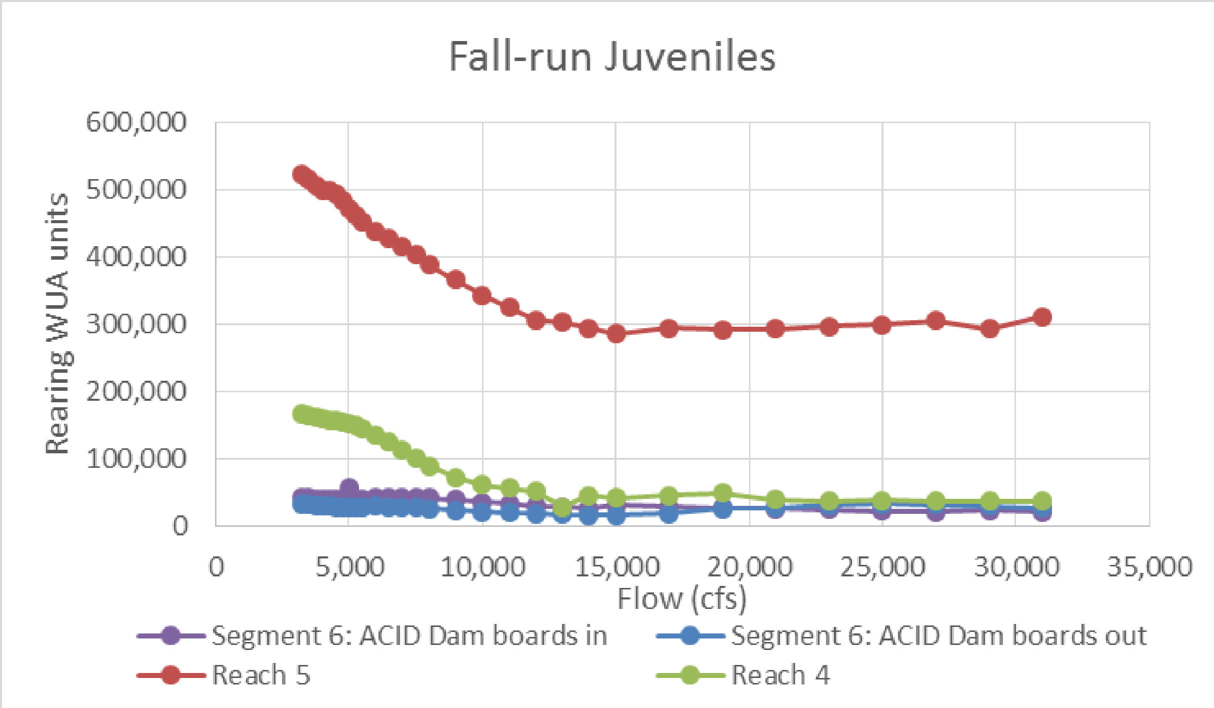

Figure O.3-37. Juvenile Rearing WUA Curves for Fall-Run Chinook Salmon in the Sacramento River. Segment 4: Battle Creek to Cow Creek; Segment 5: Cow Creek to the Anderson-Cottonwood Irrigation District (ACID) Dam; Segment 6: ACID to Keswick Dam

The USEPA-recommended 7DADM water temperatures for juvenile salmonids is 61°F in core rearing areas (upper reaches of natal rivers) and 64°F in non-core areas (lower reaches). Although based on studies of salmonids in the Pacific Northwest, this criterion was considered a reasonable threshold for evaluating the potential for adverse temperature effects based on monthly modeling results. Under both the No Action Alternative and Alternative 1, HEC-5Q estimates of mean monthly water temperatures from Keswick to RBDD do not exceed the 61°F threshold during any month or water year type during the primary Fall-Run Chinook Salmon rearing and emigration period (December through May) (Tables O.3-6 through O.3-9). Farther downstream, the 64°F threshold would be exceeded in the lower river (Knights Landing) in May under both alternatives but there would be no major differences between the alternatives in the frequency and magnitude of water temperatures above this threshold (Table O.3-10). Therefore, changes in Sacramento River flows and water temperatures resulting from Alternative 1 would have a less-than-significant effect on rearing and emigrating juvenile Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative.

Adult Upstream Migration and Holding

Fall-Run Chinook Salmon migrate upstream past RBDD on the Sacramento River between July and December. Adults may hold until the spawning season, which occurs primarily from October through January.

During the July through December migration period, CALSIM II modeling indicates that mean monthly flows under Alternative 1 at Keswick, RBDD, Hamilton City, and Wilkins Slough would be substantially lower in September and November of wet and above normal water years than those under the No Action Alternative (Tables O.3-5 and O.3-12 through O.3-14). However, mean monthly flows would be maintained at a minimum of 3,250 under both alternatives, and would not differ substantially in frequency and magnitude between the alternatives until flows exceed approximately 5,000 cfs (Figures O.3-32 and O.3-29). Within the range of flows in which major differences in flows would occur (>5,000 cfs), no adverse effects on migrating or holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable flow and water quality conditions for migrating and holding adults under both alternatives.

No water temperature requirements have been established for adult Fall-Run Chinook Salmon migration and holding in the Sacramento River. The USEPA-recommended 7DADM water temperatures is 68°F for migrating adult salmonids and 61°F for holding adults prior to spawning. Under the No Action Alternative and Alternative 1, no major differences would be expected to occur in the frequency and magnitude of monthly water temperatures exceeding 68°F; for example, at Hamilton City, modeled water temperatures in September exceeded 68°F in about 8% of the years under both the No Action Alternative and Alternative 1 (Figure O.3-23). Similarly, no major differences would be expected to occur in the exposure of holding adults to potentially stressful water temperatures; for example, at RBDD, modeled water temperatures in September exceeded 61°F in about 27% of the years under both the No Action Alternative and Alternative 1 (Figure O.3-22). As previously discussed, the modeling for Alternative 1 does not include many of the new water temperature management actions proposed for Alternative 1, and therefore does not include the potentially beneficial effects of these actions on pre-spawning Fall-Run Chinook Salmon, particularly in the upper Sacramento River. Therefore, changes in Sacramento River flows and water temperaturess associated with Alternative 1 would have a less-than-significant effect on migrating and holding adult Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative.

O.3.3.2.9 Late Fall-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

In the Sacramento River, adult Late Fall-Run Chinook Salmon spawn primarily from December through April, and eggs and alevins are present in the gravel from December through June. Most adults spawn upstream of Red Bluff Diversion Dam, with the majority spawning between Keswick Dam and the ACID Dam.

During the primary Late Fall-Run Chinook Salmon spawning and incubation period (December thorugh April), CalSim II modeling indicates that mean monthly flows at Keswick Dam under Alternative 1 would generally be higher than or similar to the flows under the No Action Alternative (Table O.3-5). Flow increases of greatest magnitude are expected to occur in wet, above normal, and below normal years, ranging from approximately 1,000 cfs to 2,000 cfs (on average) from December through February. Based on PHABSIM results (flow-habitat relationships) developed by the USFWS for the Sacramento River between Keswick Dam and Battle Creek (USFWS 2003a), higher flows under Alternative 1 would reduce the amount of available spawning habitat (as measured by WUA) (Figure O.3-38). For example, on average, spawning habitat WUA would be reduced by 18% in December and 7% in January in wet years, and percent reductions in WUA in above normal and below normal years would generally be within this range from December thorugh February. Consequently, relative to the No Action Alternative, changes in flows under Alternative 1 would have negative effects on the availability of spawning habitat for Late Fall-Run Chinook Salmon.

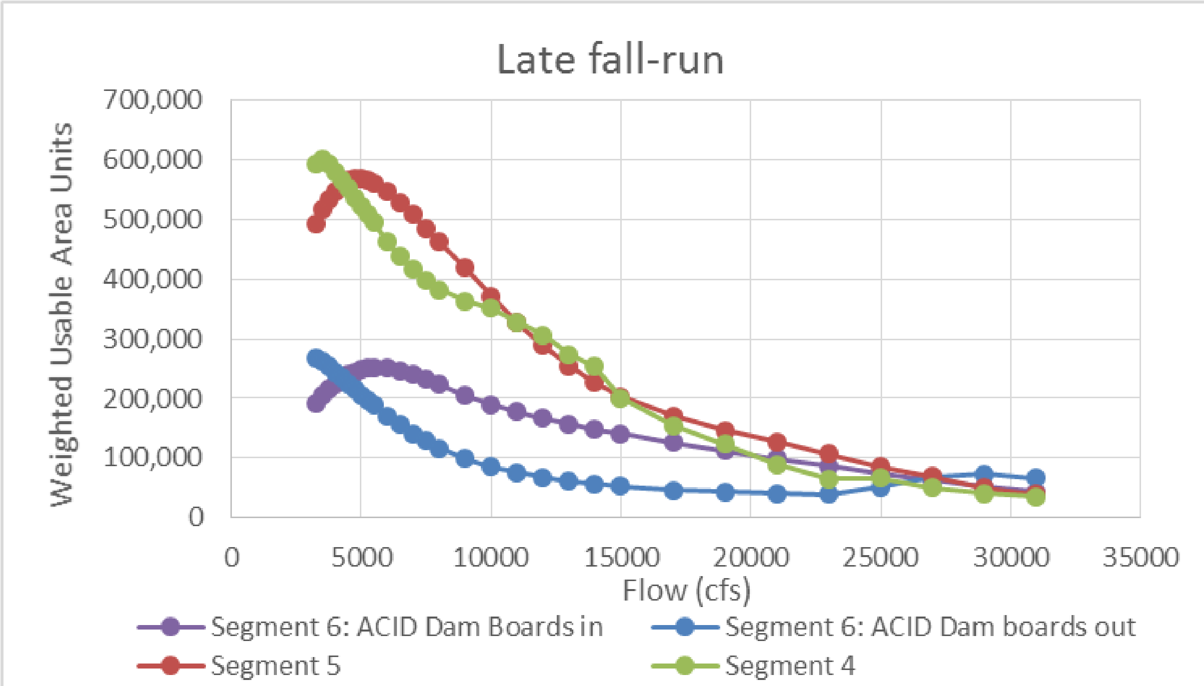

Figure O.3-38. Spawning WUA Curves for Late Fall-Run Chinook Salmon in the Sacramento River. Segment 4: Battle Creek to Cow Creek; Segment 5: Cow Creek to the Anderson-Cottonwood Irrigation District (ACID) Dam; Segment 6: ACID to Keswick Dam

HEC-5Q modeling indicates that water temperatures in the upper Sacramento River during the Late Fall-Run Chinook Salmon spawning and incubation period (December through June) would be similar under the No Action Alternative and Alternative 1 (Tables O.3-9 through O.3-9). Under both alternatives, water temperatures in the Sacramento River would be maintained below 53.5°F from Keswick Dam to the Clear Creek confluence through June of most years (Table O.3-7). As previously discussed, the modeling for Alternative 1 does not include many of the new water temperature management actions proposed for Alternative 1, and therefore does not include the potentially beneficial effects of these actions on Late Fall-Run Chinook Salmon, especially for eggs and alevins that may be present in the gravel through June. Other actions that would be expected to improve habitat conditions for spawning adults, eggs, and alevins include proposed operational and structural modifications at Shasta Dam as well as spawning habitat restoration actions (e.g., spawning gravel placement) that are proposed as part of Alternative 1. These actions would potentially improve the quantity and quality of spawning habitat for Late Fall-Run Chinook Salmon, and potentially offset reductions in the amount of available habitat predicted by the flow-habitat relationships. Therefore, the potential negative effects of higher flows on available spawning and incubation habitat for Late Fall-Run Chinook Salmon spawning and incubation would likely be less-than-significant.

Juvenile Rearing and Emigration

Late fall–run Chinook Salmon fry generally emerge from March through June, and juveniles rear in the Sacramento River through the summer before emigrating at a relatively large size (150- to 170-mm fork length) primarily from November through May.

CalSim II modeling indicates that Sacramento River flows under Alternative 1 would generally be higher than or similar to the flows under the No Action Alternative during early rearing period (March through

August) but would be substantially lower in September and November of wet and above normal water years (Table O.3-5). Based on PHABSIM results (flow-habitat relationships) for juvenile (≥60 mm) Late Fall-Run Chinook Salmon developed by the USFWS for the Sacramento River between Keswick Dam and Battle Creek (USFWS 2005), generally higher flows during spring and summer would reduce the amount of available fry rearing habitat (Figures O.3-39 and O.3-40). For example, in below normal water years, modeled monthly flows from March through June under Alternative 1 ranged from approximately 400 cfs to 1,300 cfs higher (on average) than those under the No Action Alternative (Table O.3-5), corresponding to 2% to 9% reductions in available fry rearing habitat in the upper Sacramento River (as measured by WUA). However, in wet years, flow reductions of approximately 5,700 cfs in September and 3,500 cfs in November (on average) correspond to a 36% and 33% increase, respectively, in juvenile rearing habitat in those months. Although reductions in fry habitat in the spring and summer represent a potential adverse effect on rearing habitat capacity, the proposed habitat restoration actions in the Sacramento River under Alternative 1 (e.g., side channel and floodplain creation) are expected to increase the quantity and quality of rearing habitat and potentially expand the availability of habitat under the higher spring and summer flows.

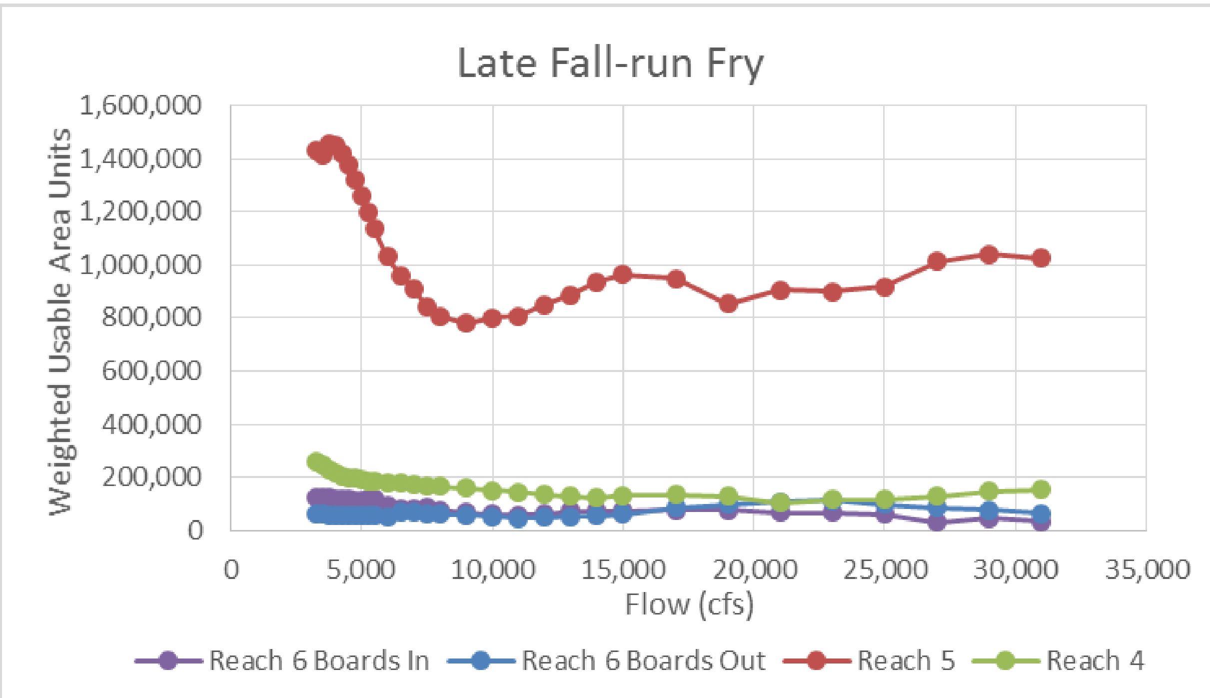

Figure O.3-39. Fry Rearing WUA Curves for Late Fall-Run Chinook Salmon in the Sacramento River. Segment 4: Battle Creek to Cow Creek; Segment 5: Cow Creek to the Anderson-Cottonwood Irrigation District (ACID) Dam; Segment 6: ACID to Keswick Dam

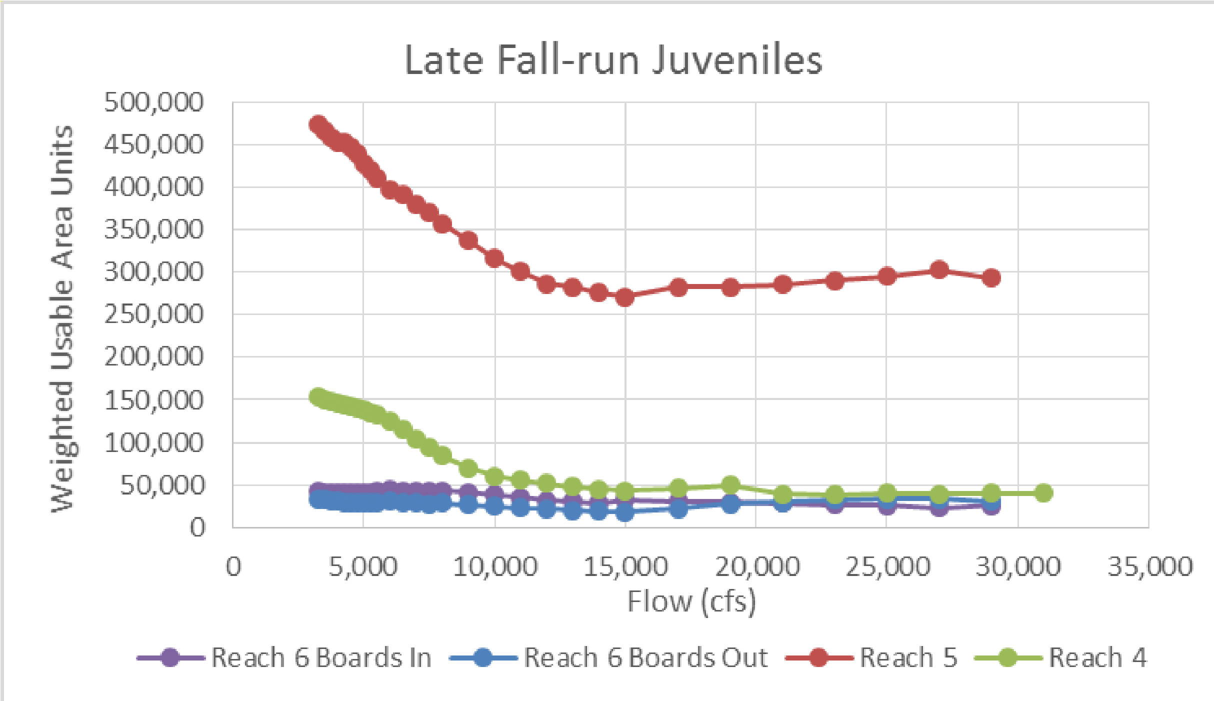

Figure O.3-40. Juvenile Rearing WUA Curves for Late Fall-Run Chinook Salmon in the Sacramento River. Segment 4: Battle Creek to Cow Creek; Segment 5: Cow Creek to the Anderson-Cottonwood Irrigation District (ACID) Dam; Segment 6: ACID to Keswick Dam

Current and proposed operations at Shasta and Keswick Dam to meet water temperature requirements for Winter-Run Chinook Salmon would be expected to maintain suitable rearing temperatures for juvenile Late Fall-Run Chinook Salmon in the upper Sacramento River through the summer. In the upper Sacramento River, monthly water temperatures exceeding the USEPA-recommended 7DADM water temperature for core rearing areas (61°F) would be limited to the summer of critical water years under both alternatives (Tables O.3-6 through O.3-9), and there would be no major differences in the frequency and magnitude of water temperatures above this threshold between the two alternatives (Figure O.3-22). Similarly, during the primary Late Fall-Run Chinook Salmon emigration period (November through May), monthly water temperatures exceeding the USEPA-recommended 7DADM water temperature for non-core rearing areas (64°F) would occur in the lower river (Knights Landing) in May under both alternatives but there would be no major differences in the frequency and magnitude of water temperatures above this threshold (Figure O.3-41). Therefore, changes in Sacramento River flows and water temperatures resulting from Alternative 1 would have a less-than-significant effect on rearing and emigrating juvenile Late Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative.

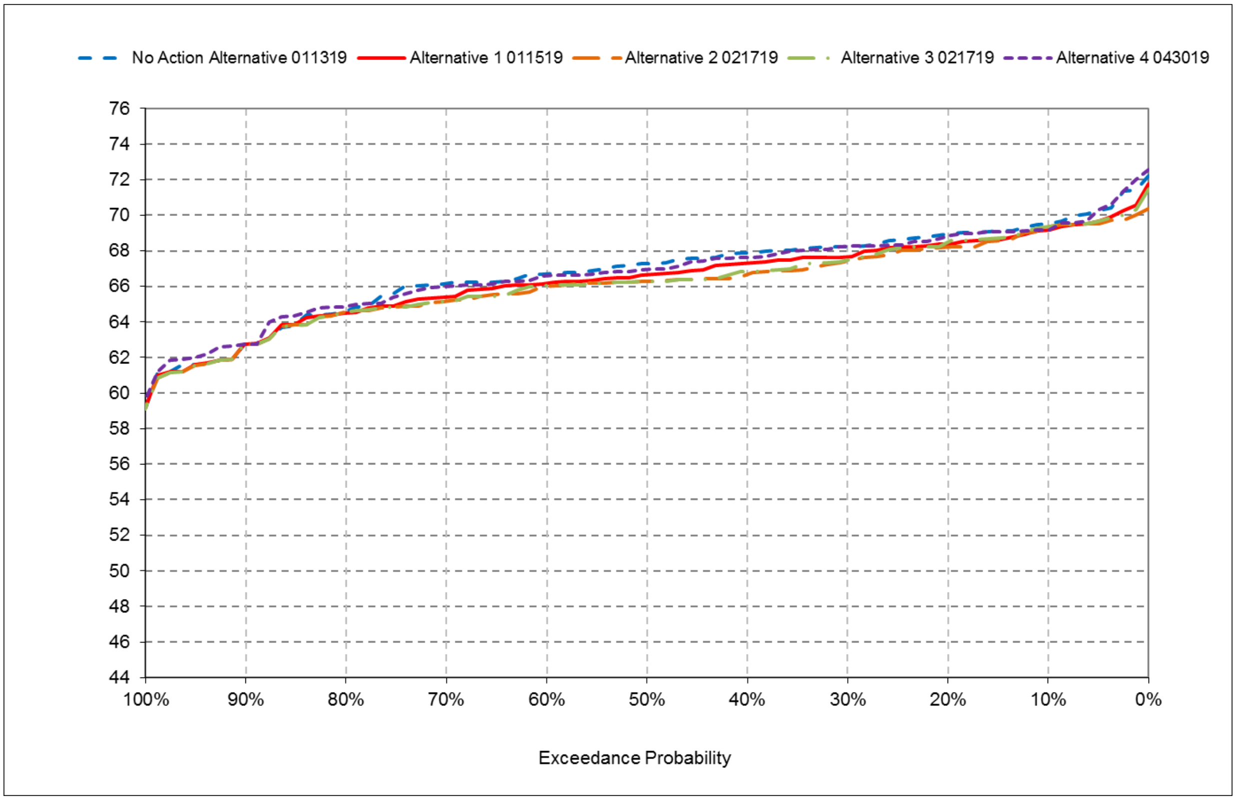

Figure O.3-41. HEC-5Q Sacramento River Water Temperatures at Knights Landing under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3, and Alternative 4; May

Adult Upstream Migration and Holding

In the Sacramento River, adult Late Fall-Run Chinook Salmon migrate from October through April, with a peak during January through March (NMFS 2009). Adults hold for 1 to 3 months prior to spawning, which occurs primarily from December through April.

During the October through April migration and holding period, CALSIM II modeling indicates that mean monthly flows under Alternative 1 at Keswick, RBDD, Hamilton City, and Wilkins Slough would be substantially lower in November of wet and above normal water years than those under the No Action Alternative (Tables O.3-5 and O.3-12 through O.3-14). However, mean monthly flows would be maintained at a minimum of 3,250 under both alternatives, and would not differ substantially in frequency and magnitude until flows exceed approximately 5,000 cfs (Figures O.3-29). Within the range of flows, no adverse effects on migrating or holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable flow and water quality conditions for migrating and holding adults under both alternatives.

HEC-5Q modeling indicates that water temperatures in the Sacramento River during the Late Fall-Run Chinook Salmon migration and holding period (October through April) would be similar under the No Action Alternative and Alternative 1 (Tables O.3-6 through O.3-9). Under both alternatives, water temperatures in the lower Sacramento River would be maintained below the USEPA-recommended 7DADM water temperatures for migrating adult salmonids (68°F) throughout the migration period (Table O.3-11). In the upper Sacramento River, monthly water temperatures exceeding the USEPA-recommended 7DADM water temperature for holding adults (61°F) would be limited to October of critical water years under both alternatives (Tables O.3-6 through O.3-9), and there would be no major differences between the alternatives in the frequency and magnitude of water temperatures above this threshold (Figure O.3-42). Therefore, changes in Sacramento River flows and water temperaturess associated with Alternative 1 would have a less-than-significant effect on migrating and holding adult Late Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative.

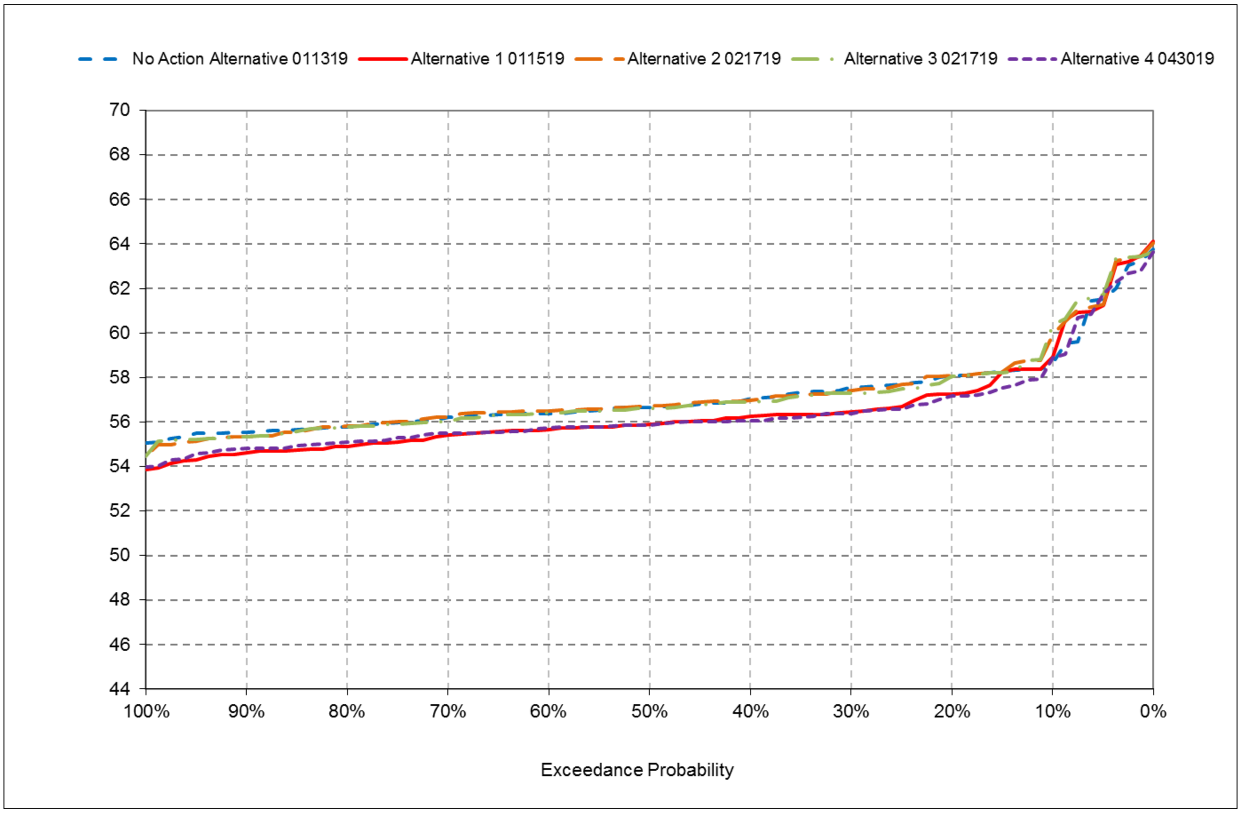

Figure O.3-42. HEC-5Q Sacramento River Water Temperatures at Red Bluff Diversion Dam under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3, and Alternative 4; October

O.3.3.2.10 <u>White Sturgeon</u>

Spawning and Egg Incubation

Elevated flows during late winter and early spring may provide an important cue for spawning White Sturgeon adults to initiate their upstream spawning migrations (Heublein et al. 2017). Spawning occurs in deep water in the middle and lower Sacramento River from Verona (RM 80) to just upstream of Colusa (~RM 156) from late February to early June, but primarily during March and April, (Moyle et al. 2015; Heublein et al. 2017). The adults typically return promptly to the Delta/Estuary after spawning. The eggs hatch about a week after fertilization (Heublein et al. 2017). Because the incubation time for White Sturgeon is so short, the peak effects-analysis period for incubating eggs is considered to be March and April.

During the March and April spawning and egg incubation period of White Sturgeon, CalSim II estimates of mean monthly flows at Wilkins Slough (RM 117) under the No Action Alternative and Alternative 1 range from about 5,200 cfs for April of critically dry water years to about 17,800 cfs for March of wet water years (Table O.3-14). These flow levels are likely to be adequate for White Sturgeon spawning and egg incubation, so no adverse effects are expected to result. Differences in flows between Alternative 1 and the No Action Alternative are small in both months, but flows are moderately higher for Alternative 1 in March of below normal and critically dry water years (Table O.3-14). Therefore, it is concluded that Alternative 1 would have no flow effects on White Sturgeon eggs and embryos relative to the No Action Alternative.

Based on presence of eggs or larvae, White Sturgeon have been found to spawn at water temperatures from 46 to 73°F, with peak spawning occurring around 57°F (Heublein et al. 2017). Laboratory studies indicate that the optimal range for normal embryo development of White Sturgeon is 57 to 63°F (Wang et al. 1985, cited in Heublien et al. 2017). Mortality increased as temperature increased until it reached 68°F, which was lethal to all the embryos. However, viable White Sturgeon embryos have been collected in the field in water temperatures above 68°F (Heublein et al. 2017).

The HEC-5Q water temperature modeling results for March and April indicated that mean monthly water temperatures at Knights Landing were well below the 63°F threshold for optimal temperatures, except in April of critically dry water years (Table O.3-11). As noted earlier, the mean monthly water temperatures for the water year types combine water temperatures for many years and therefore mask individual year variations. The monthly means for individual years show that April water temperatures exceed the 63°F threshold in 15% of years, but lie below the 68°F lethal temperature in all years (Figure O.3-43). There are no appreciable differences in water temperatures between Alternative 1 and No Action Alternative in March or April (Table O.3-11; Figure O.3-43). During June, the warmest month of the full spawning and egg incubation period, the mean monthly water temperatures are predicted to exceed the 68°F lethal temperature in all water year types, but the water temperatures are lower for Alternative 1 than for the No Action Alternative, especially in drier water years (Table O.3-11). Therefore, it is concluded that Alternative 1 would have no water temperature effects on White Sturgeon eggs and embryos relative to the No Action Alternative.

Larval and Juvenile Rearing and Emigration

The White Sturgeon juvenile stage begins when metamorphosis of the larva is complete, typically at about 45 dph (Heublein et al. 2017). Therefore, since the White Sturgeon spawn primarily in March and April, the larval period is considered to be March through June. The larvae are distributed from upstream spawning habitats downstream to the western Delta.

Laboratory studies indicate that White Sturgeon larvae have high growth rates at 68°F, but outside of controlled laboratory conditions, suitable water temperatures may be less than 61°F (Heublein et al. 2017). During the March through June larval period, water temperature modeling indicates that water temperatures frequently exceed these water temperature thresholds at Knights Landing under the No Action Alternative and Alternative 1 (Table O.3-11), especially, as noted above, in June. Such high levels of temperature threshold exceedances suggest that typical water temperature conditions in the lower Sacramento River may be highly stressful for white sturgeon larvae. In any case, the water temperatures, especially in June, are lower under Alternative 1 than under the No Action Alternative (Table O.3-11).

Juvenile white sturgeon are believed to initiate a secondary dispersal (the primary dispersal occurring at the larval stage) in spring by actively swimming downstream during the night. Dispersal likely lasts several days and covers many miles (Heublein et al. 2017).

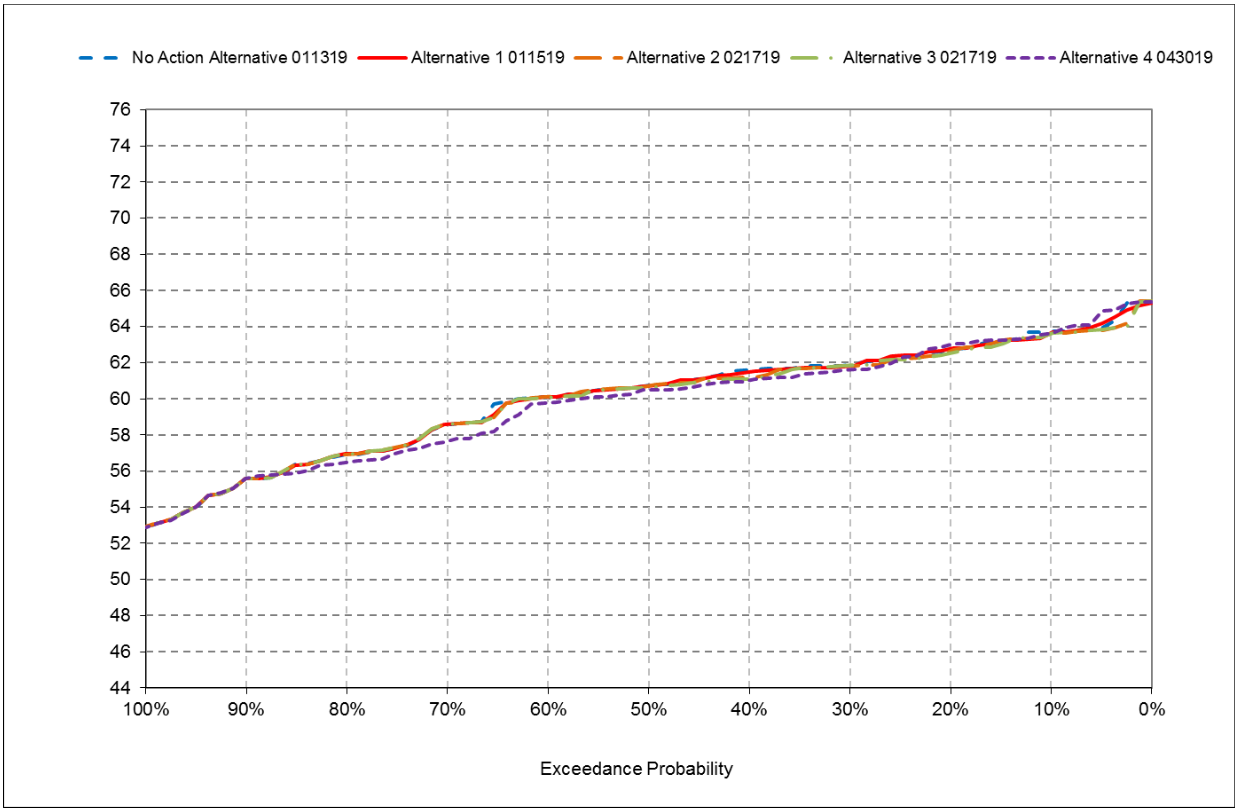
There is a positive correlation between mean daily freshwater outflow (April to July) and white sturgeon year class strength (CDFG 1992 and USFWS 1995, cited in NMFS 2018b). These relationships may result from flows transporting larvae to areas with greater food availability, dispersing larvae over a wider area, and/or enhancing nutrient availability to the Sacramento River and Delta/Estuary. The relationship of White Sturgeon year class recuitemnt and outflow is discussed in more detail in Section 0.3.3.8 Bay-Delta.

During the of White Sturgeon juvenile emigration period, approximately April to July, CalSim II results indicate that flows at Wilkins Slough during May and June would increase with Alternative 1 compared to No Action Alternative, but decrease in July of critically dry years (Table O.3-14). Alternative 1 would have a less-then significant impact on larval and juvenile White Sturgeon.

O.3.3.2.11 Adult Upstream Migration and Holding

As previously noted, White Sturgeon adults to initiate their upstream spawning migrations during late winter and early spring, presumably in response to elevated flows (Heublein et al. 2017). CalSim II flows at Wilkins Slough for December through February are not much different between Alternative 3 and No Action Alternative for all water year types. There are a few months and water year types when flows are higher under Alternative 3, such as December during wet years and January during Above Normal and below normal years. These increased flows would be beneficial for White Sturgeon migration, but all flows are between 7,800 and 19,600 cfs, which are suitable for migration. There are no temperature differences from December through February for Knights Landing. Alternative 3 would have no flow or water temperature effects on White Sturgeon adults.

The CalSim II flow results for Wilkins Slough and the HEC-5Q water temperature results for Knight Landing indicate that Alternative 1 would have a less-than-signficant impact on White Sturgeon relative to the No Action Alternative.



O.3-43. HEC-5Q Sacramento River Water Temperatures at Knights Landing under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; April

O.3.3.2.12 Sacramento Splittail

Sacramento splittail occur in the Sacramento River upstream of the Delta from about December through May. The adults begin moving upstream from the Delta in December and spawn in river-margin and inundated floodplain habitats in February through April (Feyrer et al. 2005, 2006; Sommer et al. 2007; Moyle et al. 2015). The larvae hatch several days after spawning then rear for about a month in habitat similar to the spawning habitat (Moyle et al. 2004). The juveniles also rear upstream and then begin their downstream migration during April and May, as the river level recedes back to the channel (Moyle et al. 2004; Feyrer et al. 2005). Floodplain spawning in wet years overwhelmingly dominates production, but spawning in side channels and channel margins is important during low-flow years when floodplains are not inundated. In the Sacramento River drainage, splittail spawn from Colusa to Knights Landing, but the the most important spawning areas are the inundated floodplains of the Yolo and Sutter bypasses (Feyrer et al. 2005).

High flows benefit adults migrating upstream (Feyrer et al. 2006), and greatly enhance spawning and rearing habitat for larvae and early juveniles (Crain et al. 2004). Mean monthly flows at Wilkins Slough during January through March of wet and above normal water years consistently equal or exceed 17,000 cfs under both alternatives (Table O.3-14). Such flows would be high enough to produce moderate side channel and floodplain inundation along reaches of the Sacramento River not constrained by levees, but they would not be high enough to overtop the bypass weirs and flood the bypasses, although some flooding of the bypasses occurs from local streams. As noted earlier, the mean monthly flows for the water year types combine flows for many years and therefore mask individual year variations. Figure O.3-44 shows the expected mean February flows for each year of the CalSim II record. About 15% of the years have mean February flows greater than 22,500 cfs, which is the approximate flow at which the Tisdale Weir, the first of the Sacramento River flood relief weirs that spills, begins to spill into the Sutter Bypass (DWR 2010b). In any case, differences between Alternative 1 and the No Action Alternative in flows at Wilkins Slough during December through May are relatively minor, and generally result from higher flow under the Alternative 1 (Table O.3-14; Figure O.3-44). Furthermore, as previously noted, the highest flows, which cause substantial flooding on the Yolo and Sutter bypasses, are flood flows, which are not affected by routine project operations. It is concluded that Alternative 1 would have no flow effects on Sacramento Splittail relative to the No Action Alternative.

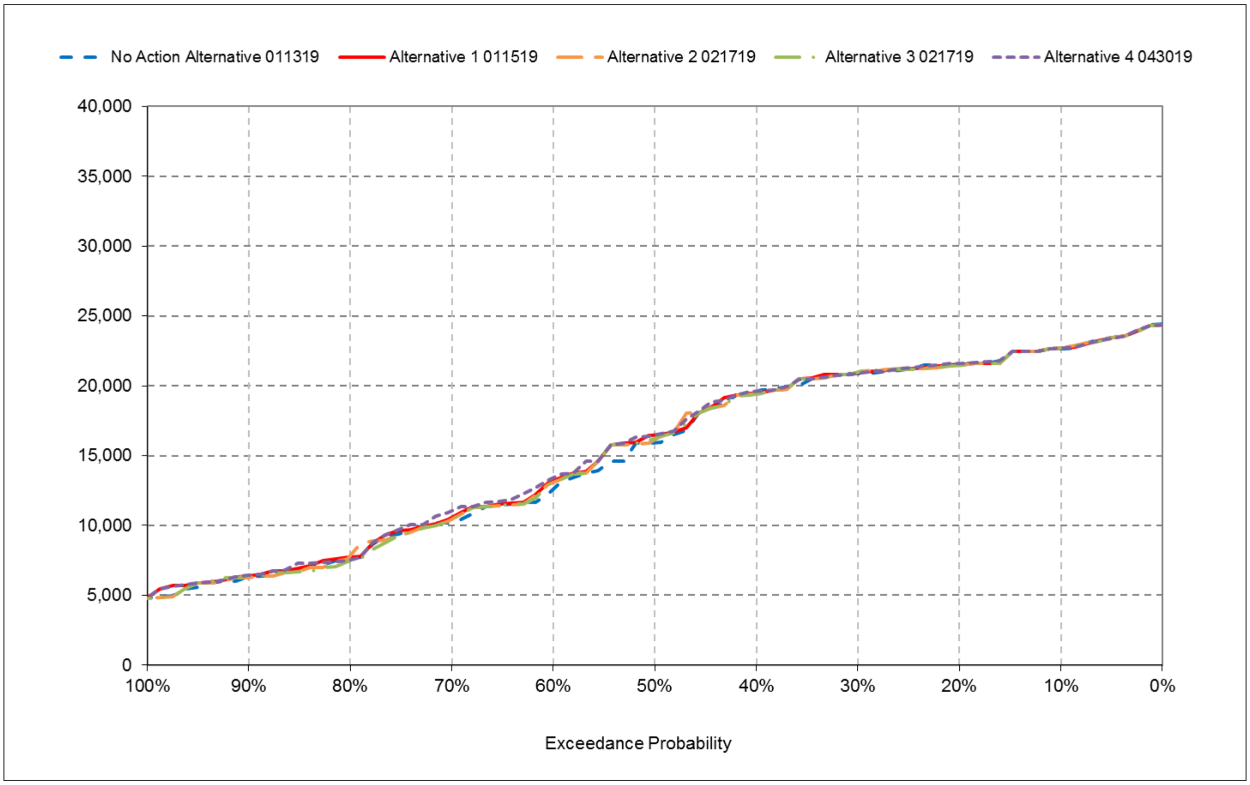


Figure O.3-44. CalSim II Sacramento River Flow at Wilkins Slough under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; February

Preferred water temperature for Sacramento splittail ranges from about 66°F for adults to about 75°F for juveniles, and the "upper limit of safe temperatures" ranges from about 75°F for adults and 81°F for juveniles (Young and Cech 1996). Mean monthly water temperatures during December through May at Knights Landing, which is at the approximate downstream limit of splittail spawning in the Sacramento River, range up to 68°F under both alternatives in May of critically dry water years (Table O.3-11). Although the monthly mean water temperatures underestimate the daily means, it is likely that the daily means infrequently exceed the 75°F threshold for adults. In any case, there are no meaningful water temperature differences between the alternatives at Knights Landing during the December through May period that Sacramento Splittial occupy the river upstream of the Delta (Table O.3-11). There is evidence that some juvenile splittail remain in the Sacramento River well upstream of the Delta through the entire year (Feyrer et al. 2005), but summer water temperatures in the more upstream locations where they have been found are considerably cooler than those at Knights Landing (compare Tables O.3-10 and O.3-11). Therefore, Alternative 1 is considered to have no water temperature effects on splittail relative to the No Action Alternative.

The CalSim II flow results for Wilkins Slough and the HEC-5Q water temperature results for Knight Landing indicate that Alternative 1 would have a less-than-signficant impact on Sacramento Splittail relative to the No Action Alternative.

O.3.3.2.13 Pacific Lamprey

Sacramento River Pacific Lamprey adults enter the Sacramento River from the Delta primarily during about March through June and hold in the river for about a year prior to spawning (Moyle et al. 2015). Spawning occurs in gravel redds in the upper river from March through July. The eggs and pro-larvae incubate for about 1 to 1.5 months. After the larvae (ammocoetes) emerge, they drift downstream and burrow into fine sediments primarily in off-channels habitats, where they rear (Schultz et al. 2014; Moyle et al. 2015). After 5 or more years, the ammocoetes metamorphose to the macropthalmia (juvenile) stage and migrate downstream to the Delta and ocean, typically migrating from March through June during pulse flow events (Moyle et al. 2015).

River flow potentially affects survival of Pacific Lamprey eggs and larvae, and migratory habitat of the juveniles and adults. Pacific lamprey build their spawning redds in shallow water (about 0.5 to 3.5 feet) (Gunckel et al. 2009; Schultz et al. 2014; Moyle et al. 2015), so reductions in water level can dewater the redds. The larvae select habitats, often off-channel, with fine sediments, low flow velocity, and shallow depths (~1 ft), so they are vulnerable to stranding by reductions in water level. Migrations of the juveniles and adults may be triggered by surges in flow (Moyle et al. 2015).

The types of variations in flow that potentially affect Pacific Lamprey, as described above, often occur on a time scale of hours or days, and therefore may not be detectable using the CalSim II monthly time-step modeling results. However, the CalSim II results mostly show little difference in Sacramento River flow between the No Action Alternative and Alternative 1, so there is no reason to expect much difference in short period flow fluctuations between the alternatives. The biggest differences in monthly mean flows occur in September and November of wet and above normal water years, when flows are lower under Alternative 1 than the No Action Alternative because Alternative 1 operations do not include releases for Fall X2 flows (Table O.3-12; Figures O.3-25 and O.3-28). Pacific lamprey are generally done spawning by late July and the prelarvae have finished emerging from their redds by early September. In contrast, the larvae are present in the river yearround and so could be vulnerable to flow reductions during September and November. However, water levels during these months are generally relatively stable because they are largely determined by Shasta and Keswick dam releases rather than runoff and because, especially under Alternative 1, maintaining stable water levels during the fall is an important objective of Shasta Dam operations to avoid dewatering Winter-Run and Spring-Run Chinook Salmon redds. The adults and juveniles carry out their migrations primarily during March through June. CalSim II modeling flow results for these months are generally higher under Alternative 1 than under the No Action Alternative, particularly for the drier water year types (Table O.3-13 and O.3-14). Therefore, Alternative 1 and the No Action Alternative are expected to similarly affect Pacific Lamprey with respect to flow in the Sacramento River.

Laboratory studies conducted on Columbia River Pacific Lamprey indicated that survival of incubating eggs and pre-larvae and of young larvae was greatest at a water temperature of 64°F and lowest at the highest water temperature included in the study, 72°F (Meeuwig et al. 2005). Young larvae showed six times as many developmental abnormalities at 72°F as at the other test temperatures. HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River between Keswick and RDBB during the March through August spawning and egg/prelarvae incubation period would be consistently below 64°F, with minor differences between the alternatives (Tables O.3-6 through O.3-9). During September, when Pacific Lamprey larvae would be present in the river, mean water temperatures would exceed the 64°F optimal temperature at RBDD in critically dry water years. September has the highest water temperatures of the year upstream of RBDD. Mean September water temperatures at RBDD for individual years exceed 64°F in about 7% of years for both alternatives, but are below 72°F for all years (Figure O.3-22). The downstream distribution of Pacific Lamprey larvae is uncertain, but if the larvae drift well downstream of RBDD or enter the Sacramento River from downstream tributaries, they would be subject to higher water temperatures, especially during July and August. However, there are few differences between July and August water temperatures at the lower temperature modeling sites (Table O.3-10 and O.3-11; Figure O.3-45). There are no biologically meaningful differences in water temperature conditions for Pacific Lamprey between the No Action Alternative and Alternative 1.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 1 would have a less-than-signficant impact on Pacific Lamprey relative to the No Action Alternative.

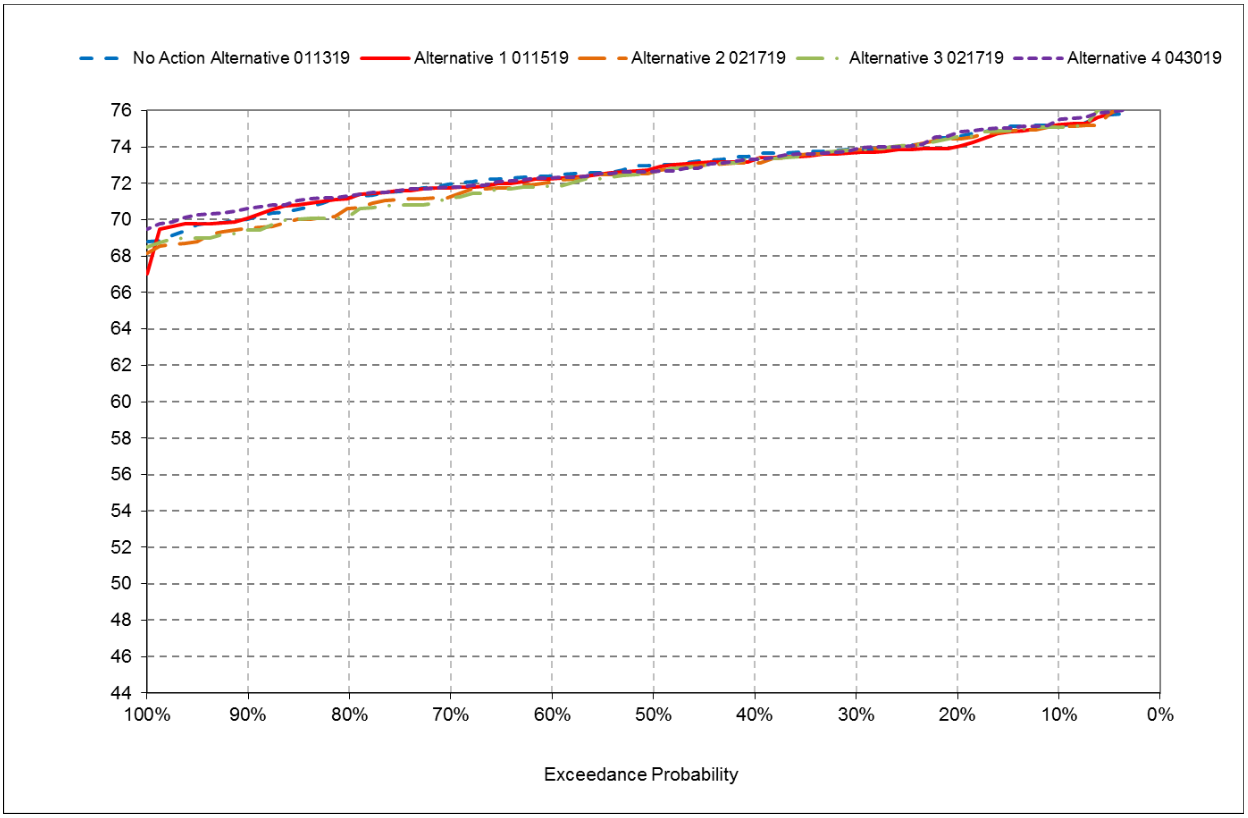

Figure O.3-45. HEC-5Q Sacramento River Water Temperatures at Knights Landing under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; August

O.3.3.2.14 <u>River Lamprey</u>

River Lamprey life history is poorly known, especially in California (Moyle et al. 2015). The adults migrate from the ocean to spawning areas during the fall and late winter (Beamish 1980). Spawning is believed to occur from February through May in small tributary streams (Moyle 2002). The redds are built at the upstream end of small riffles (Moyle 2002). After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juvenile (macrothalmia) migrate downstream in the following year from May to July (Moyle 2002).

River flow potentially affects survival of River Lamprey eggs and larvae, and migratory habitat of the juveniles and adults. River lamprey build their spawning redds in shallow water (Moyle et al. 2015), so reductions in water level can dewater the redds. Assuming River Lamprey larvae habitat requirements are similar to those of Pacific Lamprey, the larvae select habitats, often off-channel, with low flow velocity and shallow depths, so they are vulnerable to stranding by reductions in water level.

The types of variations in flow likely to cause redd dewatering and stranding of larvae often occur on a time scale of hours or days and, therefore, may not be detectable using the CalSim II monthly time-step modeling results. However, the CalSim II results mostly show little difference in Sacramento River flow between the No Action Alternative and Alternative 1, so there is no reason to expect much difference in short period flow fluctuations between the alternatives. The biggest differences in monthly mean flows occur in September and November of wet and above normal water years, when flows are lower under Alternative 1 than the No Action Alternative because Alternative 1 operations do not include releases for Fall X2 flows (Table O.3-12; Figures O.3-25 and O.3-28). River lamprey are generally done spawning by May and, assuming their incubation times are similar to those of Pacific Lamprey, the prelarvae complete their emergence from redds by June or July. In contrast, the larvae are present in the river yearround and so could be vulnerable to flow reductions during September and November. However, water levels during these months are generally relatively stable because they are largely determined by Shasta and Keswick dam releases rather than runoff and because, especially under Alternative 1, maintaining stable water levels during the fall is an important objective of Shasta Dam operations to avoid dewatering Winter-Run and Spring-Run Chinook Salmon redds.

The juveniles carry out their migrations during May through July. CalSim II modeling flow results for May and June are generally higher under Alternative 1 than under the No Action Alternative, particularly for the drier water year types, but flows for July are lower (Tables O.3-13 and O.3-14). The adults migrate upstream primarily in the fall and winter and could be adversely affected by the reductions in flow under Alternative 1 relative to the No Action Alternative during September and November (Tables O.3-13 and O.3-14), but little is know about flow needs of migrating adult River Lamprey. Overall, Alternative 1 and the No Action Alternative are expected to similarly affect River Lamprey with respect to flow in the Sacramento River.

The water temperature requirements of River Lamprey have not been studied, but they are assumed to be similar to those of Columbia River Pacific Lamprey as follows: 1) 64°F for maximum survival of eggs and prelavae and 72°F for minimum survival of eggs and prelavae, for the water temperatures included in the study, and 2) below 64°F for fewest developmental abnormalities of young larvae (Meeuwig et al. 2005). HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River between Keswick and RDBB during the February through May spawning and egg/prelarvae incubation period would be consistently below 64°F, with minor differences between the alternatives (Tables O.3-6 through O.3-9). It should be noted that River Lamprey are believed to spawn in tributary streams rather than the mainstem, but this is uncertain (Moyle et al. 2015). During September, when River Lamprey larvae would be present in the river, mean water temperatures would exceed the 64°F optimal temperature at RBDD in critically dry water years. September has the highest water temperatures of the year upstream of RBDD. Mean September water temperatures at RBDD for individual years exceed 64°F in about 7% of years for both alternatives, but are below 72°F for all years (Figure O.3-22). The downstream distribution of River Lamprey larvae is uncertain, but if the larvae drift well downstream of RBDD or enter the Sacramento River from downstream tributaries, they would subject to higher water temperatures, especially during July and August. However, there are few differences between July and August water temperatures at the lower temperature modeling sites (Table O.3-10 and O.3-11; Figure O.3-45). There are no biologically meaningful differences in water temperature conditions for River Lamprey between the No Action Alternative and Alternative 1.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 1 would have a less-than-signficant impact on River Lamprey relative to the No Action Alternative.

O.3.3.2.15 Hardhead

Hardhead are believed to spawn in riffles, runs, and heads of pools, primarily during April and May (Moyle et al. 2015). Most spawning probably occurs in tributaries rather then in the Sacramento River mainstem (Moyle et al. 2015). Larvae and juveniles likely inhabit stream margins with abundant cover, and move into deeper habitats as they grow larger. Adults occupy the deepest part of pools. Juvenile and adult Hardhead are present in the Sacramento River yearround. They tend to prefer water temperatures near 67°F (Thompson et al. 2012), but have been captured at RBDD, where water temperatures are generally much cooler (USFWS 2002) (Table O.3-9).

Spawning success of Hardhead in the lower Tuolumne River is highest when there are higher flows during in April and May (Brown and Ford 2002), which is likely true for the Sacramento River Hardhead as well. The CalSim II results indicate that monthly mean flow would be moderately higher under Alternative 1 than under the No Action Alternative during the April and May peak spawning months (Tables O.3-5, O.3-12 and O.3-13). During most of the other months, flows would generally be similar between Alternative 1 and the No Action Alternative, but they would be lower under Alternative 1 in July of critically dry water years and September and October of wet and above normal water years. The large flow reductions in September and October would likely have little effect on hardhead because they are predicted for wet and above normal years, when flows are generally high, and because by September and October, hardhead hatched in the spring would be well developed and have gravitated to deeper water. The flow reduction in July of critically dry water years would be more likely to adversely affect young hardhead. On balance, the flow effects of Alternative 1 are not expected to substantially affect hardhead.

Hardhead juveniles and adults performed well in laboratory tests at water temperatures from about 61 to 70°F (Thompson et al. 2012). They consistently preferred a mean water temperature of 67°F and avoided temperatures above about 79°F. HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River would be below 79°F at all locations under both alternatives (Tables O.3-6 through O.3-9). There would be only minor differences in mean water temperatures between the alternatives, except for moderate increases under Alternative 1 during September of wet and above normal water years. However, these mean water temperatures would be only slightly warmer than the Hardhead preferred temperature, and only at Knights Landing (Table O.3-11). There are no biologically meaningful differences in water temperature conditions for Hardhead between the No Action Alternative and Alternative 1.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 1 would have a less-than-signficant impact on Hardhead relative to the No Action Alternative.

O.3.3.2.16 Central California Roach

California Roach primarily inhabitat small tributary streams, although they may occur in backwaters with dense riparian cover along the main rivers (Baumsteiger and Moyle 2019). Roach are adaptable fish, with a broad range of habitat types and temperature tolerances (Moyle 2002). Given that most Central California Roach inhabit tributary streams rather than the mainstem Sacramento River and given its wide range of habitats and suitable temperatures, it is unlikely that flow or water temparture conditions under Alternative 1 would adversely affect California Roach. Therefore, Alternative 1 is expected to have no impact on Central California Roach relative to the No Action Alternative.

O.3.3.2.17 Striped Bass

Striped Bass spawn in the Sacramento River primarily between about Verona (RM 78) and Wilkins Slough (RM 121) during April through June (Moyle 2002). No spawning occurs until water temperature reaches 57 degrees Fahernheit (Moyle 2002). When river flows are high, the water takes longer to warm, so spawning takes place further upriver because Striped Bass migrate upstream while waiting for temperatures to rise. It also takes place later in the year. The eggs are free-floating and negatively buoyant and hatch in about two days after spawning (at 66 degrees Fahernheit) as they drift downstream. Low flows can result in eggs settling on the bottom, which they cannot survive for long. The larvae may inhabit shallow, open water of the lower river from April to mid-June and then are carried by flows to the Delta and Suisun Bay (Stevens 1966; Moyle 2002).

Other than for spawning, Striped Bass in the San Francisco Estuary primarily reside in the Delta and bays, with ocean foraging in occasional years. Adult striped bass are found in the upper Sacramento River at RBDD and upstream, primarily from late spring through early fall, where they forage heavily on juvenile salmon and other fish (Tucker et al. 1998).

High flows in April through June benefit striped bass eggs because they help prevent them from settling to the river bottom. High flows likely also accelerate transport of Striped Bass larvae to their nursery habitats in the Delta and Suisun Bay (Moyle 2002). CalSim II flow results for Wilkins Slough indicate that mean monthly flow during April through June under Alternative 1 would be similar to or higher than flow under the No Action Alternative, especially in May and June of drier water years, which would potentially benefit conditions for eggs and larvae drifting downstream (Table O.3-14). The greatest reductions in flow resulting from Alternative 1 would occur in September and November of wet and above normal water years and in July of critically dry water years. Adult Striped Bass may reside throughout the Sacramento River in July and September (Tucker et al. 1998). However, although the Alternative 1 mean monthly flows are reduced from the No Action Alternative flows, they remain close to or well above 5,000 cfs (Table O.3-12 through O.3-14), which is likely adequate for foraging Striped Bass.

Optimal spawning temperatures for Striped Bass are 59 to 68 degrees Fahernheit and spawning ceases at about 70 degrees Fahernheit (Moyle 2002). The eggs can withstand temperatures of about 54 to 75 degrees Fahernheit, with the optimum being about 64 degrees Fahernheit (Emmett et al. 1991). Larvae tolerate temperatures of 50 to 77 degrees Fahernheit, but optimal temperatures for survival are 59 to 72 degrees Fahernheit (Emmett et al. 1991). Striped Bass adults and juveniles are tolerant of a wide range and rapid swings of water temperatures. The adults appear to prefer water temperatures ranging from about 68 to 75 degrees Fahernheit (Emmett et al., 1991) and juveniles prefer rearing temperatures of 61 to 66 degrees Fahernheit (Hasler 1988). Adults are under stress at temperatures over 77 degrees Fahernheit, and temperatures over 86 degrees Fahernheit are lethal (Moyle 2002).

HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River at Knights Landing during the April through June spawning period would be within the optimal range for spawning in April of all but wet years and in May of all but critically dry years, but would be above the optimal range in June during all water year types (Table O.3-11). The mean monthly temperatures would be below the optimal range for adults during April and May of all water year types, except critically dry years in May, but would be within this range in all water year types in June. The temperatures would be acceptable for eggs and optimal for larvae throughout the spawning period (Table O.3-11). Juvenile striped bass generally do not occur in the Sacramento River upstream of the Delta. The adults, as noted earlier, may forage in the river upstream to and above RBDD from about May through early October. Mean monthly water temperatures at RBDD throughout this period would be well below the optimal range for adults (Table O.3-9).

The largest difference in water temperatures between the No Action Alternative and Alternative 1 at Knights Landing during the Striped Bass spawning season are moderate reductions in June of below normal and dry water years (Table O.3-11). With these reductions, water temperatures under Alternative 1 would be closer to the optimal range for spawning than those under the No Action Alternative, providing a minor benefit. The largest temperature differences at any time of year are substantial increases under Alternative 1 for September of wet and above normal water years. These increases would be potentially beneficial for foraging Striped Bass adults because the No Action Alternative water temperatures for these months and water year types would be well below the optimal range for adults throughout the river (Tables O.3-9 through O.3-11).

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 1, with regard to flow and water temperature, would have a less-than-signficant impact on Striped Bass relative to the No Action Alternative.

O.3.3.2.18 American Shad

American shad migrate upstream in the Sacramento River starting in March, and typically spawn from April to June. Water temperature influences the timing of runs, with peak runs and spawning usually occurring at water temperatures of 62°F to 75°F (Moyle 2002). Shad eggs drift downstream from spawning areas and hatch in 8 to 12 days at 52°F to 59°F, 6 to 8 days at 63°F, and 3 days at 75°F (MacKenzie et al. 1985). However, more rapid development at higher temperatures appears to be associated with lower survival rates of embryos (Moyle 2002). Larval shad are planktonic for about 4 weeks, after which they metamorphose to actively swimming juveniles. Juveniles spend the next several months in freshwater, and seem to prefer temperatures of 63°F to 77°F. In the Sacramento River, summer rearing habitat occurs in the main river from Colusa to the north Delta (Stevens et al. 1987). As the season progresses, juvenile shad move downstream and enter salt water primarily during September through November (Moyle 2002). In general, variations in river discharge and temperature during early larval development are considered important regulators of year-class strength and recruitment of American shad (Hinrichsen et al. 2013). Although the importance of various potential mechanisms is unknown, the abundance of juvenile American shad in the Sacramento-San Joaquin Delta has been shown to be positively correlated with freshwater inflow during the April through June spawning and nursery periods (Stevens et al. 1987, Kimmerer 2002, Kimmerer et al. 2009).

During the spawning and larval rearing period (April through June), CalSim II modeling results indicates that average monthly flows in May and June under Alternative 1 would be higher than those under the No Action Alternative, which may have positive effects on spawning and early rearing success of American shad (Table O.3-14). In addition, with higher flows under Alternative 1, HEC-5Q modeling results indicate that mean monthly temperatures in the lower Sacramento River (Knights Landing) during May and June would be lower on average, which may improve water temperatures for developing embryos and larvae (see the ROC LTO BA). The largest differences in flows and water temperatures in the Sacramento River under Alternative 1 and the No Action Alternative would occur in September of wet and above normal water years (Table O.3-11 and O.3-14). However, the importance of river inflows and river temperatures for juvenile shad in September is unknown. Correlations between Delta inflows and abundance of juvenile shad have been demonstrated for the months of April through August, with the highest correlations in April through June, suggesting that the principal factors influencing abundance occur during periods of larval dispersal and transport. Sacramento River flows and temperatures under Alternative 2 appear to have minor benefits to American Shad relative to the No Action Alternative, but because the potential effects are highly uncertain, Alternative 2 is considered to have a less-than-significant effect on American Shad.

O.3.3.2.19 Largemouth Bass

Largemouth bass are warmwater fish species that are adapted to shallow, low-velocity, and relatively clear waters with aquatic vegetation and other forms of cover (e.g., logs, brush, and debris) (Stuber et al. 1982). Consequently, they are most abundant in ponds, lakes, reservoirs, sloughs, and river backwaters that support other warmwater fish species (Moyle 2002). While populations of largemouth bass have expanded in the Delta in recent decades (Brown and Michniuk 2007), the Sacramento River above the Delta generally provides poor habitat conditions for largemouth bass because of large seasonal flow fluctuations, relatively cold water, and lack of suitable nesting and rearing habitat. Consequently, largemouth bass populations in the Sacramento River above the Delta are largely dependent on upstream sources, including reservoirs, floodplain ponds and sloughs, and irrigation canals that provide suitable conditions for spawning and rearing during the late spring and summer months.

Largemouth bass spawning activity typically starts in April when water temperatures reach 59 to 61°F, and continues through June (Moyle 2002). Optimal temperatures for successful spawning and incubation are 68 to 70°F, although spawning is generally observed over a range of 55 to 79°F (Stuber et al. 1982). Nests (shallow depressions in sand, gravel, or debris-littered bottoms) are constructed by males, typically at a depth of about 3 feet, and defended from other bass and potential predators (Brown et al. 2009a; Moyle 2002). Eggs hatch in 2 to 7 days and sac fry usually spend 5 to 8 days in the nest until they begin actively feeding (Moyle 2002). Largemouth bass fry feed mainly on zooplankton and other small invertebrates, while juveniles and adults feed increasingly on larger invertebrates and fish as they grow (Stuber et al. 1982). Optimal temperatures for growth of juvenile and adult bass range from 77 to 86°F although growth will occur over a much wider range (50 to 95°F (Moyle 2002).

The CALSIM II and HEC-5Q modeling results for Alternative 1 indicate that Sacramento River flows would be higher and water temperatures would be lower in May and June relative to the No Action Alternative, potentially affecting largemouth bass spawning and incubation (Tables O.3-11 and O.3-14). However, based on modeled mean monthly water temperatures in the lower Sacramento River at Knights Landing, no substantial changes would be expected to occur in the frequency of suitable water temperatures for spawning and incubation (Figures O.3-41 and O.3-91). The relatively large changes in flows and water temperatures in September and November of wet and above normal years under Alternative 1 (Tables O.3-11 and O.3-14) could also affect habitat conditions for juvenile and adult bass, but water temperatures would remain below optimum levels for growth under both alternatives. Consequently, the generally poor habitat conditions for largemouth bass in the Sacramento River under the No Action Alternative would persist under Alternative 1. Therefore, changes in Sacramento River flows and water temperatures associated with Alternative 1 would have a less-than-significant effect on largemouth bass in the Sacramento River relative to the No Action Alternative.

O.3.3.2.20 Smallmouth Bass

Smallmouth Bass prefer large, clear lakes and streams and rivers with abundant cover and cool (68 to 80°F) summer temperatures (Moyle 2002). The optimal temperature range for spawning is 55 to 70°F (Brown et al. 2009b) and the optimal for adult growth is approximately 77 to 80°F, but rapid growth has been seen in the wild at temperatures as high as 84°F providing prey is abundant (Moyle 2002). Young-of-year Smallmouth Bass will select temperatures as high as 84 to 87°F. Populations are rarely established in water temperatures that do not exceed 66°F in summer for extended periods, and most smallmouth populations in California are present where summer temperatures are typically 69 to 71°F. In northern California reservoirs most spawning takes place in May and June, but spawning in streams may occur into July, depending on flows and temperatures. Males start making nest depressions when water temperatures reach 55to 61°F. The nests are typically built at depths of about 3 to 8 feet (Brown et al. 2009). In streams, nesting and reproduction can be disrupted by flow reductions that lead to nest dewatering or elevated flows that wash embryos and fry out of nests or lower water temperatures excessively (Graham and Orth 1986; Lukas and Orth 1995).

CalSim II results for Wilkins Slough flow for Alternative 1 compared to No Action Alternative during the spawning season May through July indicate increased flow during May and June of all of the water year types and reduced flow in July, especially in critically dry water years (Table O.3-14). Higher flows could adversely affect embryos and fry by washing them out of the nests, but it is unknown what magnitude of flows would cause washouts.

HEC-5Q monthly mean water temperatures at Hamilton City consistently fall within the the 55 to 70°F optimal spawning range during the spawning season of May through July under both Alternative 1 and the No Action Alternative (Table O.3-10). At Knights Landing, however, the temperatures fall within the optimal range during May of all water year types, but only during June of below normal water years and July of above normal years (Table O.3-11). The water temperatures under Alternative 1 are generally similar or moderately lower than those under the No Action Alternative. The monthly mean summer water temperatures at Hamilton City consistently fall below the 66°F threshold that has been found to be a minimum for Smallmouth Bass to establish populations in California (Moyle 2002), except for critically dry water years in August and September (Table O.3-10). At Knights Landing, however, the 66°F threshold is exceeded in all summer months and water year types except September of wet and above normal years under the No Action Alternative (Table O.3-11). Note that the large wet-and-Above-Normal-year September water temperature increases under Alternative 1 result in water temperatures exceeding the threshold, which may benefit Smallmouth Bass. The mean water temperatures are consistently well below the optimal range for adult growth, 77 to 80°F, at both locations.

The CalSim II flow and HEC-5Q water temperature results indicate that Alternative 1 would have a less-than-significant impact on Smallmouth Bass relative to the No Action Alternative with regard to flow and water temperature.

O.3.3.2.21 Spotted Bass

Spotted Bass inhabit streams and reservoirs and prefer moderate-size, clear, low-gradient sections of rivers and reservoirs (McKechnie 1966). They prefer pool habitat and slower, more turbid water than Smallmouth Bass but faster water than Largemouth Bass (Moyle 2002). Their summer water temperature preference is 75 to 87°F (Moyle 2002). In streams, nests are constructed in low-current areas on bottoms ranging from debris to gravel (Moyle 2002). Spawning depths are deeper than those of Largemouth Bass (Aasen and Henry 1981). They spawn in late spring when water temperatures rise to 59°F to 64°F (Aasen and Henry 1981; Howland 1931). Spawning continues through late May and early June, until temperatures reach 71-73°F.

During the spring (April through June) spawning season, CalSim II results for Wilkins Slough monthly mean flows under Alternative 1 are mostly higher than the No Action Alternative flows during May and June, and are mostly similar in April (Table O.3-14). Higher flows could adversely affect embryos and fry by dewtering nests or washing them out of the nests, but it is unknown what magnitude of flows would have these effects.

HEC-5Q monthyly mean water temperatures at Knights Landing during the spawning season of April through June would be within the 59 - 64°F spawning range in April under Alternative 1 and the No Action Alternative, but would exceed the range in May and June under both alternatives. The preferred summer water temperatures range of 75 to 87°F would be available only in critically dry years, especially in August, under both Alternative 1 and the No Action Alternative (Table O.3-11).

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 1, with regard to flow and water temperature, would have a less-than-significant impact on Spotted Bass relative to the No Action Alternative.

Potential changes to aquatic resources in the Sacramento River from Shasta cold water pool management

As described above in the introduction to *Potential changes to aquatic resources in the Sacramento River from seasonal operations*, water temperature management during summer and fall under Alternative 1 would be based in large part on the Shasta Cold Water Pool Management. The management decisions in a given year are tied to Shasta Reservoir coldwater pool storage on May 1, combined with summer and fall storage predictions from water temperature modeling. In years with high May 1 coldwater pool storage (> 2.8 MAF), operators would manage temperature releases to maintain a water temperature of 53.5°F in the Sacramento River upstream of the Clear Creek confluence (CCR) beginning when real-time monitoring indicated that the Winter-Run Chinook Salmon population had begun spawning and ending October 31, or when fry had emerged from an estimated 95% of the Winter-Run redds, whichever was earlier. In years with an intermediate level of May 1 cold water storage, the coldwater pool is generally insufficient to maintain 53.5°F at CCR through October, so operations would target developmental-stage-specific requirements of Winter-Run eggs and alevins, maintaining the 53.5°F threshold only for the period when the most temperature-sensitive developmental stage would be present. This period would be estimated from modeling using the new analytical tools discussed above (Martin et al. 2017; Anderson 2018). The duration of the 53.5°F protection period would be adjusted in proportion to the available coldwater pool on May 1. In years with low May 1 coldwater pool storage (e.g., <2.3 MAF), the temperature maintained at CCR would be gradually increased up to 56°F as necessary to conserve remaining coldwater pool through the period of Winter-Run egg and alevin incubation. Operators would minimize adverse effects of the higher water temperatures to the greatest extent possible, as determined by the latest egg mortality models, real-time monitoring, and current and expected future cold water availability. Finally, if operators could no longer maintain 56°F at CCR, they would operate to a less than optimal duration and temperature target, which would be determined in real-time with technical assistance from NMFS and USFWS. Reclamation would regularly evalute the performance of the coldwater pool management by monitoring egg to fry survival in the river and compare actual survival levels with those expected from modeling. If actual mortality was greater than expected, Reclamation would work with the SRTTG to develop alternative protective strategies and measures for the early life stages. More detailed description of this component is provided in Section 4.3.1.3, *Cold Water Pool Management*. Management of the Shasta coldwater pool under the No Action Alternative is guided by RPAs I.2.1 to I.2.4 of NMFS's 2009 Biological Opinion. Comparisons of the effects of water temperature on focal fish species under Alternative 1 vs. the No Action Alternative are provided above in *Potential changes to aquatic resources in the Sacramento River from seasonal operations* under the species specific discussions of effects. Alternative 1 has a potentially signficant impact of elevated temperature on southern dps Green Sturgeon adults relative to the No Action Alternative (see *Southern DPS Green Sturgeon* section above), but this impact results from the cessation of Delta Fall X2 flows under Alternative 1 rather than Shasta coldwater pool management. Alternative 1 is expected to benefit Winter-Run Chinook Salmon and Spring-Run Chinook Salmon with respect to coldwater pool management relative to the No Action Alternative, and is considered to have a less-than-signficant impact on the other focal fish species.

Potential changes to aquatic resources in the Sacramento River from spring pulse flows

Under Alternative 1, Reclamation would make a spring pulse flow release of up to 150 TAF in coordination with the Upper Sacramento scheduling team when the projected total May 1 Shasta Reservoir indicates a likelihood of sufficient cold water to support summer coldwater pool management through the summer and fall. Reclamation would not make a spring pulse flow release if the release would reduce the coldwater pool such that summer Shasta temperature management drops into a Tier 4 schedule (see Section 4.3.1.3, *Cold Water Pool Management*) or would interfere with the ability to meet other anticipated demands on the reservoir. The pulse flow release would be made in March, April, or May, but only one pulse flow would occur during this period (up to 150 TAF total).

Pulse flows serve two major functions for anadromous fish species: 1) for emigrating larvae and/or juveniles they trigger emigration and reduce exposure to predation and other stressors and 2) for immigrating adults they improve conditions by enhancing environmental cues that trigger migration and improve homing fidelity. Additional potential benefits include dispersal of larvae and juvenile, passage improvements for emigrating juveniles and immigrating adults, enhancement of rearing and migratory habitat conditions, and reduced water temperatures and increased dissolved oxygen in redds. The most important potential adverse effect of the spring pulse flows is that they potentially increase the risk of exhausting the coldwater pool in Shasta Reservoir while sensitive life stages of Winter-Run and other species remain in the river and before air temperatures have cooled. The effect of the spring pulse flow release action on the focal fish species depends largely on the the degree to which the pulse flow period overlaps the period of juvenile emigration or adult immigration in the Sacramento River. Spring-Run Chinook Salmon would potentially benefit the most from spring pulse flows because the period of juvenile and smolt emigration and the period of adult immigration both overlap the spring pulse flow period of March through May. Spring-Run juveniles and smolts emigrate primarily in December and again during the spring and the adults immigrate during January through August (for timing of life stages see discussions above for individual species in *Potential changes to aquatic resources in the Sacramento River from seasonal operations.*). No other species or run overlaps the spring pulse flow period in both their emigration and immigration periods, but most overlap in one or the other period. Other species or runs that would potentially benefit because their periods of emigration substantantially overlap with the spring pulse flow period include Fall-Run Chinook Salmon, Late fall-run Chinook Salmon, and Central Valley Steelhead. Species that would potentially benefit because their adult immigration periods overlap with the spring pulse flow period include Winter-Run Chinook Salmon and Green Sturgeon. Under the No Action Alternative there are no spring pulse flows; therefore, the overall population-level effects of Alternative 1 are expected to be beneficial relative to the No Action Alternative.

Potential changes to aquatic resources in the Sacramento River from fall and winter refill and redd maintenance

Under Alternative 1, Reclamation would, in the fall, seek to balance higher flow releases to maintain cold water temperatures and to avoid dewatering Winter-Run redds with lower flow releases to rebuild storage needed for cold water releases through the subsequent summer and early fall. Maintaining releases to keep late spawning Winter-Run redds underwater carries the risk of depleting storage needed for effective temperature management in a subsequent year. If, based on their analysis, Reclamation determines releases need to be reduced to rebuild storage, targets for winter base flows (December 1 through the end of February) would be set in October based on Shasta Reservoir end-of-September storage and the current hydrology, after accounting for Winter-Run redd stranding. Table O.3-14a shows examples of possible Keswick releases based on Shasta Reservoir storage condition; these would be refined through future modeling efforts as part of the seasonal operations planning. The *Fall and Winter Refill and Redd Maintenance* and *Spring Pulse Flow* actions have in common an objective to balance flow needs for fish in one season (fall and spring, respectively) with cold water temperature needs in another season (summer and early fall).

Table O.3-14a. Keswick Dam Release Schedule for End-of-September Storage (Preliminary Estimates)

Keswick Release	Shasta End-of-September Storage
3,250 cfs	≤ 2.2 MAF
4,000 cfs	≤ 2.8 MAF
4,500 cfs	≤ 3.2 MAF
5,000 cfs	> 3.2 MAF

The Fall and Winter Refill and Redd Maintenance action would provide the greatest potential benefit to Winter-Run and Spring-Run Chinook Salmon, both of which have redds present in the upper Sacramento River during the fall period when redds are at risk of being dewatered by flow reductions and both have incubating eggs and alevins present in the upper river during the summer and early fall that are vulnerable to inadequate cold water releases. Under the No Action Alternative, efforts are generally implemented to balance fall and winter refill with redd maintenance (NMFS 2009; RPA Action I.2.2), but further measures are considered necessary to achieve adequate protection of the coldwater pool and of salmon redds ; therefore, the overall population-level effects of Alternative 1 are expected to be positive relative to the No Action Alternative.

Potential changes to aquatic resources in the Sacramento River from rice decomposition smoothing

Under Alternative 1, following the emergence of Winter-Run Chinook Salmon fry and prior to spawning of the majority of Fall-Run Chinook Salmon, upstream Sacramento Valley CVP contractors and Sacramento River Settlement Contractors would work to synchronize their diversions to lower peak rice decomposition water demand, resulting in lower Sacramento River flow in late October and early November. With the lower flows, Fall-Run Chinook Salmon would be less likely to spawn in shallow areas that would be subject to dewatering during winter base flows. However, Winter-Run and Spring-Run Chinook Salmon spawn before the proposed river flow lowering would take place, making their redds susceptible to dewatering. Therefore, the potential benefits of this action, reduced dewatering of fall-run redds and greater Shasta storage refill, must be balanced against the potential impacts, dewatering of Spring-Run redds, which spawn during August through October, and dewatering of Winter-Run redds, which spawn from May through August. Under the No Action Alternative, there is no rice decomposition smoothing; therefore, Alternative 1 would increase the risk of dewatering of Spring-Run and Winter-Run redds, while reducing the risk of dewatering fall-run redds and the risk of conserving too little storage for protection of Winter-Run eggs in the following summer. Spring-Run Chinook Salmon and Winter-Run Chinook Salmon are federally listed species, but Fall-Run Chinook Salmon is not. On balance, this action is expected to benefit Fall-Run Chinook Salmon and have a less-than-significant impact on other focal species.

Potential changes to aquatic resources in the Sacramento River from spring management of spawning locations

Under Alternative 1, Reclamation would coordinate with NMFS to conduct experiments to test two complementary hypotheses: 1) releasing colder water to the Sacramento River earlier in the year induces earlier spawning and 2) releasing colder water to the Sacramento River later in the year, i.e., keeping April to May Sacramento River temperatures warmer, induces later spawning. To avoid risking temperature stress to Winter-Run and Spring-Run Chinook Salmon in the summer and/or fall, the experiments would be run during years with high May storage and a large coldwater pool. Under these conditions, the action would have no adverse impact, and would potentially benefit both salmon runs by contributing to better temperature management of Shasta Reservoir. This action is not included under the

No Action Alternative; therefore, Alternative 1 is considered to benefit Winter-Run and Spring-Run Chinook Salmon with regard to this action.

O.3.3.3 *Clear Creek*

O.3.3.3.1 Whiskeytown Reservoir Operations

Reclamation operates Whiskeytown Lake to (1) regulate inflows for power generation and recreation; (2) support upper Sacramento River temperature objectives; and (3) provide releases to Clear Creek.

Trinity River exports are first conveyed through Carr Powerplant before being released into Whiskeytown Lake. From Whiskeytown Lake, the water either continues to flow into Spring Creek Powerplant, ultimately outflowing into the Sacramento River below Keswick Dam, or is released from Whiskeytown Lake into Clear Creek. Although Whiskeytown Lake is primarily used as a conveyance system for cross-basin transfers, operations at both Carr and Spring Creek powerplants are done in a manner to maintain specified elevations for seasonal recreation support.

Whiskeytown Lake is annually drawn down by approximately 35 TAF during November through April to regulate flows for winter and spring flood management. Heavy rainfall events occasionally result in spillway discharges to Clear Creek. Operations at Whiskeytown Lake during flood conditions are complicated by its operational relationship with the Trinity River, the Sacramento River, and Clear Creek. On occasion, imports of the Trinity River water to Whiskeytown Lake may be suspended to avoid aggravating high flow conditions in the Sacramento Basin. Joint temperature control objectives similarly interact among the Trinity River, Clear Creek, and the Sacramento River. Two temperature curtains in Whiskeytown Lake were installed to pass cold water through the bottom layer of the reservoir and limit warming from Carr Powerplant to Clear Creek or Spring Creek Powerplant.

Under Alternative 1, Whiskeytown Lake operations would be similar to those described for the No Action Alternative with minor changes to accommodate Clear Creek flow measures. Spring Creek Debris Dam operations and the Clear Creek Restoration Program would continue under Alternative 1 as described in the No Action Alternative.

Under Alternative 1, flows from Whiskeytown Dam to Clear Creek would be managed to achieve minimum base flow of 150 cfs year-round in all water year types except critically dry water year types (compared to minimum base flows of 50 cfs to 100 cfs under the No Action Alternative), downstream water rights, 1963 Reclamation proposal to USFWS and NPS, predetermined CVPIA 3406(b)(2) flows. Channel maintenance flows of 10 TAF would occur, unless flood control operations provide similar releases, using the river release outlets, in all but dry and critically dry years or pulse flows released from Whiskeytown Dam. Pulse flows of 10 TAF would occur using the river release in all but critically dry years.

Model output for Whiskeytown Lake predicts that compared to the No Action Alternative, minimum reservoir volumes would be lower under Alternative 1 from March to July (Figure O.3-46, Table O.3-15) during all water year types. During these five months, water surface elevations would be lower under Alternative 1 compared to the No Action Alternative. In all other months, Whiskeytown Lake storage volume under Alternative 1 would be within 0.1 TAF of the No Action Alternative.

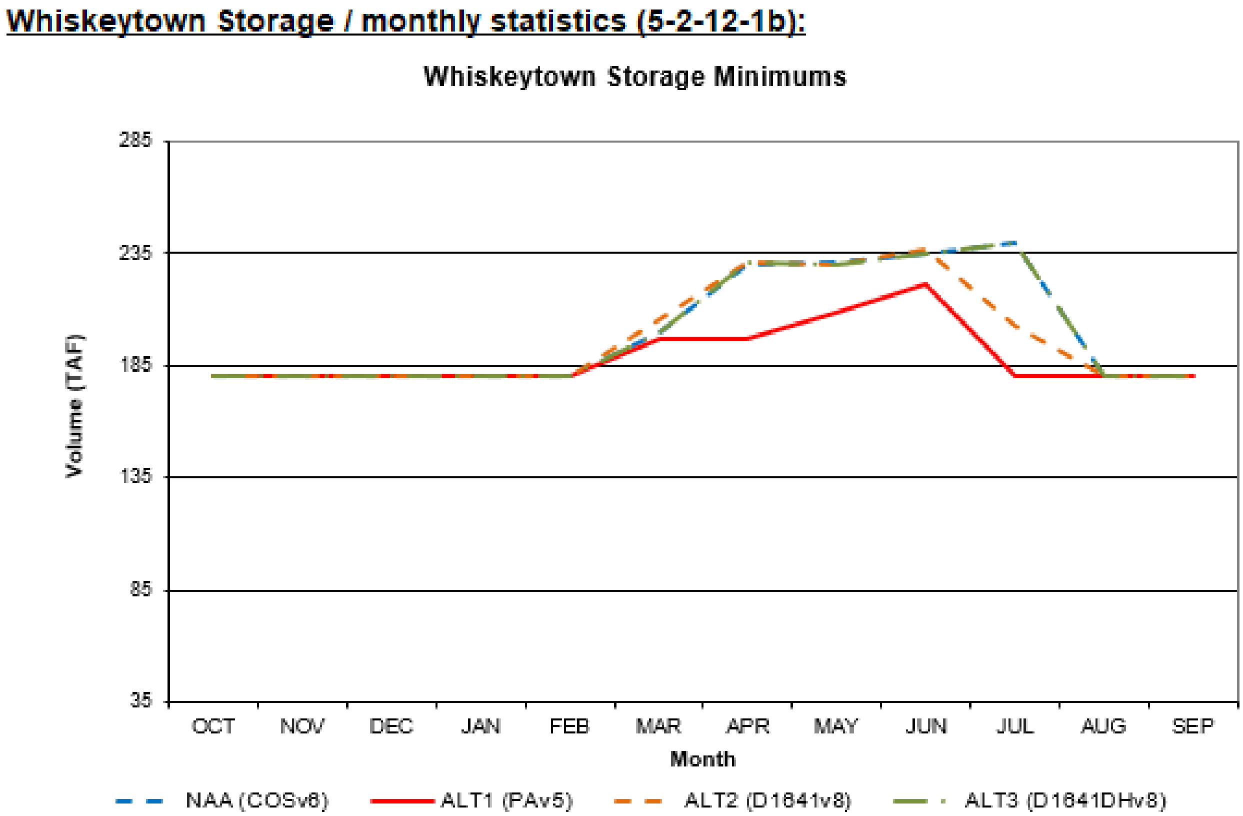

Figure O.3-46. Modeled Whiskeytown Lake Monthly Minimum Storage Volume under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 during All Water Year Types

Table O.3-15. Modeled Differences in Whiskeytown Lake Monthly Minimum Storage Volumes from March to July during All Water Year Types under Alternative 1 relative to the No Action Alternative

Month	Change in Volume from No Action Alternative (TAF)
March	-2.2
April	-2.2
May	-22.4
June	-13.5
July	-59.8

Full pool elevation of Whiskeytown Lake is 1,210 feet above sea level, representing a capacity of 241 TAF. The upper outlet is located at 1,110 feet, and the lower outlet is at 985 feet. At full pool, the historic mouths of tributary creeks (Whiskey Creek, Grizzly Creek, Clear Creek, Boulder Creek, Dry Creek, and Brandy Creek) are under water. The proposed additional seasonal draw-downs from March through July under Alternative 1 could cause bank and bed erosion in newly exposed areas of tributary stream mouths where they are devoid of stabilizing riparian vegetation. This scour could cause channel incision (i.e., down-cutting) and result in increased lake water turbidity. Channel incision can create erosional nick points that propagate upstream until they encounter scour-resistant grade-controlling materials such as bedrock, at which point a cascade can form. However, annual minimum storage volume is not expected to change under this alternative. The additional draw-downs therefore represent a change in timing and duration of lower water surface elevation, not a new type or mechanism of disturbance, and channel incision may have already occurred and stabilized as a result of past operations.

Potential changes to aquatic resources in Clear Creek from seasonal variation in water surface elevation

Hardhead

Hardhead migrate from the reservoir into tributaries in April and May to spawn upstream of Whiskeytown Lake. The timing of the increased draw-downs from March through July under Alternative 1 could affect Hardhead if the lower water surface elevations expose any previously submerged cascades at tributary mouths or create new ones. No such cascades have been documented, but if they are present or created by tributary incision at low water, they could present barriers to migration that would prevent reservoir-dwelling adult Hardhead from spawning in tributary streams. Alternately, depending on the locations of any migration barriers and the longitudinal gradient profile of tributaries, lower reservoir water levels could potentially expose more usable stream habitat for Hardhead, benefiting adults and juveniles.

Hardhead are not a cold-water species, so drawing additional cold water from the bottom layers of the reservoir would not be expected to affect them directly. Hardhead have shown sensitivity to high sediment loads (Gard 2002), so increased reservoir turbidity due to varial zone erosion during draw-down periods could reduce suitability of reservoir and downstream waters for Hardhead persistence.

The increased annual variations in reservoir water surface elevation under Alternative 1 compared to the No Action Alternative could cause Hardhead to be affected by reducing habitat connectivity and increasing water turbidity. However, under Alternative 1, the largest changes to storage volume and water surface elevation in Whiskeytown Lake would occur in July, after Hardhead upstream migration and spawning are likely to be complete.

Other Fish Species

Central California Roach are not likely to be affected by changes in reservoir operations because, although they are found in upstream tributaries, they do not reside in Whiskeytown Lake, having likely been extirpated from the reach after the reservoir was originally filled in 1963. Future operations of Whiskeytown Dam under Alternative 1 are therefore unlikely to affect either individuals or populations.

Increased annual variations in reservoir water surface elevation under Alternative 1 compared to the No Action Alternative could cause varying effects to stocked and introduced nonnative game species in Whiskeytown Lake. Stocked species would not be expected to be affected by changes in reservoir operations. Rainbow Trout, Brown Trout, Kokanee Salmon, and Brook Trout typically spawn in tributary streams, but they are capable of spawning in lakes if they are unable to access moving water. Whiskeytown Lake Kokanee spawn in the fall, a period when no differences in water levels are expected under Alternative 1 compared to the No Action Alternative. Pond species such as Largemouth Bass, Smallmouth Bass, Spotted Bass, Bluegill, Black Crappie, Channel Catfish, and Brown Bullhead are able to tolerate a wide range of conditions, but the basses and panfish spawn in relatively shallow lake areas when water warms to at least 50°F in late spring or summer, which may put some of their nests at risk of being dewatered. However, these species have rapid reproductive rates which can enable them to recover from episodic recruitment failures.

O.3.3.3.2 Clear Creek Flows

Under Alternative 1, Reclamation proposes to release Clear Creek flows in accordance with the 1960 MOA with CDFW, and the April 15, 2002 SWRCB permit, which established minimum flows to be released to Clear Creek at Whiskeytown Dam. Reclamation proposes a base flow in Clear Creek of 200 cfs from October to May and 150 cfs from June to September in all year types except critical; in critically dry years, Clear Creek base flows may be reduced below 150 cfs based on available water from Trinity Reservoir. These minimum base flows are greater than those under the No Action Alternative, where minimum base flows from January through October are 50 cfs during normal years and 30 cfs during critically dry years, and 100 cfs from November through December in normal water year types, and 30 cfs to 70 cfs in critically dry water year types based on downstream water rights, 1963 Reclamation proposal to USFWS and NPS, predetermined CVPIA 3406(b)(2) flows, and NMFS BO Action I.1.1 (Table O.3-16).

Table O.3-16. Minimum Flows at Whiskeytown Dam for Normal and Critically Dry Water Year Types

Period	No Action Alternative Normal Year (cfs)	No Action Alternative Critically Dry Year (cfs)	Alternative 1[1]
Jan to May	50	30	200
June to Sept	50	30	150
Oct	50	30	200
Nov to Dec	100	70	200

[1] All but critically dry water year types. During critically dry water year types, Clear Creek base flows may be reduced below 150 cfs based on available water from Trinity Reservoir

Reclamation also proposes creating pulse flows for both channel maintenance and spring attraction flows. Under Alternative 1, Reclamation would release 10 TAF, with daily releases up to the safe release capacity (approximately 900 cfs), from Whiskeytown Reservoir for channel maintenance flows in all but dry and critically dry water year types. In the event of a storm resulting in a Whiskeytown Gloryhole spill of at least 3,000 cfs for 3 days, Reclamation would reduce the channel maintenance flow volume for the year or following year by 5 TAF; if 2 spills meeting this criterion occur in a single year, additional channel maintenance flows would not be required. For spring attraction pulse flows, Reclamation would release 10 TAF, with daily releases up to the safe release capacity (approximately 900 cfs), in all but critically dry water year types. During critically dry water year types, Reclamation would release one spring attraction flow up to the safe release capacity for up to 3 days and would not release any channel maintenance flows. Under the No Action Alternative, channel maintenance flows occur only during flood operations at Whiskeytown and spring attraction flows are provided by two pulse flows in Clear Creek in May and June of at least 600 cfs for at least 3 days for each pulse per year.

Modeling results indicate that differences in average Clear Creek flow between Alternative 1 and the No Action Alternative are minor (Figure O.3-47), with flows increasing slightly under Alternative 1 compared to the No Action Alternative in dry and critically dry water year types (Figure O.3-48). Although Clear Creek flow is similar under Alternative 1 and the No Action Alternative, the average flow fails to reach the minimum instream flow requirements of Alternative 1 except from January to February and from April to June, whereas the flow requirements under the No Action Alternative are met in all months.

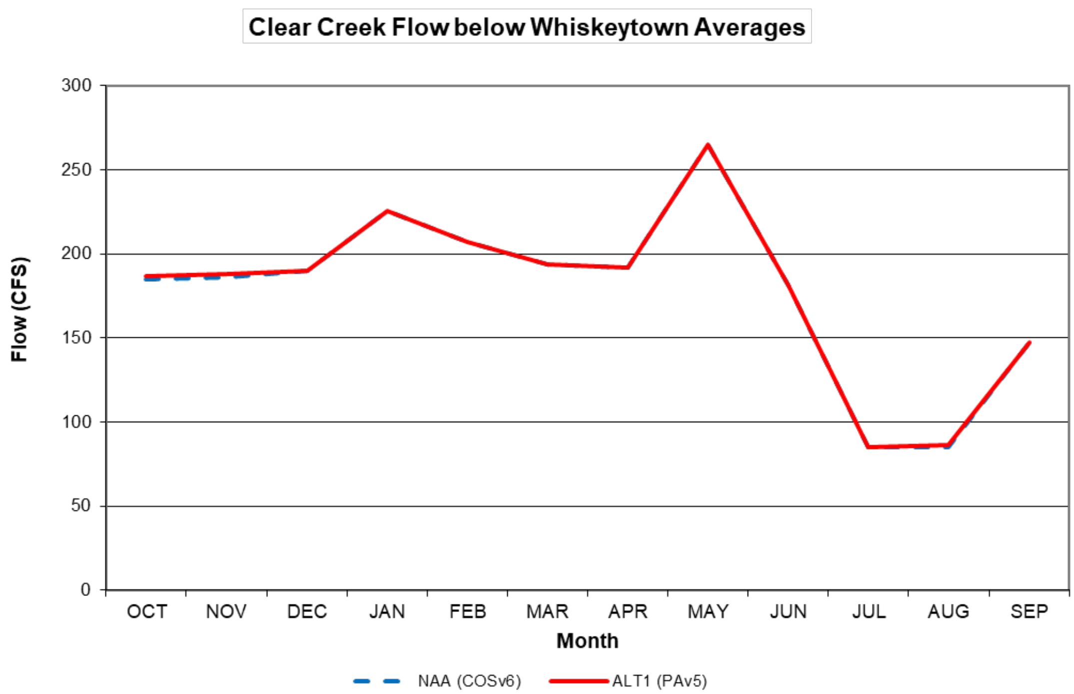

Figure O.3-47. Average Annual Flow in Clear Creek below Whiskeytown Dam for the No Action Alternative and Alternative 1 (40-30-30 Index)

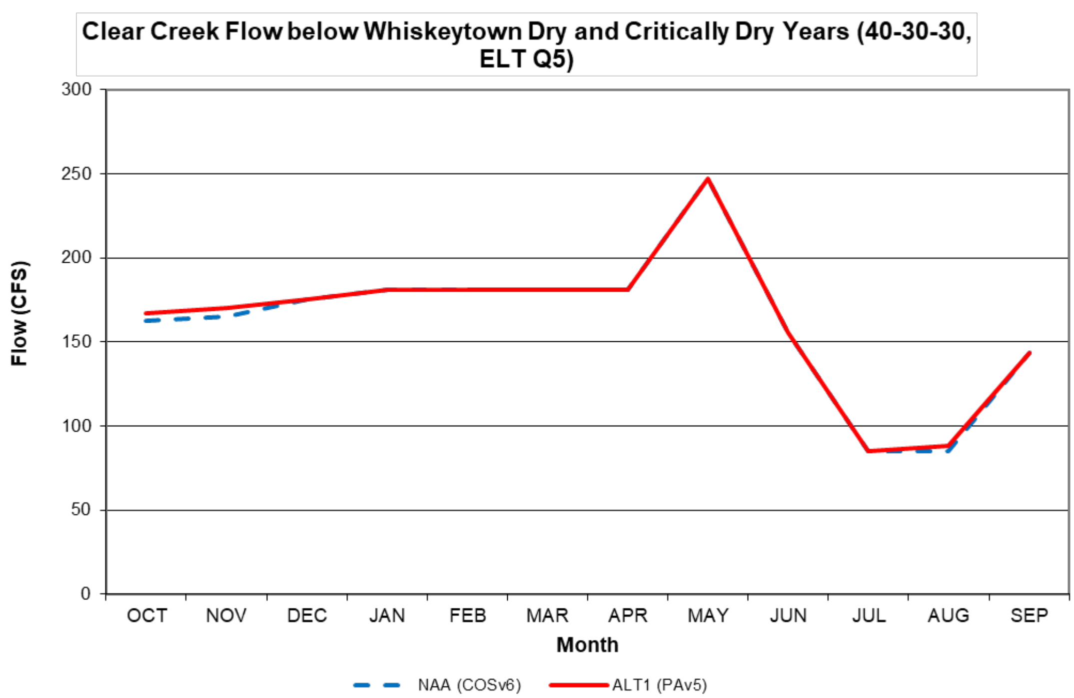

Figure O.3-48. Average Annual Flow in Clear Creek below Whiskeytown Dam for the No Action Alternative and Alternative 1 during Dry and Critically Dry Water Years (40-30-30 Index)

Under Alternative 1, Clear Creek base flows may be reduced below 150 cfs in critically dry years based on available water from Trinity Reservoir. During critically dry years, flows would be below Alternative 1 minimum instream flow requirements from June through November; during much of this period Alternative 1 flows would be slightly greater than No Action Alternative flows (Figure O.3-49).

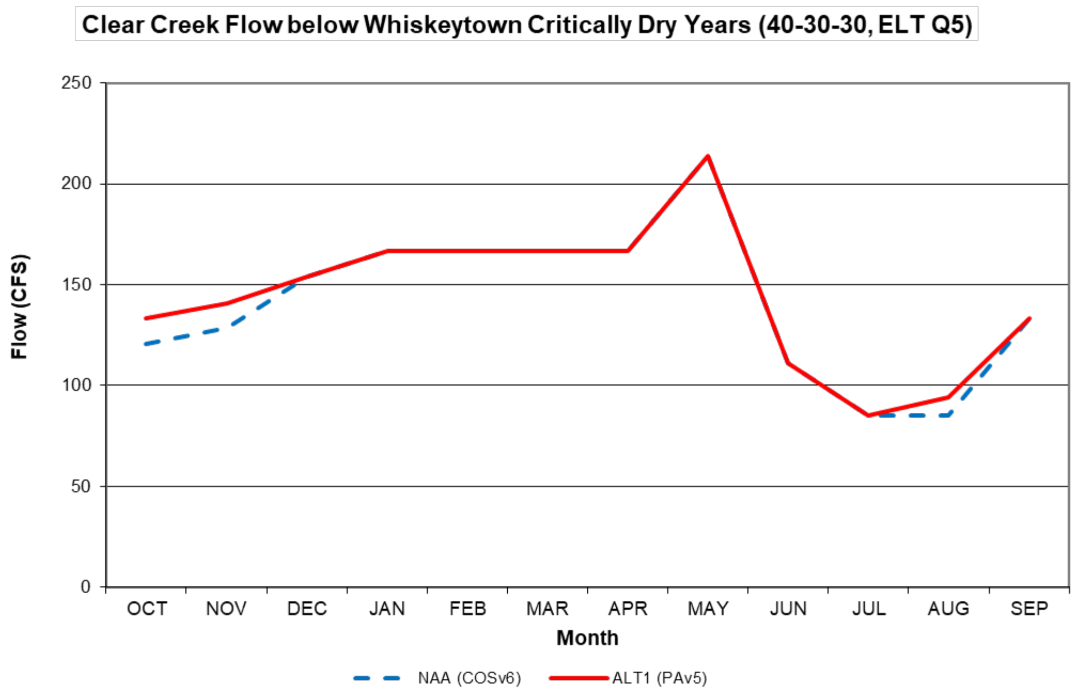

Figure O.3-49. Average Monthly Flow in Clear Creek below Whiskeytown Dam for the No Action Alternative and Alternative 1 during Critically Dry Water Years (40-30-30 Index)

Potential changes to aquatic resources in Clear Creek from variation in flow

Spring-Run Chinook Salmon

Under Alternative 1, base flows in Clear Creek downstream of Whiskeytown Dam would increase by approximately 7% compared to the flows under the No Action Alternative during the period of August to November in critically dry water years (Index 40-30-30, Figure O.3-49); flows are similar between Alternative 1 and the No Action Alternative in all other months and water years. These changes in flow would coincide with the seasonal occurrence of various life stages of Spring-Run Chinook Salmon in Clear Creek including holding adults (May to August), eggs and fry (September to October), and rearing and outmigrating juveniles (November to May). Increased flows during critically dry years would benefit adults and juveniles by increasing pool connectivity and available habitat. Increased flow would also lower temperatures and increase DO, benefiting eggs, fry, and juveniles.

Alternative 1 also allows for greater flexibility in the timing of channel maintenance and pulse flows, so releases could be scheduled in a manner beneficial to various life stages of Spring-Run Chinook Salmon based on their seasonal occurrence in Clear Creek. Relative to the No Action Alternative, Alternative 1 would potentially benefit Spring-Run Chinook Salmon in Clear Creek.

Fall-Run Chinook Salmon

Under Alternative 1, base flows in Clear Creek downstream of Whiskeytown Dam would increase by approximately 7% compared to the flows under the No Action Alternative during the period of August to November in critically dry water years (Index 40-30-30, Figure O.3-49); flows are similar between Alternative 1 and the No Action Alternative in all other months and water years. These changes in flow would coincide with the seasonal occurrence of various life stages of Fall-Run Chinook Salmon in Clear Creek including spawning adults (late-September to December) and eggs and fry (October to April). Increased flows during critically dry years would benefit adults by increasing pool connectivity and spawning habitat. Increased flow would also lower temperatures and increase DO, benefiting eggs and fry.

Alternative 1 allows for greater flexibility in the timing of channel maintenance and pulse flows, so releases could be scheduled in a manner beneficial to various life stages of Fall-Run Chinook Salmon based on their seasonal occurrence in Clear Creek. Relative to the No Action Alternative, Alternative 1 would potentially benefit Fall-Run Chinook Salmon.

Central Valley Steelhead

Under Alternative 1, base flows in Clear Creek downstream of Whiskeytown Dam would increase by approximately 7% compared to the flows under the No Action Alternative during the period of August to November in critically dry water years (Index 40-30-30, Figure O.3-49); flows are similar between Alternative 1 and the No Action Alternative in all other months and water years. These changes in flow would coincide with the seasonal occurrence of California Central Valley DPS Steelhead adult migration (September to October). Increased flows during critically dry years would benefit migrating adult Steelhead by increasing pool connectivity, reducing water temperatures, and increasing foraging habitat and shelter.

Alternative 1 allows for greater flexibility in the timing of channel maintenance and pulse flows, so releases could be scheduled in a manner beneficial to various life stages of California Central Valley DPS Steelhead based on their seasonal occurrence in Clear Creek. Relative to the No Action Alternative, Alternative 1 would potentially benefit California Central Valley DPS Steelhead.

Pacific Lamprey

Under Alternative 1, base flows in Clear Creek downstream of Whiskeytown Dam would increase by approximately 7% compared to the flows under the No Action Alternative during the period of August to November in critically dry water years (Index 40-30-30, Figure O.3-49); flows are similar between Alternative 1 and the No Action Alternative in all other months and water years. These changes in flow would coincide with the seasonal occurrence of various life stages of Pacific Lamprey in Clear Creek, including holding adults (year-round), ammocoetes (year-round), and outmigrating adults (peak early winter to spring). Increased flows during critically dry years would benefit these life stages by increasing pool connectivity, reducing water temperatures, and increasing foraging habitat and shelter.

Alternative 1 allows for greater flexibility in the timing of channel maintenance and pulse flows, so releases could be scheduled in a manner beneficial to various life stages of Pacific Lamprey based on their seasonal occurrence in Clear Creek. Relative to the No Action Alternative, Alternative 1 would potentially benefit Pacific Lamprey.

Potential changes to aquatic resources in Clear Creek from variation in water temperature

Water temperature objectives under Alternative 1 would be similar to those required under the No Action Alternative, with the exception of dry and critically dry water year types when it might not be possible for Reclamation to meet these temperature requirements. In these water year types Reclamation would operate as close to these temperatures as possible.

Modeling results indicate that average water temperatures in Clear Creek above the Sacramento River would be nearly identical under the No Action Alternative and Alternative 1 (Figure O.3-50); however, maximum temperatures do differ between the two scenarios (Figure O.3-51). Under the No Action Alternative, modeled maximum water temperatures exceed those under Alternative 1 in October by up to 7°F, but modeled maximum water temperature under Alternative 1 exceed those under the No Action Alternative by approximately 1°F in September (Figure O.3-51).

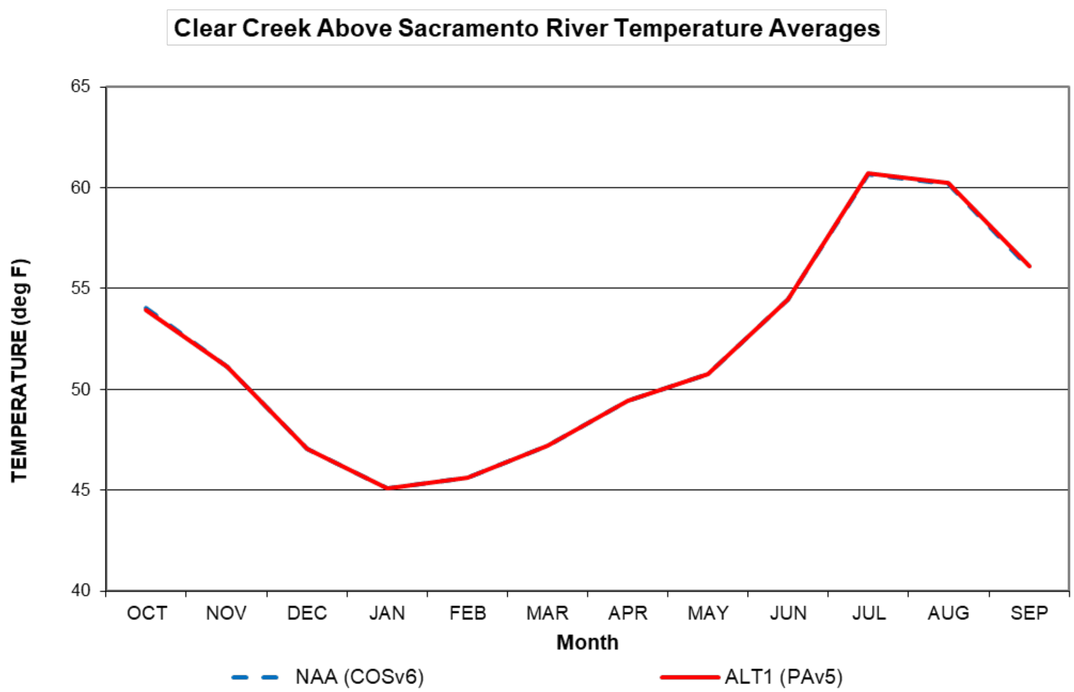

Figure O.3-50. Average Monthly Water Temperatures in Clear Creek above the Sacramento River for the No Action Alternative and Alternative 1

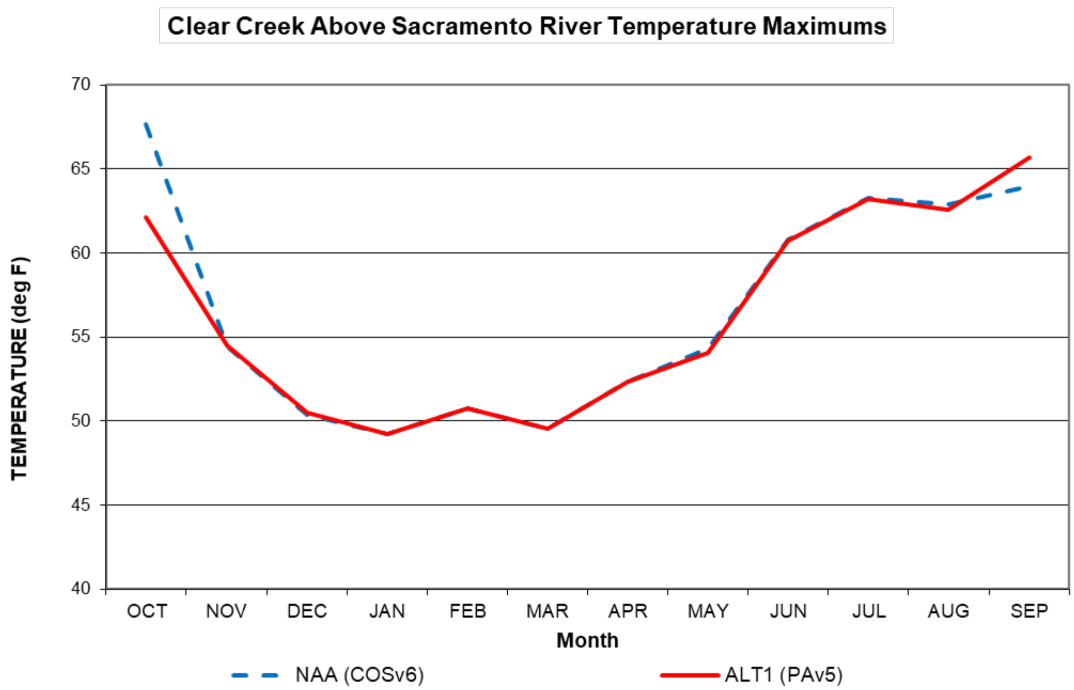

Figure O.3-51. Maximum Modeled Water Temperatures in Clear Creek above the Sacramento River under the No Action Alternative and Alternative 1

Table O.3-17. Water Temperatures Suitable for Spring-Run and Fall-Run Chinook Salmon, Central Valley Steelhead, and Pacific Lamprey by Life Stage

Life Stage	Peak Occurrence	Optimal	Suboptimal	Stress-inducing
Spring-Run Chinook Salmon				
Eggs to fry	September to October	< 54°F	54°F to 58°F	> 58°F
Rearing to out-migrating	November to May	< 60°F	60°F to 65°F	> 65°F
Migrating adults	March to June	< 56°F	56°F to 65°F	> 65°F
Adult holding	May to August	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Fall-Run Chinook Salmon				
Eggs to fry	October to April	48.2°F to 55.4°F	55.4°F to 62.6°F	> 62.6°F
Rearing to out-migrating	April to June	55.4°F to 68°F	68°F to 75.2°F	> 75.2°F
Migrating adults	June to April	50°F to 68°F	68°F to 69.8°F	> 69.8°F
Central Valley Steelhead				
Eggs to fry	January	46°F to 52°F	52°F to 55°F	> 55°F
Rearing to out-migrating	January to May	< 65°F	65°F to 68°F	> 68°F
Migrating adults	September to October	< 52°F	52°F to 70°F	> 70°F
Adult holding	December to March	< 60.8°F	60.8°F to 66.2°F	> 66.2°F

Sources: NMFS 2016a; Stillwater Sciences 2006; CDFG 2012a, 2012b.

Spring-Run Chinook Salmon

Effects of water temperature on Spring-Run Chinook Salmon have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance in Clear Creek (Table O.3-17).

On average, modeled Alternative 1 and No Action Alternative water temperatures are essentially identical (Figure O.3-50), so no difference in effects of water temperature on Spring-Run Chinook Salmon is generally expected. Maximum temperatures under the No Action Alternative, however, reach higher levels in October but lower levels in September than they do under Alternative 1 (Figure O.3-51). Spring-Run Chinook eggs and fry are present during this period (Table O.3-17) and would be exposed to the possible adverse effects of elevated water temperature, including effects of physiologic stress such as slower growth rates and an inability to satisfy metabolic demand (Stillwater Sciences 2006; Martin et al. 2017). Maximum water temperatures under both scenarios exceed stress-inducing levels for Spring-Run Chinook eggs and fry in September and October, but maximum water temperatures under the No Action Alternative remain stress-inducing for a longer period (Figure O.3-51). Minimal difference in effects of water temperature on Spring-Run Chinook Salmon is expected between Alternative 1 and the No Action Alternative, but since temperatures remain at stress-inducing levels longer under the No Action Alternative, there is potential for beneficial effects on eggs and fry under Alternative 1 when temperatures reach their maximum levels.

Fall-Run Chinook Salmon

Effects of water temperature on Fall-Run Chinook Salmon have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance in Clear Creek (Table O.3-17).

On average, modeled Alternative 1 and No Action Alternative water temperatures are essentially identical (Figure O.3-50), so no difference in effects of water temperature on Fall-Run Chinook Salmon is generally expected. Maximum temperatures under the No Action Alternative, however, reach higher levels in October but lower levels in September than they do under Alternative 1 (Figure O.3-51). Fall-Run Chinook eggs and fry are present during October (Table O.3-17) and would be exposed to the possible adverse effects of elevated water temperature, including effects of physiologic stress such as slower growth rates and an inability to satisfy metabolic demand (Stillwater Sciences 2006; Martin et al. 2017). Maximum water temperatures under the No Action Alternative remain at stress-inducing levels for a longer period (Figure O.3-51). Under Alternative 1, therefore, minimal difference in effects of water temperature on Fall-Run Chinook Salmon is expected, but there is potential for beneficial effects on eggs and fry when temperatures reach their maximum levels.

Central Valley Steelhead

Effects of water temperature on Central Valley Steelhead have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance in Clear Creek (Table O.3-17).

On average, modeled Alternative 1 and No Action Alternative water temperatures are essentially identical (Figure O.3-50), so no difference in effects of water temperature on Central Valley Steelhead is generally expected. Maximum temperatures under the No Action Alternative, however, reach higher levels in October and lower levels in September than they do under Alternative 1 (Figure O.3-51). Migrating adult Steelhead are present during this period (Table O.3-17) and would be exposed to the possible adverse effects of elevated water temperature, including effects of physiologic stress such as an inability to satisfy metabolic demand (Stillwater Sciences 2006; Martin et al. 2017). Maximum water temperatures under both scenarios remain at suboptimal levels for migrating adult Steelhead throughout their September to October period of peak occurrence (Figure O.3-49). Under Alternative 1, therefore, minimal difference in effects of water temperature on Central Valley Steelhead is expected.

Pacific Lamprey

Pacific Lamprey temperature tolerance has been less studied than that of salmonids. Periods of life stage occurrence and associated temperatures for Pacific Lamprey are provided in Table O.3-18.

Table O.3-18. Summary Table of Water Temperatures Suitable for Pacific Lamprey by Life Stage

Life Stage	Peak Occurrence	Temperature Range
Ammocoetes	Year-round	< 82°F [1]
Spawning	January to May	50°F to 64°F, peak 57°F to 59°F
Adult out-migration	Early winter to spring	<68°F

Source: Stillwater Sciences 2014.
[1] Temperature of 82°F is lethal to ammocoetes of four North American species of lamprey; however, it is uncertain if Pacific Lampreys have similar tolerances.

On average, modeled Alternative 1 and No Action Alternative water temperatures are essentially identical, so no difference in effects of water temperature on Pacific Lamprey is generally expected. Maximum temperatures under the No Action Alternative, however, reach higher levels in October and lower levels in September than they do under Alternative 1 (Figure O.3-51). Pacific Lamprey ammocoetes are present during this period (Table O.3-18) and would be exposed to the possible adverse effects of elevated water temperature, including effects of physiologic stress such as slower growth rates and an inability to satisfy metabolic demand (Stillwater Sciences 2006; Martin et al. 2017). Maximum water temperatures under both scenarios remain at suitable levels for Pacific Lamprey ammocoetes year-round (Figure O.3-49). Under Alternative 1, therefore, minimal difference in effects of water temperature on Central Valley Steelhead is expected.

O.3.3.3.3 Spring Creek Debris Dam

Under Alternative 1 Reclamation proposes to implement the interim operation while a revised MOU is developed by Reclamation, CDFW, SWRGB, and EPA. This interim operation includes more stringent water quality criteria based on criteria for the protection of aquatic life in the upper Sacramento River as described in the Water Quality Control Plan for the Sacramento River and San Joaquin River Basins (Basin Plan) (SWRCB 1998), and the California Toxics Rule (CTR) (provided in SWRCB 2003). The point of compliance is below Keswick Dam, and sets a maximum concentration for acute exposure of 5.6 µg/L (dissolved copper) and 16 µg/L (dissolved zinc). Maximum concentration for chronic exposure are set at 4.1 µg/L (dissolved copper) and 54 µg/L (dissolved zinc).

Potential changes to aquatic resources due to Spring Creek Debris Dam operations

The most recent five-year review of the project (EPA 2018: i) found that there has been a significant decrease in total copper and total zinc measured at lower Spring Creek. This is largely a result of operational remedies (see description of remedies under NAA) implemented in an effort to comply with the Basin Plan standards in the Sacramento River below Keswick Dam and objectives laid out in applicable RODs. Between 2012 and 2017, the range of total copper and zinc concentrations measured at lower Spring Creek decreased to approximately 50 µg/L to 150 µg/L and 90 µg/L to 800 µg/L, respectively. Water quality below Keswick Dam has likewise shown dramatic improvement. The prescribed remedies are effectively protecting the Sacramento River as important fish habitat and there has been a 97% reduction in heavy metals downstream of Keswick Dam, eliminating fish kills and greatly improving water quality downstream (CVRWQCB 2002: 23). This trend of decreasing copper and zinc contamination in affected waters as a result of SCDD operational remedies will be reinforced under Alternative 1 through adherence to applicable water quality objectives under the Basin Plan at the compliance point below Keswick Dam. As a result, fisheries resources, including Central Valley Steelhead, Green sturgeon, and all runs of Chinook Salmon, in affected reaches of the upper Sacramento River would be exposed to improved water quality, leading to potential individual and population-level benefits.

O.3.3.3.4 Clear Creek Restoration Program

The Clear Creek Restoration Program is being implemented under both Alternative 1 and the No Action Alternative. Therefore, Alternative 1 and the No Action Alternative are likely to have similar effects on aquatic resources.

O.3.3.4 *Feather River*

O.3.3.4.1 FERC Project #2100-134

DWR, under Alternative 1, would operate Oroville Dam consistent with the NMFS, USFWS, and CDFW environmental requirements applicable for the current Oroville Complex FERC License (FERC Project #2100-134). Reclamation would operate Oroville Dam with minimum flows of 700 cfs to 800 cfs below the Thermalito Diversion Dam in the low flow channel (2006 Settlement Agreement), 750 cfs to 1,700 cfs below the Thermalito Afterbay outlet (1983 DWR-CDFG Agreement), and the DFG/DWR operation objective of 2,800 cfs at the mouth of the Feather River from April through September, with options to vary flow depending on year types. Reclamation would also operate Oroville Dam to meet minimum instream flow requirements below the Thermalito Afterbay outlet in the HFC of 1,000 cfs to 1,700 cfs depending on the time of year and the preceding April to July unimpaired runoff (Table O.3-19).

Under the No Action Alternative, DWR would operate Oroville Dam in accordance with ongoing management policies, criteria, and regulations, including water right permits and licenses issued by the SWRCB and operational requirements of the 2008 USFWS BO and the 2009 NMFS BO. Under the No Action Alternative, DWR typically releases water from Lake Oroville to meet the requirements of instream flows and D-1641.

Table O.3-19. Feather River HFC Minimum Instream Flow Requirements

Preceding April to July Unimpaired Runoff (Percent of Normal)	Oct to Feb Minimum Instream Flow (cfs)	March Minimum Instream Flow (cfs)	April to Sept Minimum Instream Flow (cfs)
55% or greater	1,700	1,700	1,000
Less than 55%	1,200	1,000	1,000

Potential changes to aquatic resources in the Feather River due to seasonal variation in flow

CalSim II model output shows that Feather River flows under Alternative 1 and the No Action Alternative would comply with Feather River HFC minimum instream flow requirements during all months in wet, above normal, and below normal water years. In dry years where the preceding April to

July unimpaired runoff is less than 55% of normal, Alternative 1 and the No Action Alternative would comply with minimum instream flow requirements in the HFC; however, where the preceding April to July unimpaired runoff is greater than 55% of normal, Alternative 1 would not comply with minimum instream flow requirements from October through March (Table O.3-19 and Figure O.3-52). In critically dry years where the preceding April to July runoff is greater than 55% of normal, Alternative 1 and the No Action Alternative would not comply with minimum instream flows from October to March; however, where the preceding April to July runoff is less than 55% of normal, Alternative 1 and the No Action Alternative would only not comply with minimum instream flow requirements in the HFC in November (Table O.3-19 and Figure O.3-52).

Figure O.3-52. CalSim II Estimates of Feather River Long-Term Average Flow below Thermalito, All Scenarios in Wet, Above Normal, Below Normal, Dry, and Critically Dry Water Years

Overall, simulated flows under the Alternative 1 and No Action Alternative scenarios are similar, but flows under the No Action Alternative are higher in September of wet and above normal years, and flows under Alternative 1 are slightly higher from April through June of above normal, below normal, dry, and critically dry water years and much higher in February of below normal years (Figure O.3-52).

Winter-Run Chinook Salmon

Winter-Run Chinook are not likely to be affected by changes in flow under Alternative 1 compared to the No Action Alternative due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Spring-Run Chinook Salmon would be exposed to the effects of Alternative 1 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Eggs and emerging fry of Spring-Run Chinook Salmon may occur in the Feather River from September through February (NMFS 2016a); juvenile Spring-Run Chinook Salmon occur in the Feather River year-round, with peak abundance from November through May; and adult Spring-Run Chinook Salmon peak in abundance in the Feather River from March through June. All life stages would thus be exposed to the effects of Alternative 1.

Spring-Run Chinook Salmon eggs and emerging fry would benefit from increased Alternative 1 flows, leading to increased dissolved oxygen in February of below normal years when Alternative 1 flows are significantly higher than No Action Alternative flows (Figure O.3-52). Juvenile Spring-Run Chinook Salmon would also benefit from increased Alternative 1 flows relative to No Action Alternative flows from November through March of wet years, January through April of above normal years, and February of below normal years when the increased flows result in increased rearing and foraging habitat and higher dissolved oxygencontent (Figure O.3-52). Adult Spring-Run Chinook Salmon would benefit from increased Alternative 1 flows relative to No Action Alternative flows from April through June of below normal, dry, and critically dry years due to the resulting increased attraction flows and holding habitat (Figure O.3-52). Because Spring-Run Chinook Salmon benefit from increased Alternative 1 flows relative to No Action Alternative flows during key months of all life stages and because Alternative 1 flows do not comply with minimum instream flow requirements only in dry and critically dry years (Table O.3-19, Figure O.3-52), flow-related actions under Alternative 1 would have beneficial effects on Spring-Run Chinook Salmon.

Fall-Run Chinook Salmon

Fall-Run Chinook Salmon would be exposed to the effects of Alternative 1 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Fall-Run Chinook Salmon occur in the Feather River year-round, with eggs and emerging fry occurring between January and April; juveniles out-migrating year-round with peaks from January to April and August to November; and holding and migrating adults occurring between April and July (NMFS 2016a). All life stages would thus be exposed to the effects of Alternative 1.

Fall-Run Chinook Salmon eggs and emerging fry would benefit from the increased dissolved oxygendue to higher Alternative 1 flows from January to April of wet and above normal years and in February of below normal years (Figure O.3-52). Juvenile Fall-Run Chinook Salmon would benefit from increased Alternative 1 flows relative to No Action Alternative flows from January to April of wet and above normal years and in February of below normal years when increased flows result in increased rearing and foraging habitat, and higher dissolved oxygencontent (Figure O.3-52). Migrating adult Fall-Run Chinook Salmon would benefit from increased Alternative 1 flows relative to No Action Alternative flows from April to July of below normal, dry, and critically dry years due to increased attraction flows and holding habitat (Figure O.3-52). Because Fall-Run Chinook Salmon benefit from increased Alternative 1 flows relative to No Action Alternative flows during key months of all life stages and because Alternative 1 flows do not comply with minimum instream flow requirements only in dry and critically dry years

(Table O.3-19, Figure O.3-52), flow-related actions under Alternative 1 would have beneficial effects on Fall-Run Chinook Salmon.

Central Valley Steelhead

Central Valley Steelhead would be exposed to the effects of Alternative 1 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Central Valley Steelhead eggs and fry occur in the Feather River from December to May; rearing juveniles occur year-round and out-migrate from January to May; peak adult migration occurs in September and October; and adult holding occurs from December to March (NMFS 2016a).

Alternative 1 flows can affect Central Valley Steelhead by influencing water temperature, DO, sedimentation, substrate composition, habitat, food availability, predation, entrainment and stranding risk, habitat availability, and migration cues. Differences in flow under Alternative 1 and the No Action Alternative are minimal during the January to May period in which Central Valley Steelhead juveniles are out-migrating in all but below normal water years, when Alternative 1 flows are considerably higher than No Action Alternative flows from mid-January through mid-March (Figure O.3-52). The increased flow under Alternative 1 during mid-January through mid-March of below normal years can benefit juveniles via increased rearing and foraging habitat and higher dissolved oxygencontent. The same is true for the December to May period in which Central Valley Steelhead eggs and fry are present in the Feather River. During the September and October adult peak migration period, No Action Alternative flows are higher than Alternative 1 flows in September of wet and above normal water years, which could create higher levels of flow attraction (Figure O.3-52); there are minimal differences during all other water years. During adult holding from December to March, differences between Alternative 1 and No Action Alternative flows are minimal except for in February of below normal water years when increased flows could increase available habitat (Figure O.3-52). Because Central Valley Steelhead benefit from increased Alternative 1 flows relative to No Action Alternative flows during key months of all life stages and because Alternative 1 flows do not comply with minimum instream flow requirements only in dry and critically dry years (Table O.3-19, Figure O.3-52), flow-related actions under Alternative 1 may have beneficial effects on Central Valley Steelhead.

North American Green Sturgeon

North American Green Sturgeon would be exposed to the effects of Alternative 1 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Green Sturgeon eggs and larvae occur in the Feather River from March to July; larvae and juveniles occur from April to August; subadults occur year-round; and adults occur from March to August (NMFS 2016a).

Differences in flow under Alternative 1 and the No Action Alternative are minimal during all water years in the March to August period in which Green Sturgeon eggs, larvae, juveniles, and adults occur in the Feather River. Because subadults occur year-round, only subadults would be exposed to the larger differences between Alternative 1 and No Action Alternative flows; exposure would occur in February of below normal water years when Alternative 1 flows are greater than they are under the No Action Alternative and in September of above normal and wet water years when No Action Alternative flows are greater than flows under Alternative 1 (Figure O.3-52). Because flow differences between Alternative 1 and the No Action Alternative during key periods of Green Sturgeon presence in the Feather River are minimal and flows below the minimum instream flow requirements occur only in dry and critically dry years (Table O.3-19, Figure O.3-52), flow-related actions under Alternative 1 are not anticipated to substantially affect North American Green Sturgeon.

Potential changes to aquatic resources in the Feather River due to changes in water temperature from differences in flow

Water flow, combined with other environmental drivers, has the potential to affect aspects of water quality such as temperature. Water temperature has the potential to influence the condition and survival of fish species during all stages of their life cycle. Optimal water temperatures can facilitate physiological responses that range from faster growth rates to a heightened immune system, leading to a higher likelihood of survival. In contrast, effects of elevated water temperatures include an inability to satisfy metabolic demand and acute to chronic physiological stress, eventually leading to mortality (Stillwater Sciences 2006; Martin et al. 2017).

HEC-5Q/RecTemp modeling results provide predictions of water temperature at multiple locations in the Feather River HFC from below the Thermalito Afterbay to the mouth of the Feather River. Average water temperatures in the Feather River HFC at Gridley Bridge follow a seasonal pattern where they increase to a high point around 72°F in July or August and decrease to a low point around 47°F in January (Figure O.3-53). Flow releases from Oroville facilities influence Feather River water temperature primarily in summer and fall when these releases can help to lessen water temperatures when air temperatures and solar radiation levels are at their highest. Average water temperatures in the Feather River do not change substantially between water year type in winter, but water temperatures can reach levels up to 4°F warmer (approximately 75°F) in critically dry years than in wet years (approximately 71°F) (Figure O.3-54).

Alternative 1 was designed to follow flow regulation procedures similar to procedures under the No Action Alternative as a way to minimize potential adverse temperature-related effects on various fish species in the Feather River. Certain water temperature objectives were developed to aid the development of Alternative 1 operations (Table O.3-20).

Table O.3-20. Maximum Daily Mean Water Temperature Objectives for the Feather River HFC

Period	**Temperature (°F)**
January 1 to March 31	56
April 1 to 30	61
May 1 to 15	64
May 16 to 31	64
June 1 to August 31	64
September 1 to 8	61
September 9 to 30	61
October 1 to 31	60
November 1 to December 31	56

Source: NMFS 2016a.

Modeled average water temperatures under both Alternative 1 and the No Action Alternative (Figure O.3-53) exceed the daily average water temperature objectives of 64°F from June 1 to August 31 and 61°F from September 1 to 30 (Table O.3-20). There is, therefore, potential for adverse temperature-related effects on Feather River anadromous fish species, although the presence and magnitude of these effects would vary between the different species and life stages. In particular, these modeled average temperatures would reach suboptimal or stress-inducing levels for Spring-Run Chinook eggs, fry, and adults, migrating Central Valley Steelhead, and Green Sturgeon eggs, fry, and post-spawn adults.

Modeling results indicate that water temperatures under Alternative 1 operations would be similar to temperatures under the No Action Alternative for much of the year (Figures O.3-53 and O.3-54). In August and September, though, the water in the Feather River HFC at Gridley Bridge would reach temperatures, on average, up to 1°F warmer than under the No Action Alternative (Figure O.3-53). The most pronounced difference in August and September water temperatures between Alternative 1 and No Action Alternative scenarios would occur in wet years when this temperature difference could reach as much as 3°F, whereas no difference is projected in drier water years (Figure O.3-54). In dry water years, a small difference in water temperature between Alternative 1 and No Action Alternative scenarios would occur instead in June, when Alternative 1 water temperatures would surpass No Action Alternative temperatures by approximately 1°F (Figure O.3-54). These differences in water temperature between Alternative 1 and the No Action Alternative would therefore occur in summer months when water temperatures are higher (> 60°F) and more likely to lead to physiological stress and mortality. The effects of water temperature on fish in the Feather River vary among species and life stages; however, water temperatures under the No Action Alternative and Alternative 1 scenarios would surpass suboptimal levels for Chinook Salmon between 58°F and 75.2°F, for Steelhead between 55°F and 70°F, and for Green Sturgeon between 66°F and 70°F (Table O.3-21).

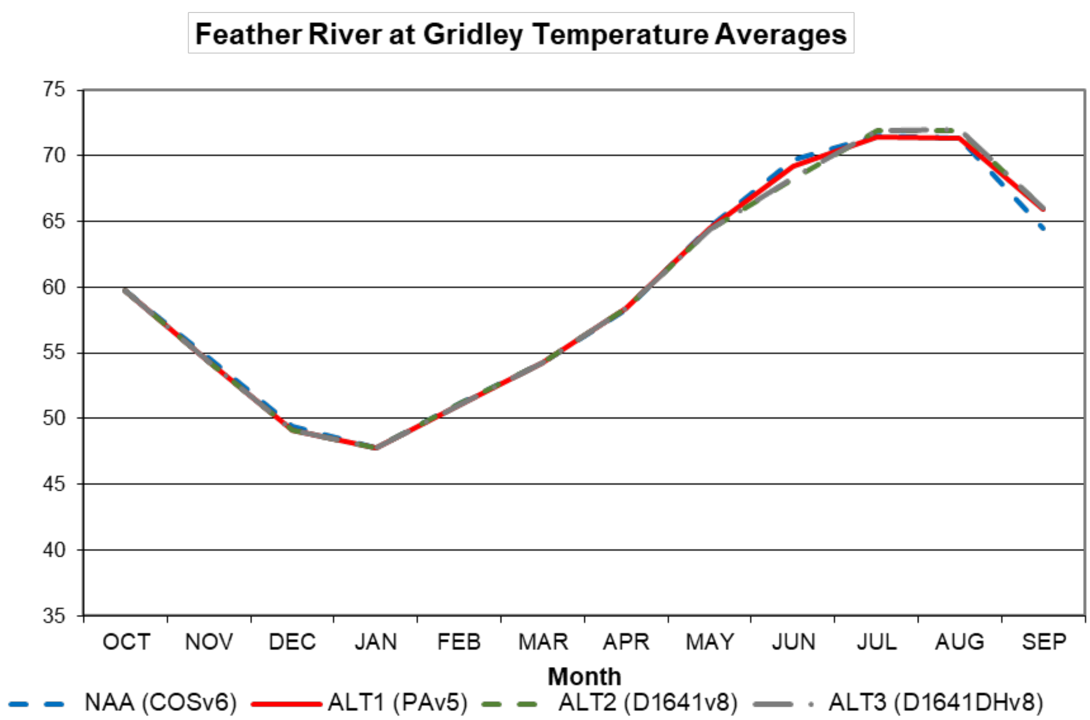

Figure O.3-53. RecTemp Average Feather River Water Temperatures at Gridley Bridge under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 Scenarios

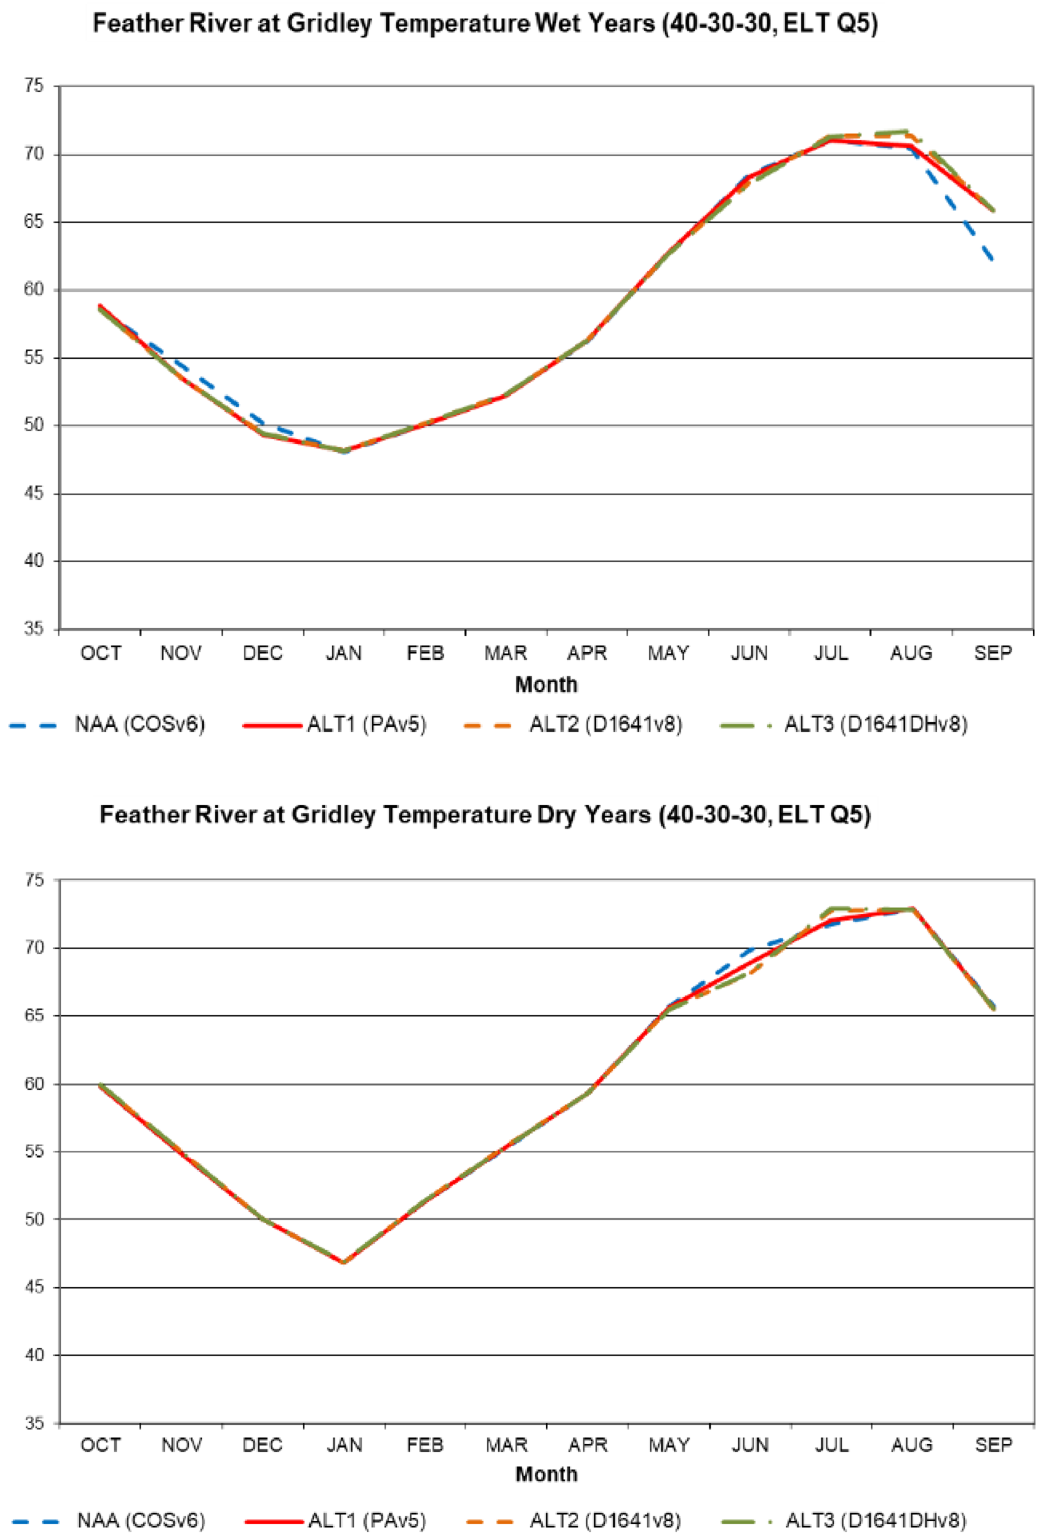

Figure O.3-54. RecTemp Average Estimated Feather River Water Temperatures at Gridley Bridge in Wet and Dry Water Year Types under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 Scenarios

Table O.3-21. Water Temperatures Suitable for Spring-Run and Fall-Run Chinook Salmon, Central Valley Steelhead, and Green Sturgeon by Life Stage

Life Stage	Peak Occurrence	Optimal	Suboptimal	Stress-inducing
Spring-Run Chinook Salmon				
Eggs to fry	September to October	< 54°F	54°F to 58°F	> 58°F
Rearing to out-migrating	November to May	< 60°F	60°F to 65°F	> 65°F
Migrating adults	March to June	< 56°F	56°F to 65°F	> 65°F
Adult holding	May to August	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Fall-Run Chinook Salmon				
Eggs to fry	October to April	48.2°F to 55.4°F	55.4°F to 62.6°F	> 62.6°F
Rearing to out-migrating	April to June	55.4°F to 68°F	68°F to 75.2°F	> 75.2°F
Migrating adults	June to April	50°F to 68°F	68°F to 69.8°F	> 69.8°F
Central Valley Steelhead				
Eggs to fry	January	46°F to 52°F	52°F to 55°F	> 55°F
Rearing to out-migrating	January to May	< 65°F	65°F to 68°F	> 68°F
Migrating adults	September to October	< 52°F	52°F to 70°F	> 70°F
Adult holding	December to March	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Green Sturgeon				
Eggs to fry	May to July	53°F to 65°F	65°F to 66°F	> 66°F
Rearing to out-migrating	May to October	58°F to 66°F	66°F to 69°F	> 69°F
Migrating adults	March to May	53°F to 64°F	64°F to 66°F	> 66°F
Post-spawn adults	March to August	46°F to 68°F	68°F to 70°F	>70°F

Winter-Run Chinook Salmon

Winter-Run Chinook are not likely to be affected by changes in flow under Alternative 1 compared to the No Action Alternative due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Effects of water temperature on Spring-Run Chinook have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance (Table O.3-21).

A difference in water temperature between Alternative 1 and No Action Alternative scenarios during the peak occurrence period for Spring-Run Chinook eggs and emerging fry would occur in in September of wet water years when temperatures under Alternative 1 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-54 and Table O.3-21). This would result in potentially adverse effects from the slightly higher water temperatures under Alternative 1 than under the No Action Alternative, yet water temperatures under both scenarios would fall in the stress-inducing range for this life stage (Table O.3-21). During the peak abundance period of juvenile Spring-Run Chinook (November to May), there is no projected difference between water temperatures under Alternative 1 and the No Action Alternative (Figure O.3-53 and Table O.3-21). For the majority of the peak occurrence range for migrating and holding adults, there is no difference in water temperature between Alternative 1 and the No Action Alternative (Figure O.3-53 and Table O.3-21); in June of dry water years, however, water temperatures under Alternative 1 could be up to 1°F lower than under the No Action Alternative (Figure O.3-54). The effect on adult Spring-Run Chinook would likely be negligible because modeled water temperatures would cross the threshold for stress-inducing temperatures under both Alternative 1 and the No Action Alternative for both life stages (Figure O.3-54 and Table O.3-21).

Alternative 1 therefore has the potential for slightly adverse water temperature-related effects on eggs and fry but very slightly beneficial effects on adults, so its overall effect on Spring-Run Chinook relative to the No Action Alternative is negligible.

Fall-Run Chinook Salmon

Effects of water temperature on Fall-Run Chinook have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-21).

Fall-Run Chinook eggs and fry are present in the Feather River between October and April when there is no projected difference between water temperatures under Alternative 1 and the No Action Alternative (Figure O.3-53 and Table O.3-21). In June of dry water years, water temperatures under Alternative 1 could be up to 1°F lower than under the No Action Alternative, possibly affecting juvenile and migrating adult Fall-Run Chinook (Figure O.3-54). The effect of the June temperature difference would be beneficial but could be slightly more pronounced for both juveniles and adults than otherwise expected since water temperatures under Alternative 1 in these years would remain at optimal levels longer, while they would rise to suboptimal levels under No Action Alternative flows (Figure O.3-54 and Table O.3-21). For migrating adults, water temperatures under Alternative 1 would also remain at stress-inducing and then suboptimal levels approximately one month longer than in the No Action Alternative scenario in September of wet water years (Figure O.3-54 and Table O.3-21). The net effect of Alternative 1 water temperatures on migrating adult Fall-Run Chinook relative to the No Action Alternative would be expected to be slightly adverse overall due to the greater magnitude of the water temperature difference between Alternative 1 and the No Action Alternative in September of wetter years relative to the difference in June of drier years but would ultimately depend on the rainfall levels experienced in the watershed.

Alternative 1 therefore has the potential for both slightly beneficial and slightly adverse water temperature-related effects on Fall-Run Chinook relative to the No Action Alternative, so its overall effects would be negligible.

Central Valley Steelhead

Effects of water temperature on Central Valley Steelhead have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance (Table O.3-21).

Central Valley Steelhead eggs, fry, juveniles, and holding adults are present in the Feather River in winter and spring months when there is no projected difference between water temperatures under Alternative 1 and the No Action Alternative (Figure O.3-53 and Table O.3-21). Migrating (ocean to river) adult

Steelhead peak in abundance in the Feather River between September and October (Table O.3-21). Modeled water temperatures for Alternative 1 and the No Action Alternative differ in September of wet water years when temperatures under Alternative 1 could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-54), yet water temperatures would remain in the suboptimal range for migrating adults under Alternative 1 and the No Action Alternative (Table O.3-21). Adverse effects of water temperature on this life stage are therefore anticipated to be slightly less severe under the No Action Alternative than under Alternative 1. Alternative 1 therefore has the potential for slightly adverse water temperature-related effects on migrating adults relative to the No Action Alternative.

North American Green Sturgeon

Effects of water temperature on Green Sturgeon have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-21).

Green Sturgeon eggs and emerging fry occur in the Feather River from May to July, rearing and out-migrating juveniles from May to October, and post-spawn adults from March to August (Table O.3-21). All life stages would be exposed to water temperatures up to 1°F lower under Alternative 1 than under the No Action Alternative in June of dry water years (Figure O.3-54), yet modeled water temperatures are above the threshold for stress-inducing temperatures for eggs and fry under both Alternative 1 and the No Action Alternative (Table O.3-21). For juveniles and post-spawn adults, though, water temperatures would rise to stress-inducing and suboptimal levels, respectively, later in June under Alternative 1 than under the No Action Alternative (Table O.3-21). Juvenile Green Sturgeon are also present in the Feather River during September when, in wet water years, water temperatures under Alternative 1 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-54 and Table O.3-21). Water temperatures in wet water years would drop from stress-inducing levels for juveniles to suboptimal levels and again to optimal levels later in the month under Alternative 1 than under the No Action Alternative (Figure O.3-54, Table O.3-21). The effects of water temperature on juvenile Green Sturgeon under Alternative 1 would then be dependent on water year types with slightly beneficial effects in dry water years and slightly adverse effects in wet water years, so the net effect would be negligible. Migrating (ocean to river) adult Green Sturgeon reach the Feather River between March and May and do not experience any temperature differences between Alternative 1 and the No Action Alternative.

Alternative 1 therefore has the potential for slightly adverse water temperature-related effects on juveniles in wet water years but very slightly beneficial effects on eggs, fry, juveniles, and post-spawn adults in dry water years, so its overall effect on North American Green Sturgeon relative to the No Action Alternative is minor and dependent on annual rainfall totals.

O.3.3.5 *American River*

Potential changes to aquatic resources in the American River from flood control

Flood control would be similar under Alternative 1, compared to the No Action Alternative and would include following the USACE Water Control Manual, with the addition of working with the American River Stakeholders to define the “planning minimum”, an appropriate amount of storage in Folsom Reservoir that represents the lower bound for typical forecasting processes at the end of calendar year. The objective of the planning minimum is to preserve storage to protect against future drought conditions and to facilitate the development of the coldwater pool when possible. The objective of incorporating the planning minimum into the forecasting process is to provide releases of salmonid-suitable temperatures to the lower American River and reliable deliveries to American River water agencies. Analysis of Folsom

Storage indicates that under average conditions, there would be little difference in flood control storage under Alternative 1, compared to the No Action Alternative (Figure O.3-55). Flood control storage would be slightly greater in dry years (Figure O.3-56), and the same in wet years (Figure O.3-57), compared to the No Action Alternative.

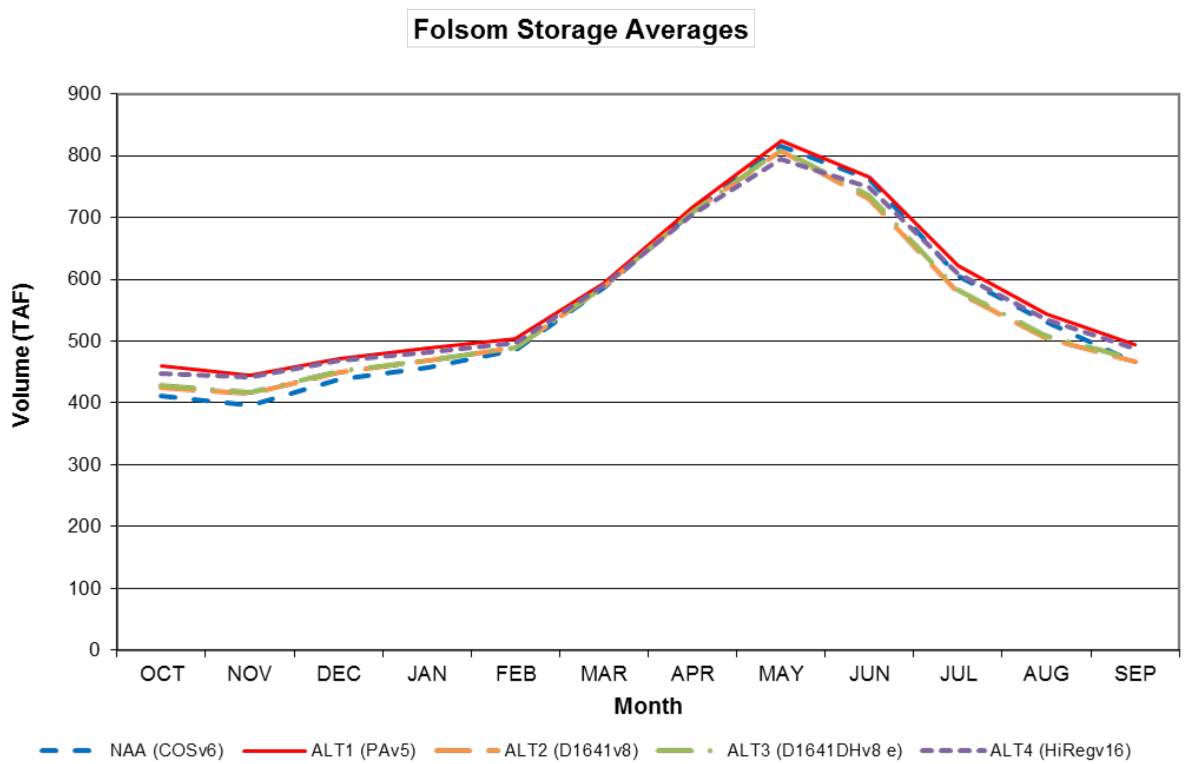

Figure O.3-55. Folsom Reservoir Storage under Average Conditions

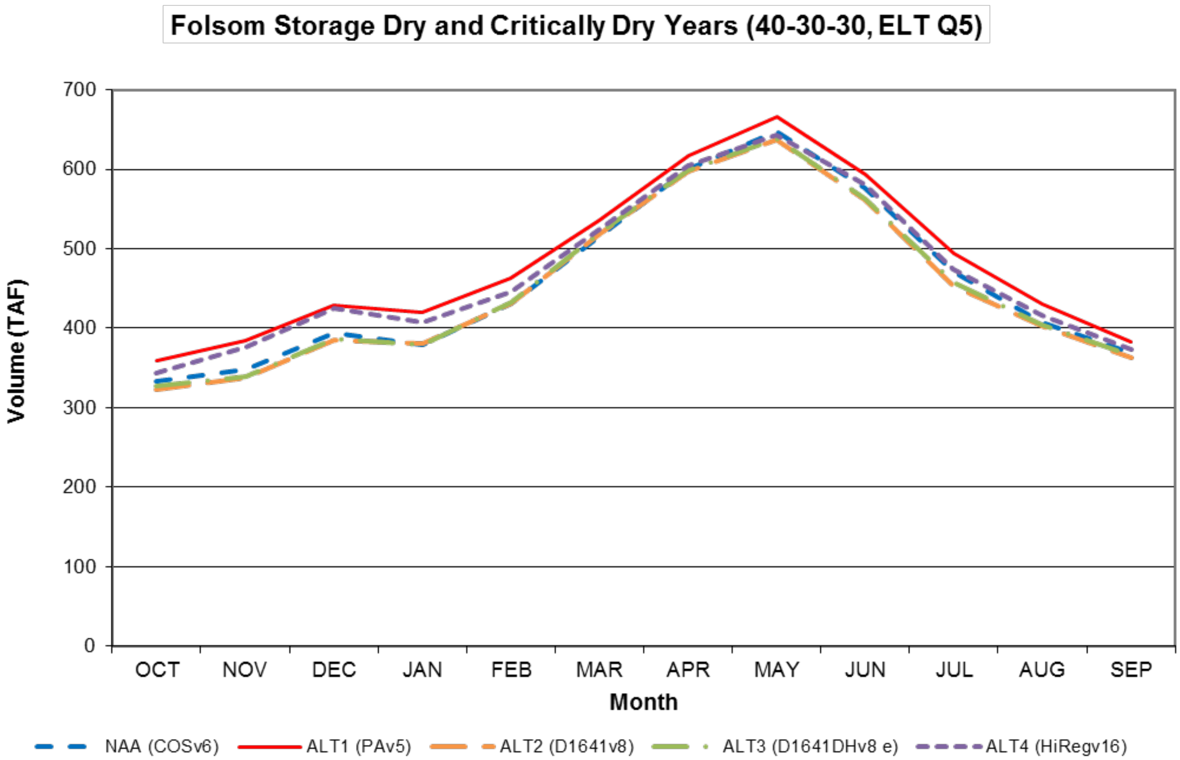

Figure O.3-56. Folsom Reservoir Storage in Dry and Critically Dry Years

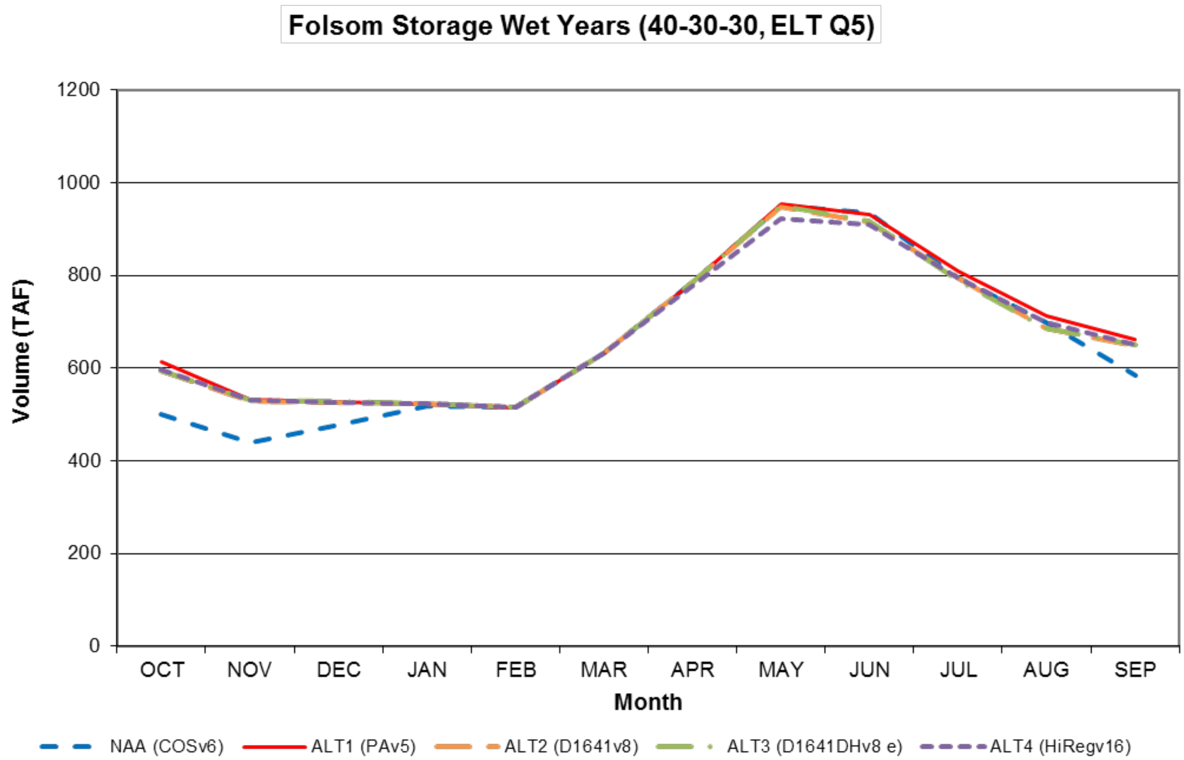

Figure O.3-57. Folsom Reservoir Storage in Wet Water Years

Potential changes to aquatic resources from Folsom Reservoir operations in the American River to meet Delta salinity requirements

Folsom Reservoir operations to address Delta water quality requirements under D-1641 would not change under Alternative 1, compared to the No Action Alternative. Folsom Reservoir flow requirements includes releases to meet Delta standards under D-1641, as needed. Since Folsom Reservoir is the closest reservoir to the Delta, releases from Folsom can more quickly address Delta water quality requirements. Releases to address Delta water quality objectives would be conducted, as needed, in coordination with the American River stakeholders. Releases to address Delta water quality objectives would improve water quality conditions, and thus habitat conditions for fish and other aquatic species in the Delta when hydrologic conditions are negatively affecting salinity levels.

Potential changes to aquatic resources from flows in the American River

Flow objectives for Alternative 1 are similar to the objectives for the No Action Alternative with the intent of providing suitable conditions for Fall Chinook and Steelhead. Flows under Alternative 1 are according to the 2017 Flow Management Standard, where additional flow measures include minimizing releases above 4,000 cfs during sensitive life stages, redd dewatering protective measures in January through May (holding releases relatively constant), providing spring pulse flows, and continued summer releases for instream temperature control. Although these objectives result additional flow measures, the modeling indicates that overall change to flows in the American River below Nimbus Dam are minor, and that instream flows during critically dry periods for Fall Chinook Salmon and Steelhead are driven more by hydrologic conditions (wet versus dry years) than the operations to meet objectives.

Flows in the American River below Nimbus Dam would be similar throughout the year under Alternative 1 with relatively minor differences in average flows (Figure O.3-58) and in wet years (Figure O.3-59), under Alternative 1 compared to the No Action Alternative. In dry and critically dry years, flows would be similar under Alternative 1 and the No Action Alternative, with some differences in the late winter/early spring months and in the summer months, (Figure O.3-60). Flows would be higher in February through March, slightly lower in July, and higher in August and September.

Changes to minimum flows in the American River below Nimbus Dam would be more evident in low water years, with lower minimum flows in October through January, higher minimum flows in February and March, and higher flows in July through September compared to the No Action Alternative (Figure O.3-60).

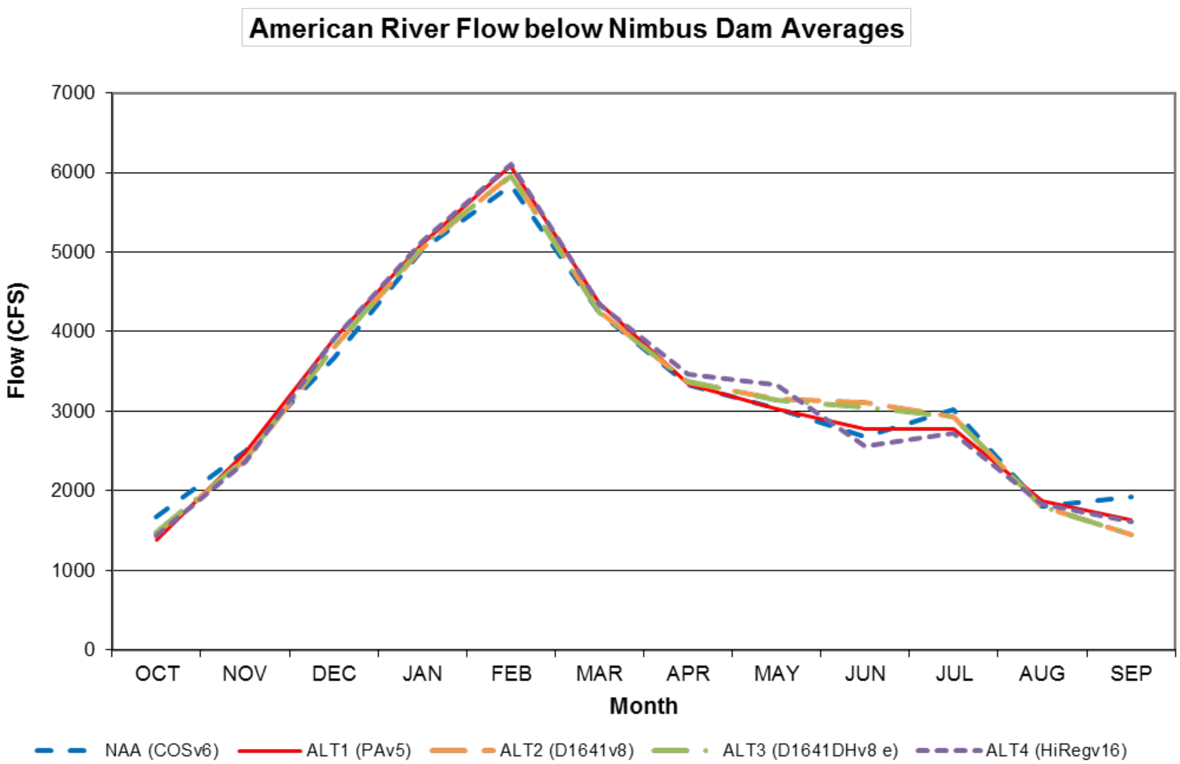

Figure O.3-58. Average Flows in the American River below Nimbus Dam at Watt Avenue

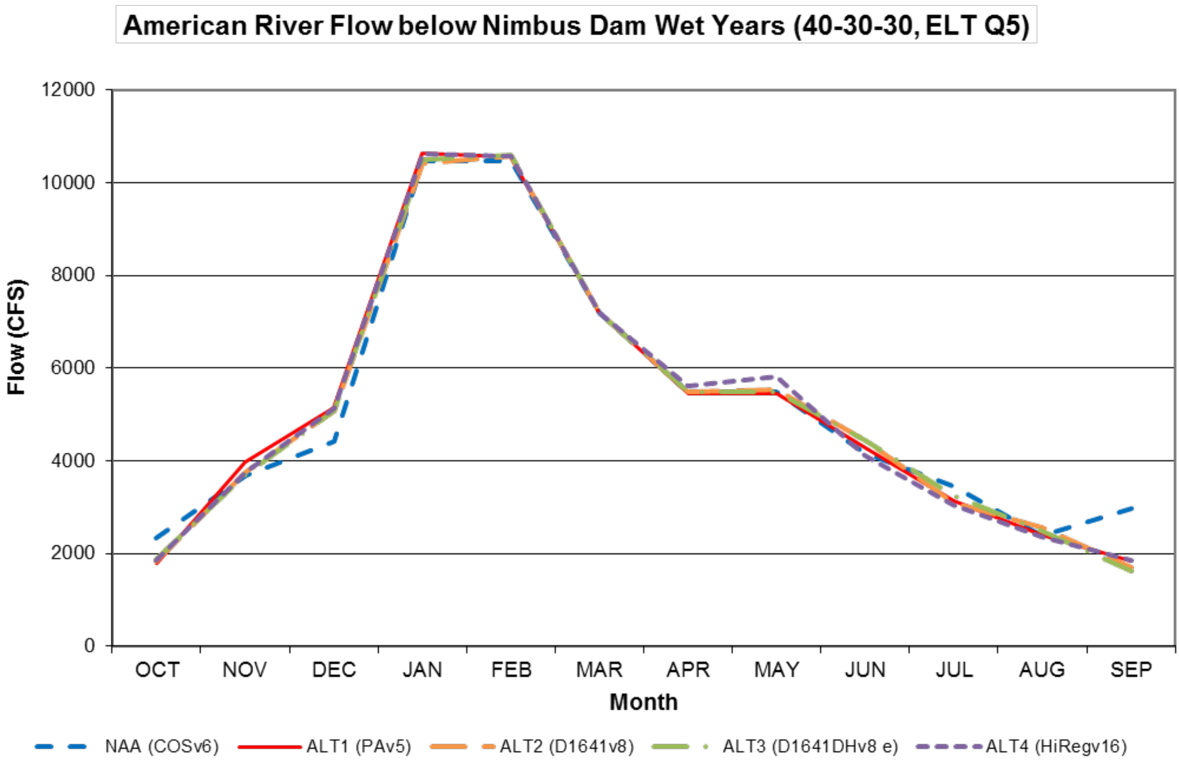

Figure O.3-59. Flows in the American River below Nimbus Dam in Wet Water Years

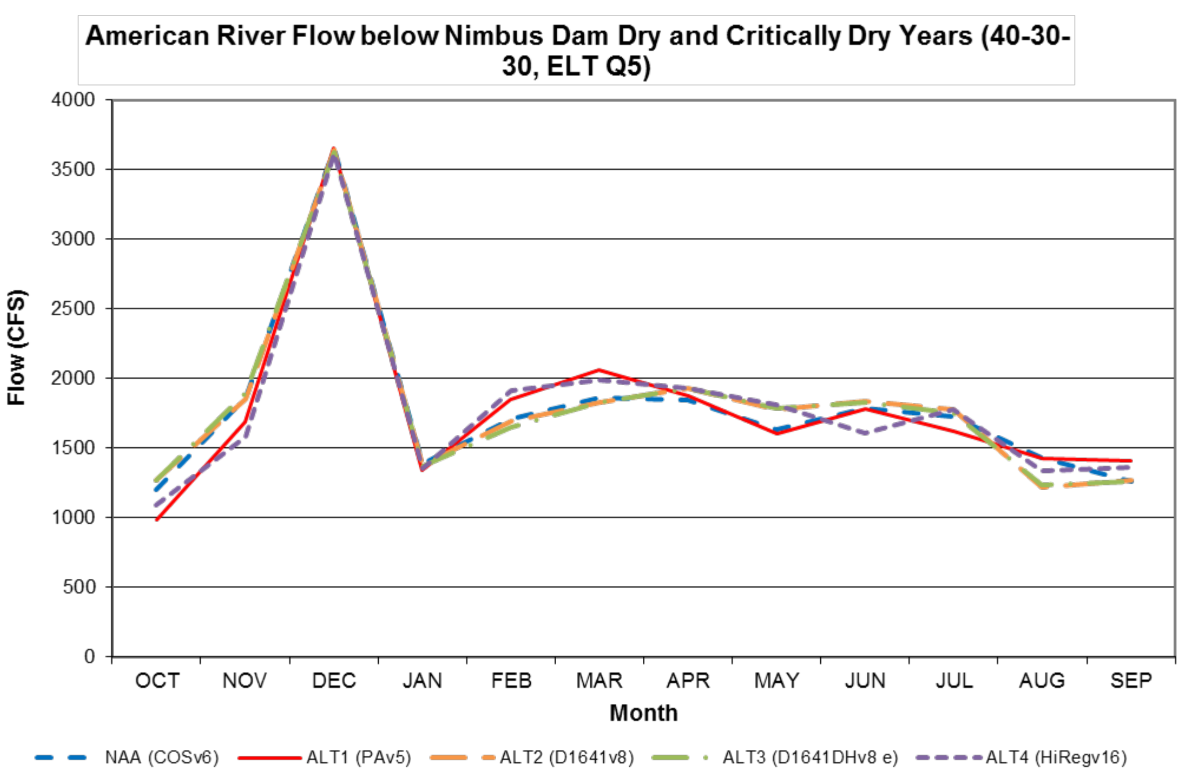

Figure O.3-60. Flows in the American River below Nimbus Dam in Dry and Critically Dry Years

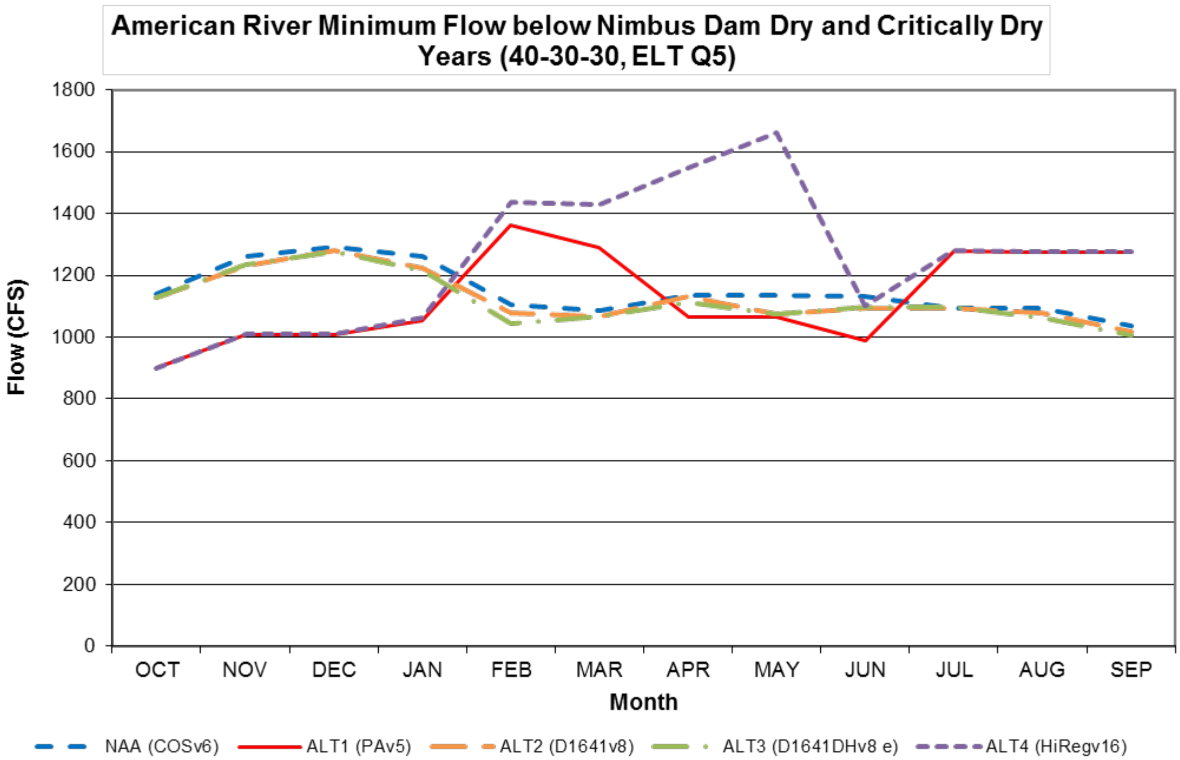

Figure O.3-61. Minimum Flows in the American River below Nimbus Dam in Dry and Critically Dry Years

Potential changes to aquatic resources in the American River due to changes in water temperature

The water temperature objectives for Alternative 1 are similar the objectives for the No Action Alternative. The objectives address the needs for Steelhead incubation and rearing during the late spring and summer, and for fall–run Chinook Salmon spawning and incubation starting in late October or early November. Specific additional objectives for Alternative 1 are to maintain a daily average water temperature of 65°F (or other temperature as determined by the temperature modeling) or lower at Watt Avenue Bridge from May 15 through October 31, to provide suitable conditions for juvenile Steelhead rearing in the lower American River, and to provide cold water for Fall-Run Chinook Salmon spawning. In addition, the proposed alternative shutter configurations at Folsom Dam to allow temperature flexibility as part of adaptive management may provide for additional improved water temperatures.

Average water temperatures are similar throughout the year in the lower American River under Alternative 1, compared to the No Action Alternative (Figure O.3-62). Differences in water temperatures are more a function of hydrologic conditions than operations to meet objectives, wither lower summer high temperatures wet years (Figure O.3-63) than in dry years (Figure O.3-64). Maximum water temperatures are lower for Alternative 1 in summer months in comparison to the No Action Alternative and the other action alternatives, which would beneficially affect fishery resources (Figure O.3-65).

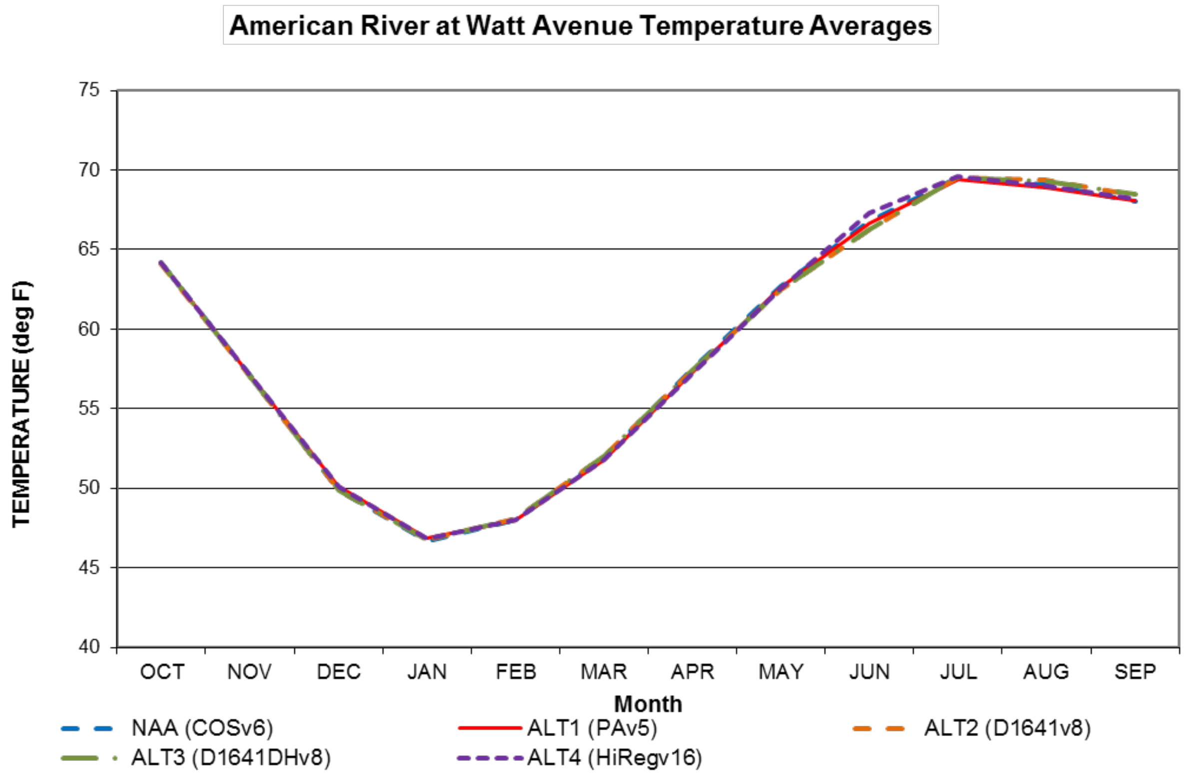

Figure O.3-62. Average Temperatures at Watt Avenue on the American River

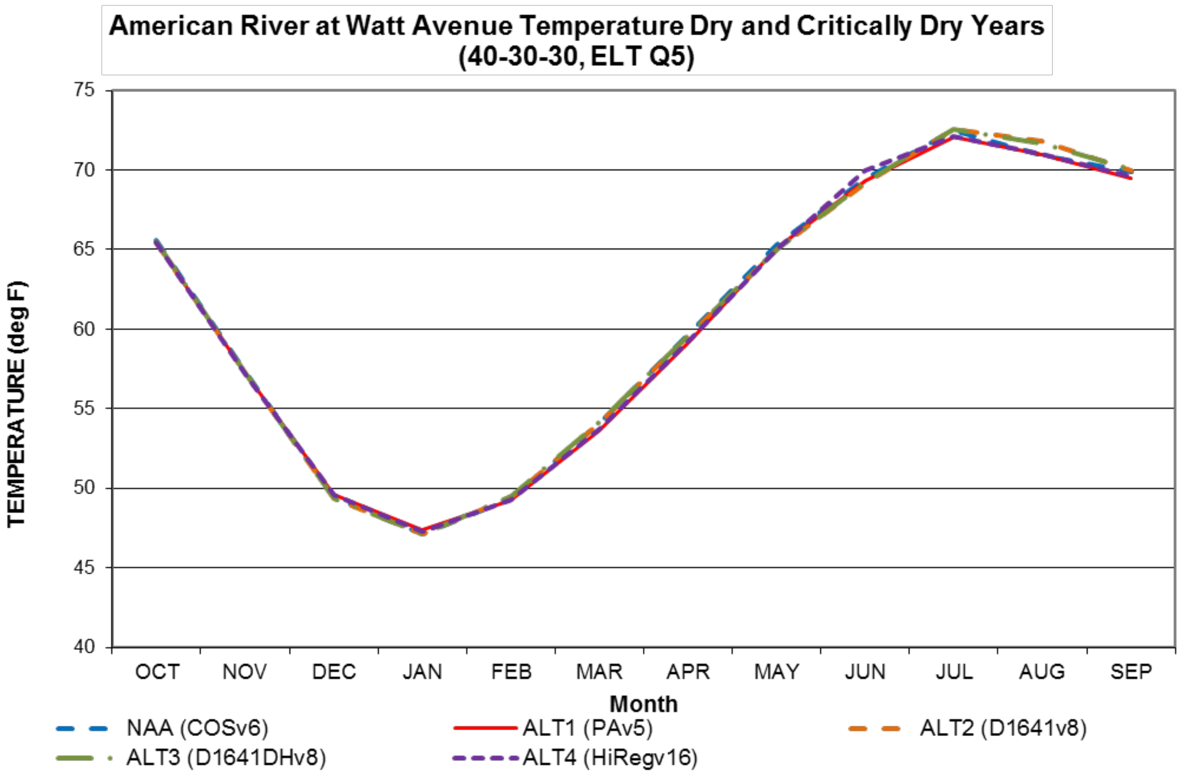

Figure O.3-63. Average Temperatures at Watt Avenue on the American River in Dry and Critically Dry Years

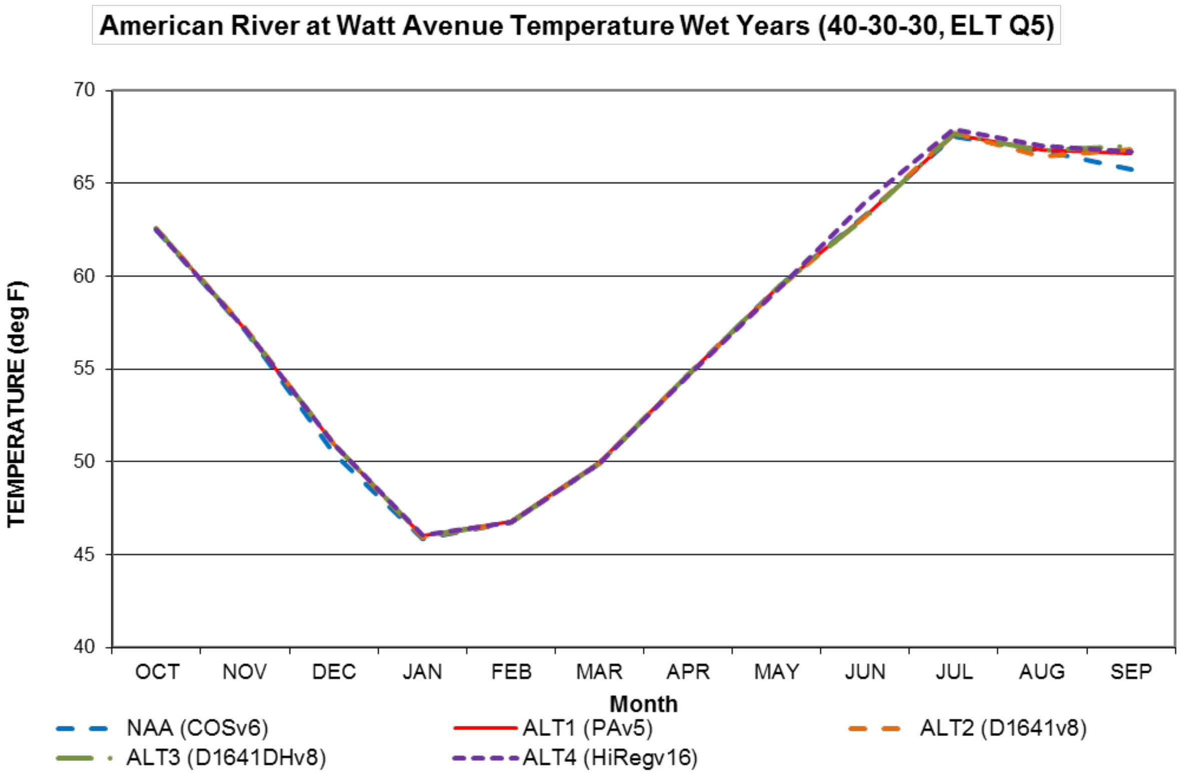

Figure O.3-64. Average Temperatures at Watt Avenue on the American River

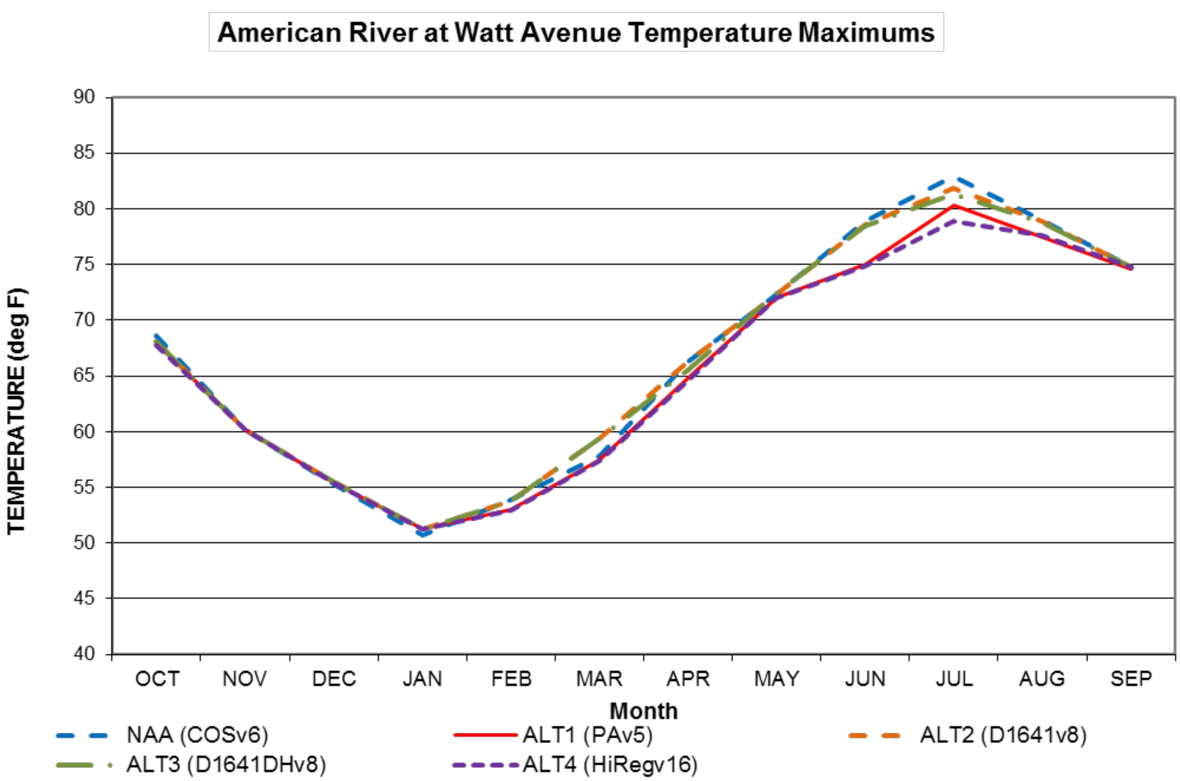

Figure O.3-65. Maximum Temperatures at Watt Avenue on the American River

Potential changes to aquatic resources in the American River from habitat restoration

Habitat for Chinook Salmon and Steelhead in the lower American River would be improved under Alternative 1, compared to the No Action Alternative. Alternative 1 includes implementation of spawning and rearing habitat projects in the American River and its tributaries. This action will likely result in long-term improvements to the habitat and conditions for Fall-Run Chinook Salmon, Steelhead, and other aquatic inhabitants. The spawning and rearing habitat projects would result in increased total spawning habitat area, increased and improved side channel habitat, improved intragravel incubation conditions, increased and improved total rearing habitat area, improved overall habitat complexity, and cover and refugia.

O.3.3.6 *Stanislaus River*

Potential changes to aquatic resources in the Stanislaus River due to changes in flow

Reclamation has several control points in the Stanislaus River to measure flow. Those control points are located at Goodwin Dam (below) and at mouth of Stanislaus River. Additionally, storage and releases are factored in at New Melones Reservoir.

Under Alternative 1, Reclamation would operate New Melones Reservoir (as measured at Goodwin Dam) in accordance with a Stepped Release Plan (SRP) that varies by hydrologic conditions/water year type as shown in Table O.3-22. The SRP would be implemented similarly to current operations under the 2009 BO RPA Action III.1.3 with a default daily hydrograph, and the ability to shape monthly and seasonal flow volumes to meet specific biological objectives. The SRP would be a sustainable operation on the Stanislaus River that strives to meet requirements for fish flows, temperature, water quality, dissolved oxygen, and water deliveries.

Table O.3-22. New Melones Stepped Release Plan—Annual Releases by Water Year Type

Water Year Type	Annual Release (TAF)
Critically Dry	184.3
Dry	233.3
Below Normal	344.6
Above Normal	344.6
Wet	476.3

Below Goodwin Dam

Under Alternative 1, flows are generally lower when compared to the No Action Alternative (Figures O.3-66 and O3-67.); however, the overall change to flows below Goodwin Dam are minor. Central Valley Steelhead, Fall- /Late Fall-Run Chinook Salmon, and Spring-Run Chinook Salmon would experience minor effects associated with the minor decrease in average flows. Flows under Alternative 1 are generally better for salmonids as water operations are similar to the No Action Alternative.

Additionally, under Alternative 1, spawning and rearing habitat restoration are proposed to offset effects related to changes in flow. Restoration activities for spawning and rearing habitat would yield immediate benefits. Existing riparian vegetation would be increased with the creation of side-channel habitat, providing instream object cover and overhanging object cover; new shaded riverine habitat; and additional area for food source. The creation of the side-channel and floodplain rearing habitat would also increase the aquatic habitat complexity and diversity within the Stanislaus River and provide additional predator escape cover. The habitat restoration would result in increased survival of juvenile salmonids in the Stanislaus River.

Mouth of Stanislaus River

Flows at the mouth of the Stanislaus River under Alternative 1 are similar to the below Goodwin Dam control point (Figures O.3-68 and O.3-69). Effects to salmonids are similar to those described above due to water operations being similar to the No Action Alternative.

Figure O.3-69. Average Monthly Flow at the Mouth of the Stanislaus River

Potential changes to aquatic resources in the Stanislaus River due to changes in water temperature

Under Alternative 1, Reclamation proposes to implement the New Melones SSRP to create a sustainable operation on the Stanislaus River that strives to meet requirements for fish flows, temperature, water quality, dissolved oxygen, and water deliveries. Managing the cold water at New Melones with the SRP will benefit Central Valley Steelhead, as well as aide in Reclamation meeting the temperature objects for the restoration of Central Valley Chinook Salmon. The temperature targets are include in Table O.3-23**.**

Table O.3-23. Temperature Objectives for the Restoration of Central Valley Chinook Salmon

Monthly Water Temperature Objectives for the San Joaquin River Restoration Program

Spring-Run and Fall-Run Chinook Salmon

Life Stage	Jan	Feb	Mar	Apr	May	June	Jul	Aug	Sep	Oct	Nov	Dec
Adult Migration			Optimal: ≤59°F (15°C) Critical: 62.6 – 68°F (17 – 20°C) Lethal: >68°F (20°C)									
Adult Holding (Spring-Run Only)				Optimal: ≤55°F (13°C) Critical: 62.6 – 68°F (17 – 20°C) Lethal: >68°F (20°C)								
Spawning								Optimal: ≤57°F (13.9°C) Critical: 60 – 62.6°F (15.5 – 17°C) Lethal: 62.6°F or greater (17°C)				
Incubation and Emergence								Optimal: ≤55°F (13°C) Critical: 58 – 60°F (14.4 – 15.6°C) Lethal: >60°F (15.6°C)				
In-River Fry/Juvenile	Optimal: ≤60°F (15.6°C), young of year rearing; ≤62.6°F (18°C), late season rearing (primarily spring-run) Critical: 64.4 – 70°F (18-21.1°C) Lethal: >75 °F (23.9°C), prolonged exposure											
Floodplain Rearing*	Optimal: 55 – 68°F (13 – 20°C), unlimited food supply											
Outmigration	Optimal: ≤60°F (15.6°C) Critical: 64.4 – 70°F (18 – 21.1°C) Lethal: >75°F (23.9°C), prolonged exposure

Note:

* Floodplain rearing temperatures represent growth maximizing temperatures based on floodplain condition. No critical or lethal temperatures are cited assuming fish have volitional access and egress from floodplain habitat to avoid unsuitable conditions.

Shaded box indicates life stage is present Key:

°F = degrees Fahrenheit

°C = degrees Celsius

Source: Conceptual Models of Stressors and Limiting Factors for San Joaquin River Chinook Salmon

As described earlier, Reclamation would implement the New Melones SRP similar to current operations with a default daily hydrograph, and the ability to shape monthly and seasonal flow volumes to meet specific biological objectives. The default daily hydrograph is the same as prescribed under current operations (No Action Alternative) for critically dry, dry, and below normal water year types; above normal and wet year types follow daily hydrographs for below normal and above normal year types respectively. As a result, flows would be reduced in above normal and wet year types. The difference between Alternative 1 and the No Action Alternative during above normal years and wet years, where the minimum release requirement for wetter year types is reduced from No Action Alternative to promote storage for potential future droughts and preserve coldwater pool, leads to improved coldwater pool performance in droughts, benefitting salmonid eggs.

The SRP under Alternative 1 would provide coldwater pool performance in droughts, but would reduce flow releases in above normal and wet years. This could result in less inundated rearing habitat, lower out-migration flows, and potentially warmer temperatures in some years, affecting rearing of outmigrating juvenile salmonids.

Under Alternative 1, storage at New Melones Dam is increased in comparison to No Action Alternative (Figures O.3-101 and O.3-102). The overall average increase in TAF benefits salmonids in the Stanislaus River by increasing coldwater pool available for flow management through warmer months. Recognizing that there is no ability for Reclamation to release water from different depths at New Melones, increased water depth above the static intake structure would function like a thermal cap, keeping the water below cooler. More cold water in New Melones Reservoir may lower water temperatures downstream of Goodwin Dam, even at relatively lower flow magnitudes, which would benefit salmonids in all life stages in the lower Stanislaus River.

Potential change to aquatic resources in the Stanislaus River due to changes to dissolved oxygen

Current operations are required to meet a year-round dissolved oxygen minimum of 7 mg/L, from June 1 to September 30 in the Stanislaus River at Ripon to protect salmon, Steelhead, and trout in the river (CDFW 2018a). Under Alternative 1, Reclamation proposes to move the compliance location to Orange Blossom Bridge, where the species are primarily located at that time of year (June through September). Without Alternative 1, there would be no water temperature management. Therefore, the proposed temperature compliance point is beneficial to the species, because the majority of salmonid eggs, alevin and/or fry are found in locations where summer dissolved oxygen levels would be expected to be maintained at or near 7 mg/L. However, based on the typical seasonal occurrence of this life stage in the river (July to October), adult migrating salmonids would be expected to be exposed to the effects of the relaxation of dissolved oxygen requirements at Ripon. During low flow periods in the Stanislaus River there could be delay of adults migrating up the Stanislaus River if dissolved oxygen is too low.

O.3.3.7 *San Joaquin River*

Effects would be expected to be similar under Alternative 1 to the potential effects as previously described for the No Action Alternative. A full description of potential effects are described in Section O.3.2.7.

O.3.3.8 *Bay-Delta*

O.3.3.8.1 <u>Delta Smelt</u>

Potential changes to Delta Smelt due to seasonal operations

Seasonal operations under Alternative 1 would change the frequency of the low salinity zone being located within the productive habitat of Suisun Marsh and bay during some seasons, relative to the No Action Alternative. As described in more detail in the ROC LTO BA, seasonal operations have the potential to affect various habitat attributes hypothesized to be important to Delta Smelt, including predation risk, food availability, harmful algal blooms, and size and location of the low salinity zone. These are discussed in turn in the paragraphs below.

As described in the ROC LTO BA, flows entering the Delta have the potential to affect Delta Smelt predation risk through effects on sediment delivery and turbidity. There would be expected to be little difference in this habitat attribute between Alternative 1 and the No Action Alternative given the similarity in CalSim-modeled flows in the Sacramento River at Rio Vista (e.g., Appendix E, Attachment 3-2, Figures 32-9 through 32-14), particularly during the high-flow portion of the year when most sediment is delivered to the Delta. As described in the ROC LTO BA, predation risk on Delta Smelt eggs/larvae is hypothesized to largely be a result of Silversides, and Silverside abundance is negatively correlated with June–September Delta inflow and March–May south Delta exports. Under Alternative 1, March–May south Delta exports would be greater compared to the No Action Alternative (Appendix E, Attachment 3-3, Figures 53-12 through 53-14), which would tend to suggest the potential for lower abundance of Silversides under Alternative 1 compared to the No Action Alternative. In contrast, June–September Delta inflow (Freeport + Vernalis + Yolo + Mokelumne flows) under Alternative 1 is generally similar to the No Action Alternative, except for September in wet and above normal years when the inclusion of the USFWS (2008) BO RPA for fall X2 under the No Action Alternative results in greater Freeport flow and therefore total inflow compared to Alternative 1 (Appendix E, Attachment 3-2, Figures 29-15 through 29-18), potentially resulting in greater abundance of Silversides under Alternative 1 compared to the No Action Alternative. The extent to which the opposing effects of differences in exports and inflow could affect Silverside abundance under Alternative 1 is uncertain, particularly given that the relationships are correlations and do not necessarily imply causality and require further investigation (Reclamation 2019). As discussed in the ROC LTO BA, predation risk for subadult Delta Smelt could increase under Alternative 1 relative to the No Action Alternative as a result of less overlap of the low salinity zone with more turbid areas (see additional discussion regarding area and extent of the low salinity zone below), but seasonal operations would not be expected to affect temperature to the point that predation risk is influenced by Alternative 1 (which is true for all Delta Smelt life stages). The ROC LTO BA summarizes studies suggesting that the age-0 abundance of another Delta Smelt predator, Striped Bass, is positively correlated to fall Delta outflow (negative correlation with X2), but a potential reduction in Striped Bass abundance because of less fall outflow under Alternative 1 compared to the No Action Alternative is uncertain because of the relatively low correspondence between abundance trends for age 0 and age 1 Striped Bass and apparent density dependence between ages 1 and 2.

Various aspects of seasonal operations have the potential to affect Delta Smelt food availability. For adult Delta Smelt, flooding of Yolo Bypass in winter/spring could affect food availability (Reclamation 20198). However, CalSim modeling suggests little difference in Yolo Bypass flows between Alternative 1 and the No Action Alternative (Appendix E, Attachment 3-2, Figures 25-6 through 25-18). For larval Delta Smelt, the ROC LTO BA (notes a positive correlation between spring Delta outflow and the Delta Smelt zooplankton prey *Eurytemora affinis* (i.e., a negative correlation with March to May X2). CalSim modeling indicates that there would be somewhat less spring Delta outflow under Alternative 1 compared to the No Action Alternative and therefore somewhat greater X2 (see Appendix E, Attachment 3-2, Figures 41-12 through 41-14; Attachment 3-7, Figures 45-9 through 45-11 of the ROC LTO BA), with the potential effect of reducing *E. affinis* abundance under Alternative 1 compared to the No Action Alternative. As noted in the ROC LTO BA, there is uncertainty in the predictive relationship between X2 and *E. affinis* abundance, and Alternative 1 includes completion of the remainder of the 8,000 acres of restoration to offset potentially negative effects on Delta Smelt prey, as well as other potentially beneficial actions for Delta Smelt food availability as described elsewhere in this analysis (see sections discussing *Potential changes to Delta Smelt from food subsidies (Sacramento Deepwater Ship Channel Food Study; North Delta Food Subsidies/Colusa Basin Drain Study; Suisun Marsh Roaring River Distribution System Food Subsidies Study*). For Delta Smelt juveniles in summer/early fall (July–September), the ROC LTO BA noted the positive correlation between Delta outflow and the subsidy of the Delta Smelt zooplankton prey *Pseudodiaptomus forbesi* to the low salinity zone, with flows in the lower San Joaquin River potentially being of importance given the higher density of *P. forbesi* there. DSM2-HYDRO modeling suggests that the percentage of years with net negative lower San Joaquin River flows would be similar in July (~32% for Alternative 1 vs. ~37% for No Action Alternative) and August (~60% for Alternative 1 vs. 58% for No Action Alternative) (Figures O.3-70 and O.3-71), whereas in September, the frequency of net negative flows would be greater under Alternative 1 (51% of years) than the No Action Alternative (35% of years) (Figure O.3-72); therefore there may be less potential for transport of *P. forbesi* to the low salinity zone under Alternative 1 compared to the No Action Alternative in September. As previously noted, various potentially beneficial actions are included in Alternative 1 to provide benefit to Delta Smelt food availability, thereby potentially offsetting this potentially negative effect. For subadult Delta Smelt in fall (September–December), the ROC LTO BA notes that while the same *P. forbesi* subsidy effect would apply as discussed for juvenile Delta Smelt, there was no evidence for a correlation between overall calanoid copepod zooplankton prey and Delta outflow (X2) based on a recent analysis, so the negative effects under Alternative 1 relative to No Action Alternative may be limited to *P. forbesi* subsidy during September.

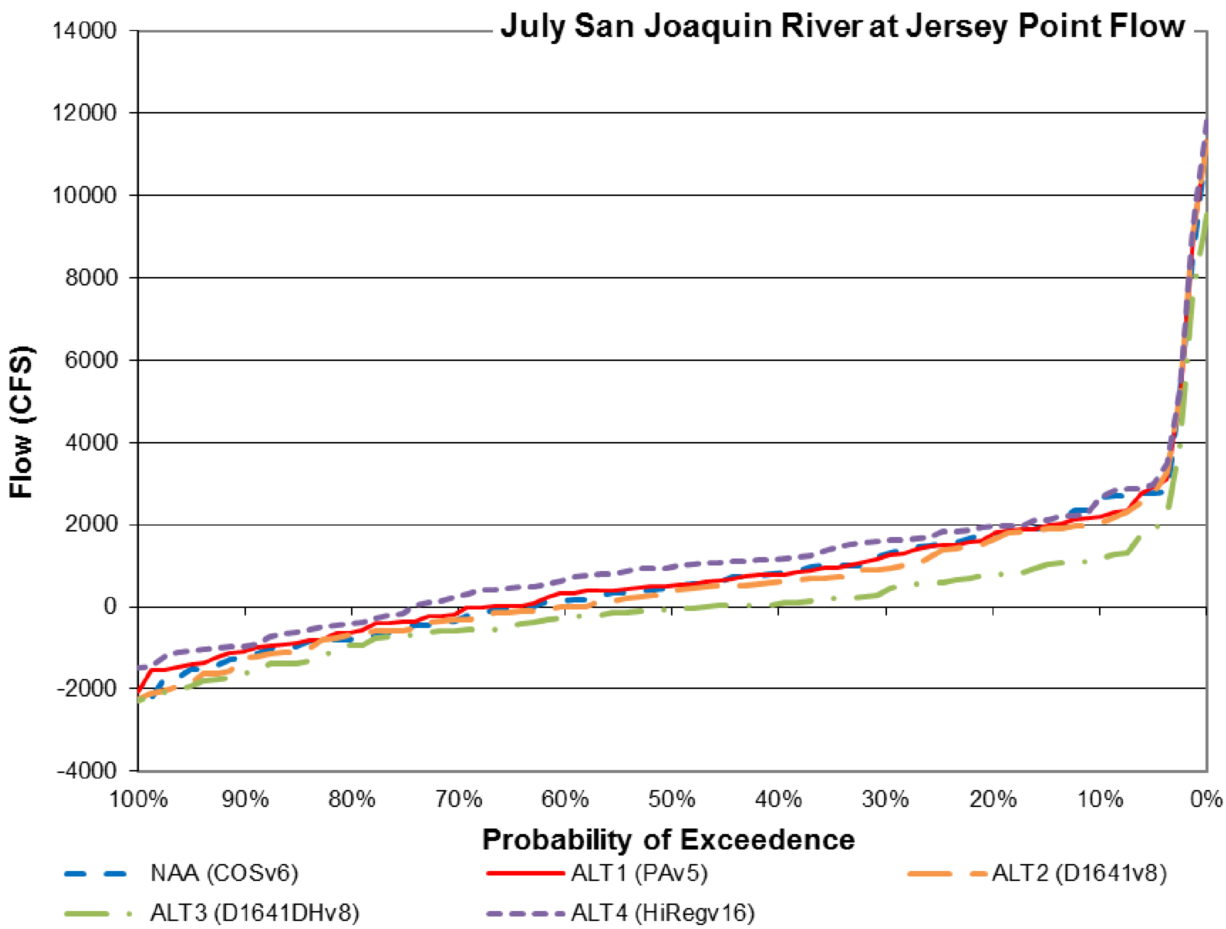

Figure O.3-70. DSM2-HYDRO-Modeled Probability of Exceedance of San Joaquin River Flow at Jersey Point, July

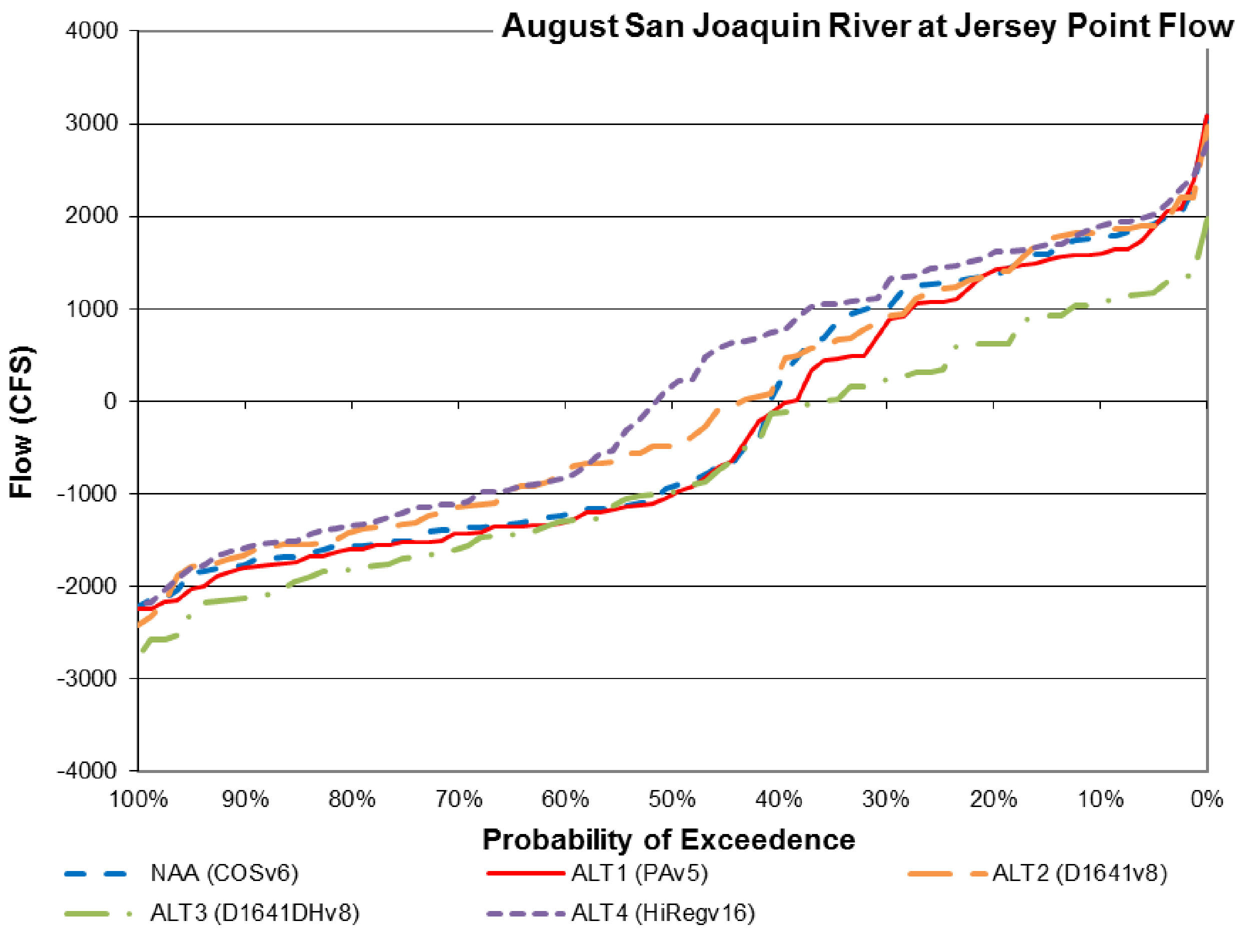

Figure O.3-71. DSM2-HYDRO-Modeled Probability of Exceedance of San Joaquin River Flow at Jersey Point, August

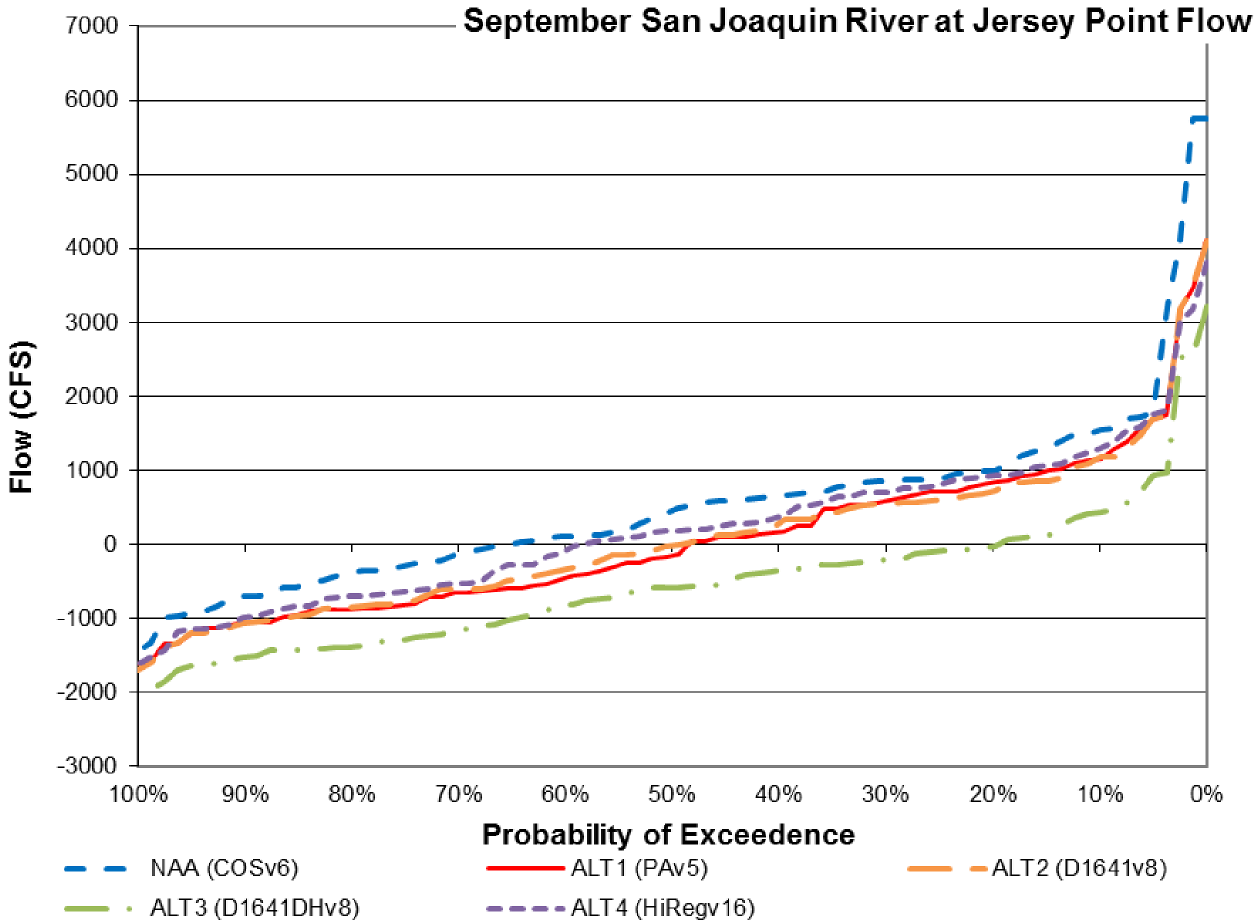

Figure O.3-72. DSM2-HYDRO-Modeled Probability of Exceedance of San Joaquin River Flow at Jersey Point, September

As described in the ROC LTO BA, the size and location of the low salinity zone is hypothesized to affect subadult Delta Smelt abundance, survival, and growth, although evidence is mixed and additional investigations are thought to be needed to provide further support. On the basis of modeled X2, Alternative 1 would be expected to appreciably reduce the size of the low salinity zone in September–November of wet and above normal years compared to the No Action Alternative, as a result of Alternative 1 not including the USFWS (2008) BO RPA fall X2 action: applying the methods from the ROC LTO BA, the area of the low salinity zone would be similar under Alternative 1 and the No Action Alternative in critical, dry, and below normal years (i.e., ~50–100% exceedance), whereas in above normal (~30–50% exceedance) and in particular wet years (i.e., ~0–30% exceedance) the area of the low salinity zone would be considerably lower under Alternative 1 compared to the No Action Alternative (Figures O.3-73, O.3-74, and O.3-75). As discussed in the ROC LTO BA, the percentage of time that X2 is ≥ 85 km is an indicator of how often the low salinity zone rearing habitat is outside of Suisun Bay, important Delta Smelt rearing habitat. Modeling suggests that in June–August, there would be little difference between Alternative 1 and the No Action Alternative in the percentage of time that X2 is ≥ 85 km, whereas in September–December, X2 would be ≥ 85 km considerably more of the time under Alternative 1 than the No Action Alternative (Figure O.3-76). Collectively, modeling of the area of low salinity zone habitat and the percentage of years with X2 ≥ 85 km thus suggest the potential for negative effects to Delta Smelt juveniles/subadults under Alternative 1 relative to the No Action Alternative, based on the hypothesized importance of these factors. However, the Delta Smelt Habitat conservation measure analyzed below in *Potential changes to Delta Smelt from actions for Delta Smelt summer-fall habitat* would aim to meet several environmental and biological goals for Delta Smelt. The modeling discussed herein does not include representation of habitat operations components. In addition, to the extent that tidal restoration (i.e., the completion of the remaining acreage as part of 8,000 acres of tidal habitat restoration) provides new low salinity zone habitat that is occupied by rearing Delta Smelt, this could provide some offsetting of potential reductions in the size and area of the low salinity zone resulting from operations.

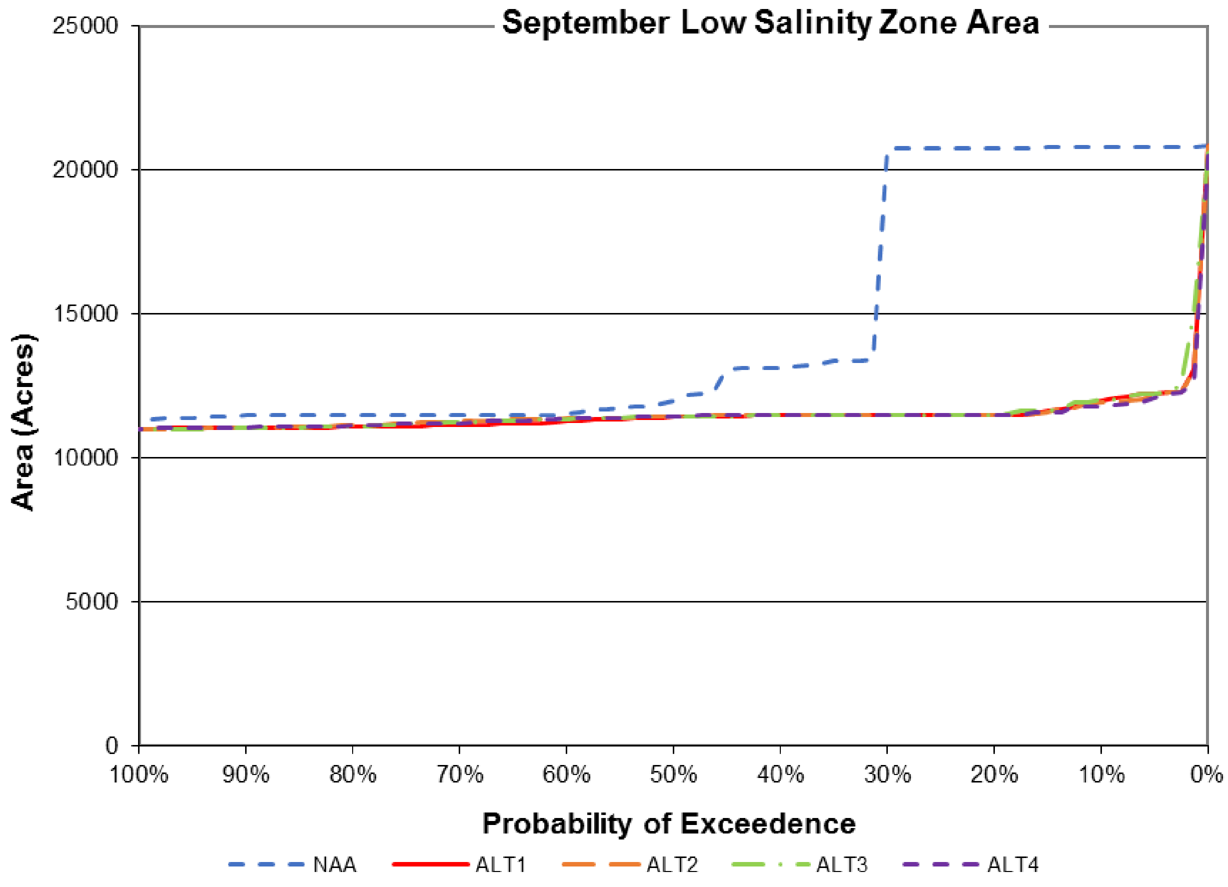

Figure O.3-73. Low Salinity Zone Area Estimated from CalSim X2, September

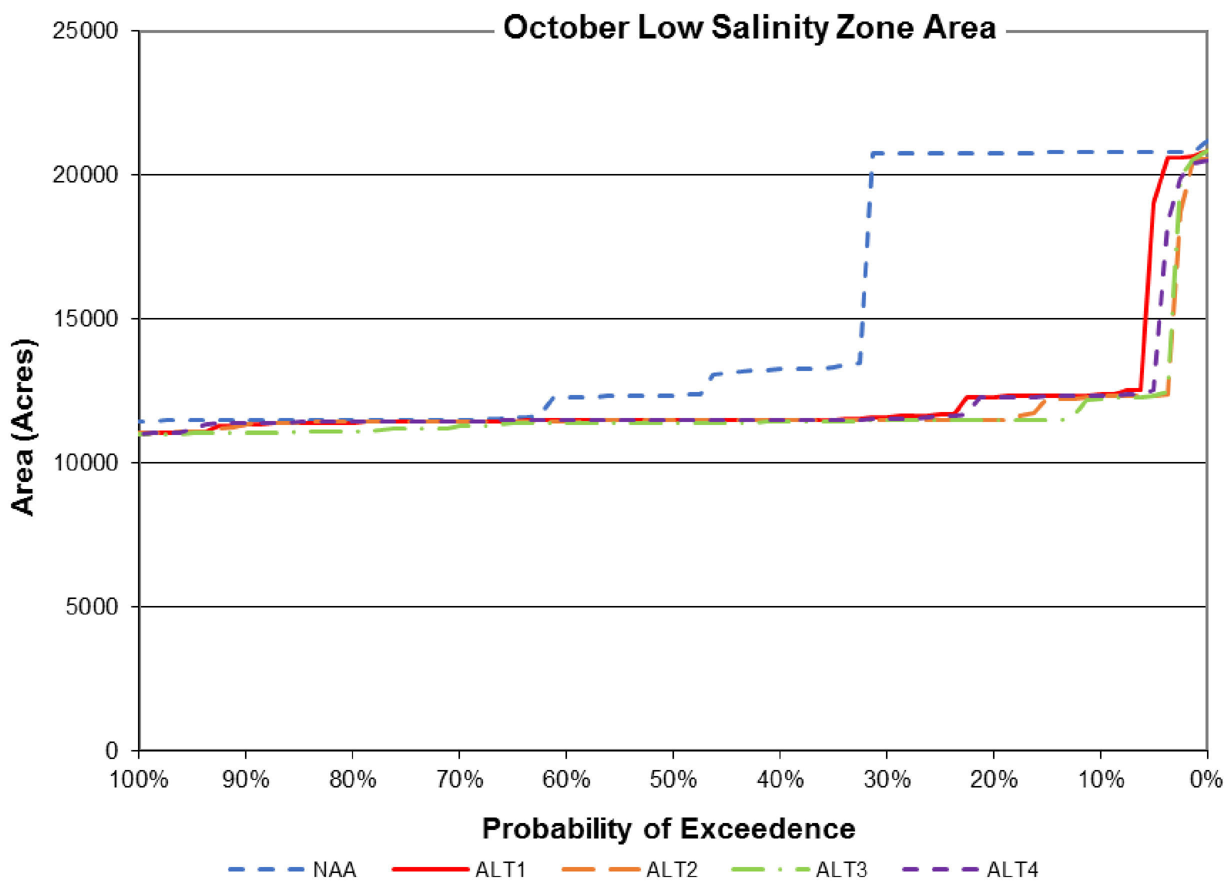

Figure O.3-74. Low Salinity Zone Area Estimated from CalSim X2, October

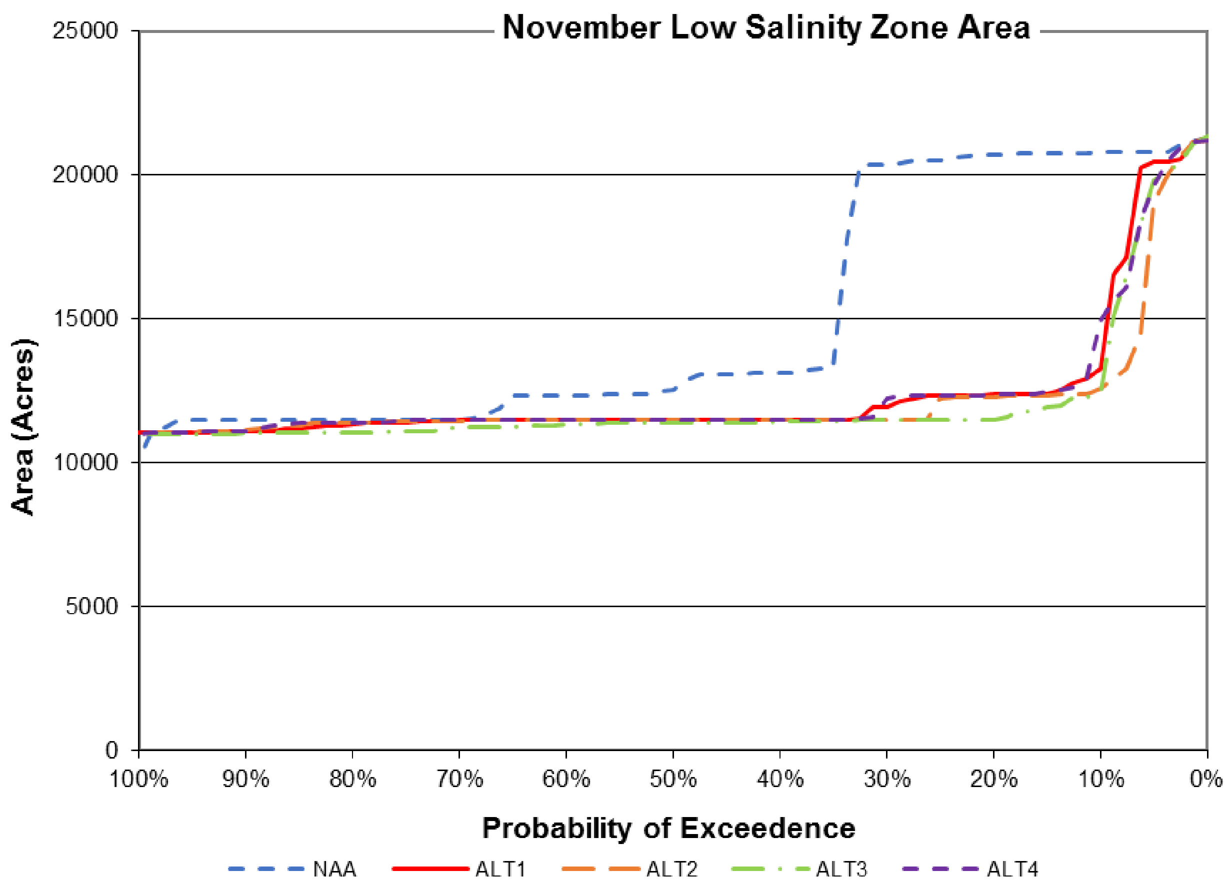

Figure O.3-75. Low Salinity Zone Area Estimated from CalSim X2, November

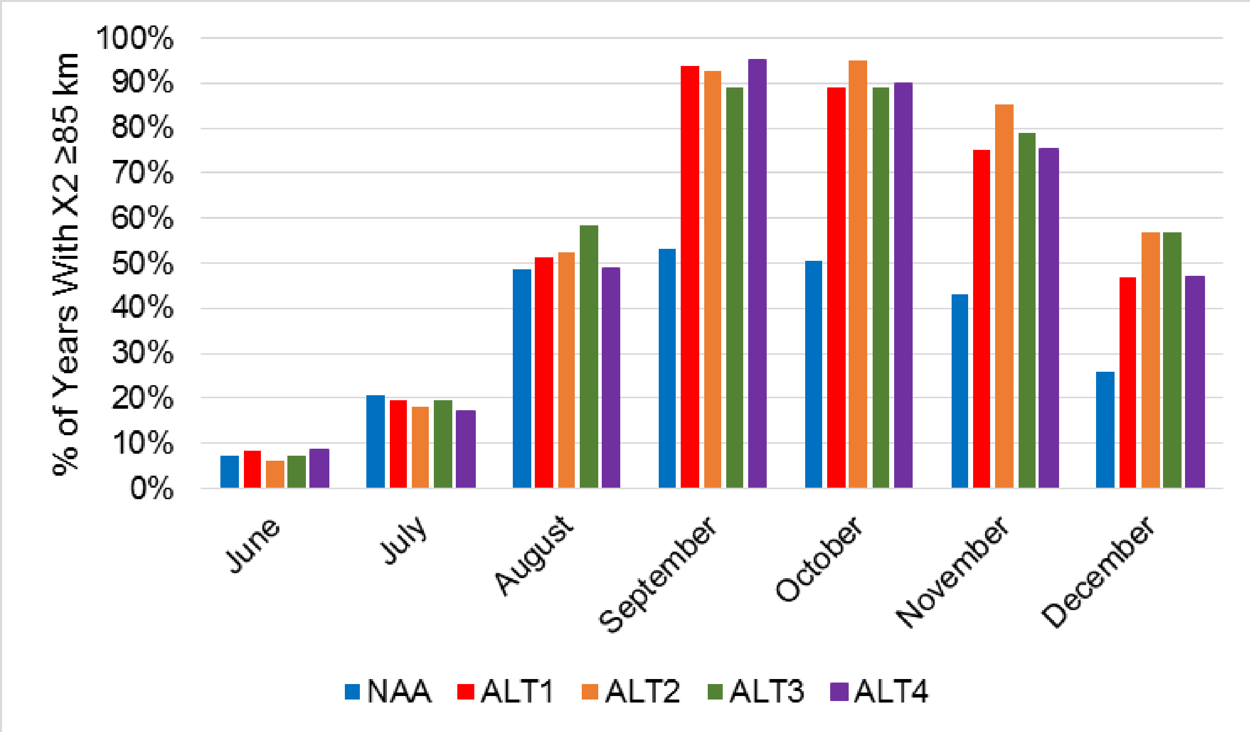

Figure O.3-76. Percentage of Years with Mean X2 ≥ 85 km, June–December

As discussed in the ROC LTO BA, water operations potentially could affect harmful algal blooms (*Microcystis*) and therefore Delta Smelt or Delta Smelt prey. However, as shown in the ROC LTO BA, there is little difference in modeled velocity (a potential indicator of harmful algal bloom disruption) between Alternative 1 (represented by the PA scenario) and the No Action Alternative (represented by the COS scenario) (see Figures 5.16-19 through 5.16-26 of the ROC LTO BA). This suggests that there would be little difference in harmful algal bloom potential between Alternative 1 and the No Action Alternative.

Potential changes to Delta Smelt due to OMR management

As described in more detail in the analysis of OMR Management in the ROC LTO BA, Delta Smelt entrainment risk is a function of water diversions, hydrology, and turbidity. During the main period of adult Delta Smelt entrainment risk (December–March), CalSim modeling suggests that OMR flows would generally be similar or slightly lower under Alternative 1 compared to the No Action Alternative (see Appendix F, Attachment 3-2, Figures 40-9 through 40-12 of the ROC LTO BA). In March–June, the larval/early juvenile Delta Smelt entrainment risk period, the modeled OMR flows suggest that the difference between Alternative 1 and the No Action Alternative would be greater. However, Alternative 1 includes protective criteria as described in more detail in Section 4.3.6.5, *OMR Management* of Appendix D. These criteria, including real-time adjustments to operations in response to physical and biological criteria, would be expected to limit entrainment risk of Delta Smelt from Alternative 1.

Potential changes to Delta Smelt due to changes in Delta Cross Channel operations

As noted in the ROC LTO BA, it is unknown what if any direct impacts occur to Delta Smelt from opening or closing the DCC gates, and there is limited occurrence of Delta Smelt near the DCC. DCC operations under Alternative 1 would differ somewhat compared to the No Action Alternative (Section 4.3.6.1, *Delta Cross Channel* of Appendix D), although the extent to which this would give effects on Delta Smelt is unclear; factors such as entrainment risk in the south Delta would be considered when operating the DCC, to limit potential negative effects.

Potential changes in Delta Smelt survival related to the Temporary Barriers Project

Under Alternative 1, potential effects of the three south Delta agricultural barriers on Delta Smelt would be expected to be similar to the effects under the No Action Alternative (i.e., near-field predation and potential effects on transport of *P. forbesi* to the low salinity zone; see also ROC LTO BA). Relative to the No Action Alternative, Alternative 1 would not include the spring HOR barrier, so any effects (near-field predation, far-field hydraulic effects) that would occur under the No Action Alternative would not occur under Alternative 1. However, given the low presence of Delta Smelt near the HOR barrier and the fact that far-field hydraulic effects would be factored into entrainment risk as part of OMR management, there may be little difference in effects to Delta Smelt between the No Action Alternative and Alternative 1.

Potential changes to Delta Smelt from Contra Costa Water District operations

Contra Costa Water District operations would not differ between Alternative 1 and the No Action Alternative, so the effects to Delta Smelt would be expected to be similar under Alternative 1 as the No Action Alternative, i.e., negligible entrainment and hydrodynamic effects (Reclamation 2019).

Potential changes to Delta Smelt from North Bay Aqueduct operations

North Bay Aqueduct Barker Slough Pumping Plant operations would not differ between Alternative 1 and the No Action Alternative, so the effects to Delta Smelt would be expected to be similar under Alternative 1 as the No Action Alternative, i.e., potential entrainment, impingement, near-field predation, and entrainment of Delta Smelt food, which could have limited effects on Delta Smelt given low occurrence in the vicinity of the Barker Slough Pumping Plant (Reclamation 2019). Alternative 1 also includes sediment removal with a suction dredge that could entrain Delta Smelt individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Delta Smelt occurring near the removal; given the lack of Delta Smelt association with vegetation (Ferrari et al. 2014), Delta Smelt would not be expected to be occurring close to vegetation removal. At the broader scale, effects from both sediment removal and aquatic weed removal in any case would be expected to be limited given the low occurrence in the vicinity of the Barker Slough Pumping Plant, as previously noted for operational effects.

Potential changes to Delta Smelt from water transfers

Alternative 1 includes an expanded transfer window (July to November) relative to the No Action Alternative (July to September). As described in the ROC LTO BA, the expanded window generally does not overlap the presence of Delta Smelt in the south Delta, but there could be potential exposure of an occasional Delta Smelt to increased pumping from water transfers, resulting in entrainment or predation risk. However, entrainment would be limited as discussed in the analysis of *Potential changes to Delta Smelt due to OMR management*.

Potential changes to Delta Smelt from Clifton Court aquatic weed and algal bloom management

As described in Section 4.3.6.5, *Clifton Court Aquatic Weed and Algal Bloom Management,* of Appendix D, under Alternative 1 Clifton Court aquatic weed removal efforts may be expanded relative to the No

Action Alternative by including additional herbicides and the treatment period. However, given the low occurrence of Delta Smelt during the principal period of application, as well as various protective measures to limit potential effects such as salvage monitoring for presence of listed fishes including Delta Smelt, aquatic weed removal and algal bloom management in Clifton Court would be expected to have minimal effects on Delta Smelt. As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to Delta Smelt due to changes from Tracy and Skinner fish facilities

Tracy and Skinner Fish Facility operations under Alternative 1 would remain largely the same as the No Action Alternative, except for installation of a carbon dioxide injection device to allow remote controlled anesthetization of predators in the secondary channels of the Tracy facility (see Section 4.3.6.6, *Tracy Fish Collection Facility Carbon Dioxide Injection and Release Sites* in Appendix D). As described in the ROC LTO BA, this has the potential to increase salvage efficiency of adult Delta Smelt at the Tracy facility. Such effects would be expected to be limited given that OMR management would be undertaken to limit the potential for occurrence of Delta Smelt in the south Delta.

Potential changes to Delta Smelt due to changes from Suisun Marsh facilities

Aside from changes to Suisun Marsh Salinity Control Gates operations (discussed below in *Potential changes to Delta Smelt from actions for Delta Smelt summer-fall habitat*), project-level operations of the Suisun Marsh facilities would remain the same as the No Action Alternative (there may be changes to RRDS and other facility operations, as part of the food subsidy actions included in Delta Smelt summer-fall habitat operations). The potential effects of the Suisun Marsh facilities on Delta Smelt are described in more detail in the ROC LTO BA, which notes risk from factors such as entrainment is limited.

Potential changes to Delta Smelt from actions for Delta Smelt summer-fall habitat

Alternative 1 includes structured decision making by DWR and Reclamation to identify and use a variety of actions to achieve various environmental and biological goals for Delta Smelt summer-fall habitat (see Section 4.3.6.8, *Delta Smelt Summer-Fall Habitat*, of Appendix D). Summer and fall management of salinity, potentially including operation of the Suisun Marsh Salinity Control Gates for up to 60 days and Delta outflow to maintain contiguous low salinity habitat from Suisun Marsh upstream to the Cache Slough Complex, would aim to improve Delta Smelt food supply and habitat, thereby contributing to the recruitment, growth, and survival of Delta Smelt. Relative to the No Action Alternative, this conservation measure has the potential to improve habitat, from the perspective of salinity-driven conditions, during the summer, whereas in fall there could be a lesser extent of low salinity zone habitat than otherwise would occur under the No Action Alternative with implementation of the USFWS (2008) fall X2 action. However, the extent to which this would be a negative effect may depend on other aspects included in the action, particularly food subsidy actions in the North Delta/Colusa Basin Drain, Sacramento Deepwater Ship Channel, and Suisun Marsh/RRDS (see discussion in *Potential changes to Delta Smelt from food subsidies (Sacramento Deepwater Ship Channel Food Study; North Delta Food Subsidies/ Colusa Basin Drain Study; Suisun Marsh Roaring River Distribution System Food Subsidies Study).* These food subsidy actions may provide Delta Smelt with additional food relative to the No Action Alternative. If the summer-fall Delta Smelt habitat operations action includes operations of the SMSCG or a fall X2 action, the difference in Delta outflow and X2 between Alternative 1 and the No Action Alternative would tend to be less than suggested by the CalSim modeling described above in *Potential changes to Delta Smelt due to seasonal operations.* The CalSim modeling for Alternative 1 **suggests** potential negative effects relative to the No Action Alternative, as previously described in more detail in *Potential changes to Delta Smelt due to seasonal operations*. In years with the summer or fall Delta Smelt habitat operation actions, the potential negative effects would be less than indicated in the Alternative 1 modeling.

Potential changes to Delta Smelt from the San Joaquin Basin Steelhead Telemetry Study

The San Joaquin Steelhead telemetry study would not affect Delta Smelt as it would be primarily in the San Joaquin River upstream of the areas where Delta Smelt occur, and also does not involve trapping or other mechanisms to affect Delta Smelt of any life stage (Reclamation 2019).

Potential changes to Delta Smelt due to reintroduction by the Fish Conservation and Culture Laboratory

Under Alternative 1, development and successful implementation of a supplementation strategy by the Fish Conservation and Culture Laboratory (see Section 4.3.6.11, *Intervention Components,* of Appendix D) would have the potential to benefit Delta Smelt, given the production capacity and apparent low population numbers (Reclamation 2019). Potential negative effects such as propagation and spread of nuisance species are generally similar to those that could occur at the proposed Delta Fish Species Conservation Hatchery (see ROC LTO BA), and would be limited through risk management strategies.

O.3.3.8.2 Longfin Smelt

Potential changes to Longfin Smelt due to seasonal operations

The principal potential effect of seasonal operations on Longfin Smelt would be changes in population abundance as a result of changes in Delta outflow. Several analyses have correlated Longfin Smelt indices of abundance with Delta outflow or X2 as a proxy for Delta outflow (e.g., Kimmerer et al. 2009; Nobriga and Rosenfield 2016). During the December–May period identified as important for Delta outflow by Nobriga and Rosenfield (2016), CalSim modeling suggests that under Alternative 1 Delta outflow would be similar or somewhat greater than No Action Alternative in December, generally similar in January–March, and less by several hundred to several thousand cfs in April and May (Appendix F, Attachment 3-2, Figures 41-9 through 41-14). Under Alternative 1, the negative differences in April/May have the potential to negatively affect Longfin Smelt through reductions in population abundance. However, the magnitude of the difference may be limited because of density-dependent effects (Nobriga and Rosenfield 2016), there is appreciable (several orders of magnitude) variability in the estimates generated by the Nobriga and Rosenfield (2016) model, and other analyses have found stronger correlations with general hydrological conditions rather than Delta outflow specifically (Maunder et al. 2015). As described for the No Action Alternative, completion of the 8,000 acres of tidal habitat restoration would have the potential to provide positive effects to Longfin Smelt larvae in the north Delta and therefore provide some offsetting of potential negative effects from seasonal operations, although this offsetting may be limited because Longfin Smelt would tend to be more downstream of restored areas than Delta Smelt, for which the restoration is primarily intended.

Potential changes to Longfin Smelt due to OMR management

Alternative 1 proposes OMR management focused on federally listed species, although Longfin Smelt could receive some protection from these measures as well. During the December–March period of adult Longfin Smelt vulnerability to south Delta entrainment, CalSim modeling suggests that OMR flows generally would be similar or somewhat less under Alternative 1 compared to the No Action Alternative (Appendix F, Attachment 3-2, Figures 40-9 through 40-12). January–March represents the main period of larval vulnerability to south Delta entrainment, and during this time DSM2-HYDRO modeling of the flow in the lower San Joaquin River at Jersey Point (an indicator of entrainment risk into the south Delta) suggests that south Delta larval entrainment risk would be similar (January and March) or somewhat greater (February) under Alternative 1 compared to the No Action Alternative (Figures O.3-77 through O.3-79). During the principal period of juvenile Longfin Smelt south Delta entrainment vulnerability (April–May), CalSim modeling suggests that OMR flows under Alternative 1 would be appreciably less than under the No Action Alternative, although generally greater than -4,000 cfs (Appendix F, Attachment 3-2, Figures 40-13 and 40-14). Overall, the modeling for Alternative 1 suggests that Longfin Smelt south Delta entrainment risk would be greater than under the No Action Alternative. However, it should be borne in mind that the modeling does not reflect continued adherence to the criteria of the CDFG (2009) SWP ITP, nor to any subsequent ITP that may govern Longfin Smelt south Delta entrainment protection. In addition, while entrainment risk may be relatively greater under Alternative 1 compared to the No Action Alternative, estimates of Longfin Smelt population-level entrainment loss during the D-1641-based regulatory period (i.e., prior to 2007, and what is included under Alternatives 2 and 3) suggest that low percentages (0–3.6%) of Longfin Smelt were lost to entrainment (ICF International 2016, Table 4.2-10 [p. 4-286] and Table 4.2-11 [p. 4-288]). This suggests that Longfin Smelt proportional entrainment loss under Alternative 1 would also be limited.

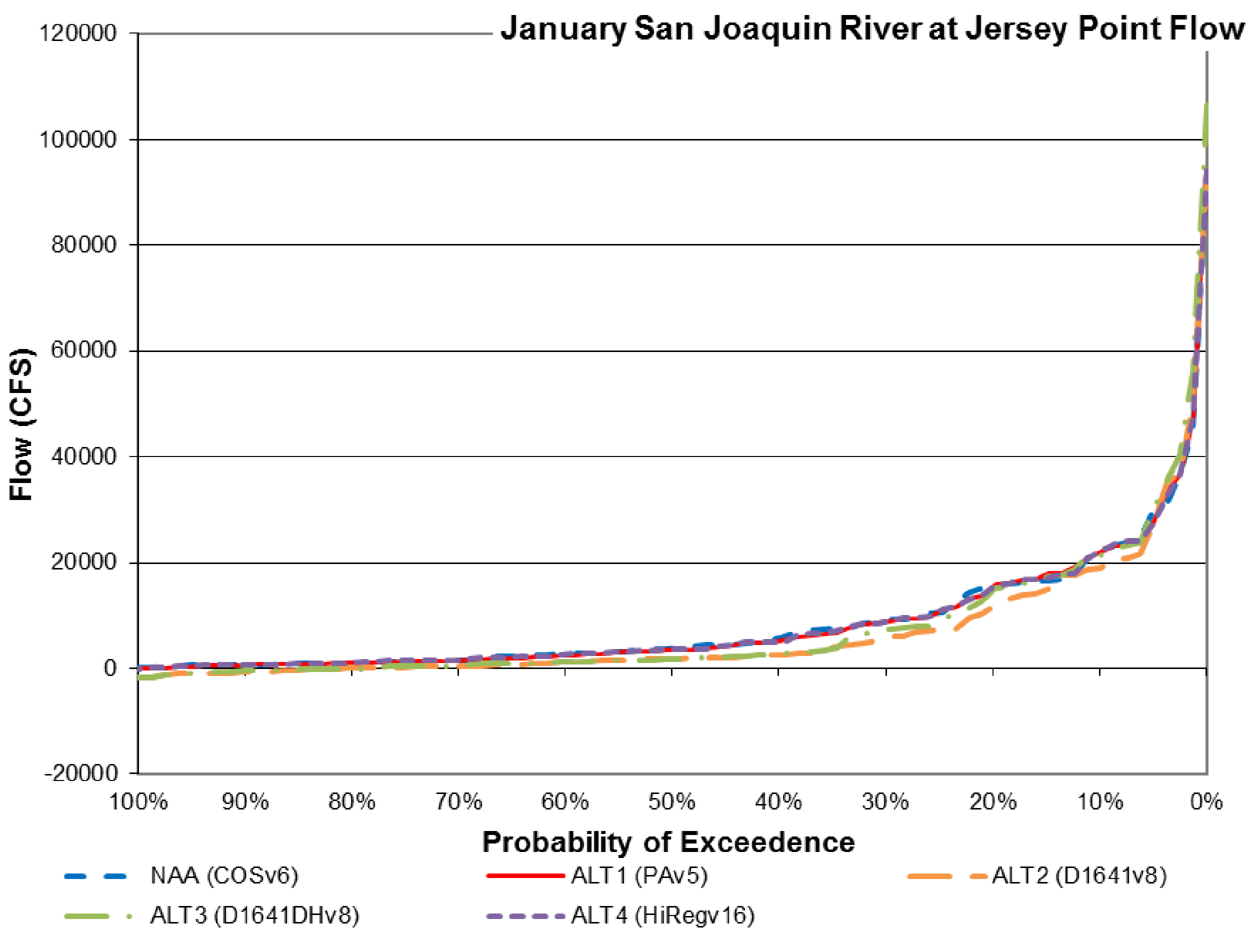

Figure O.3-77. DSM2-HYDRO-Modeled Probability of Exceedance of San Joaquin River Flow at Jersey Point, January

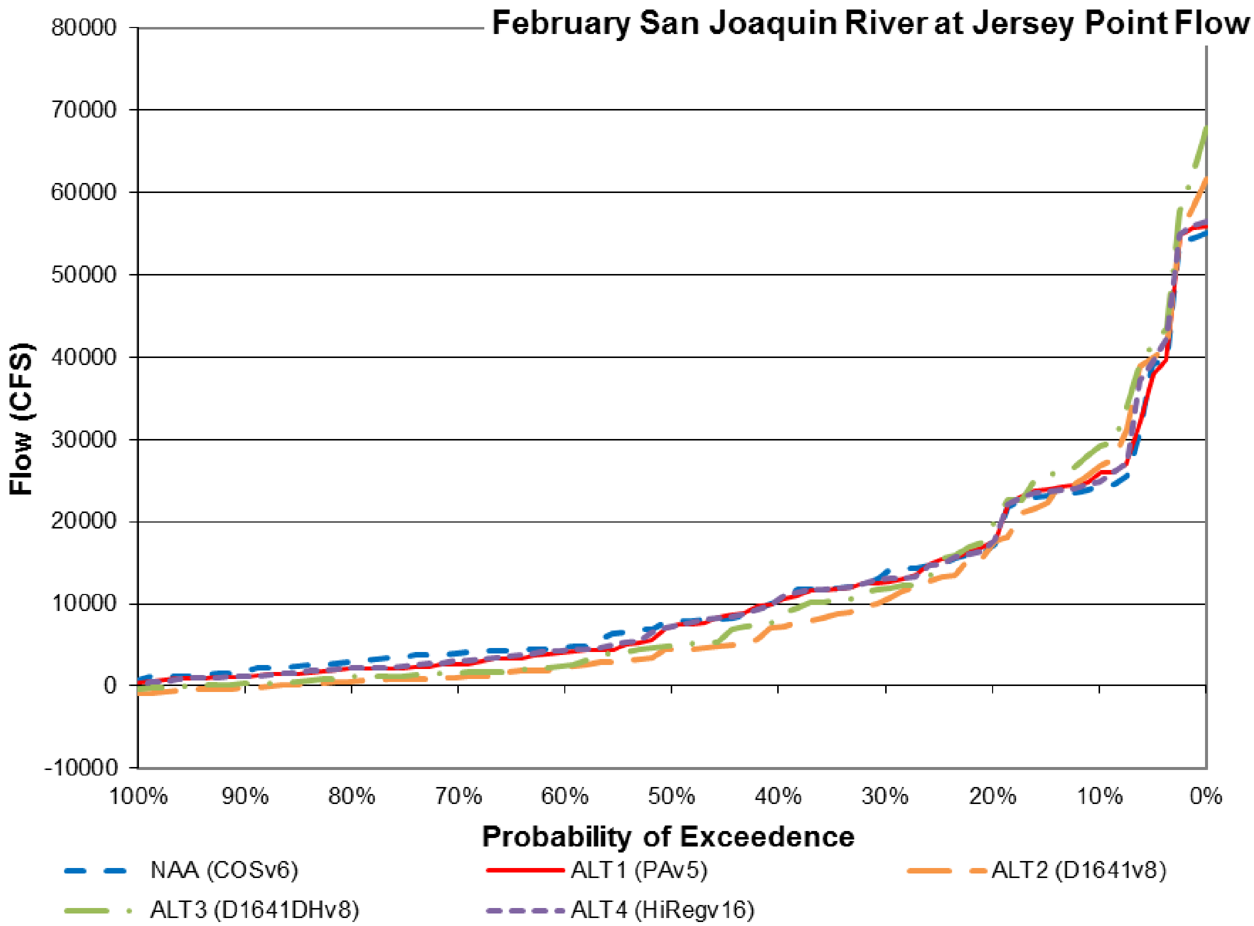

Figure O.3-78. DSM2-HYDRO-Modeled Probability of Exceedance of San Joaquin River Flow at Jersey Point, February

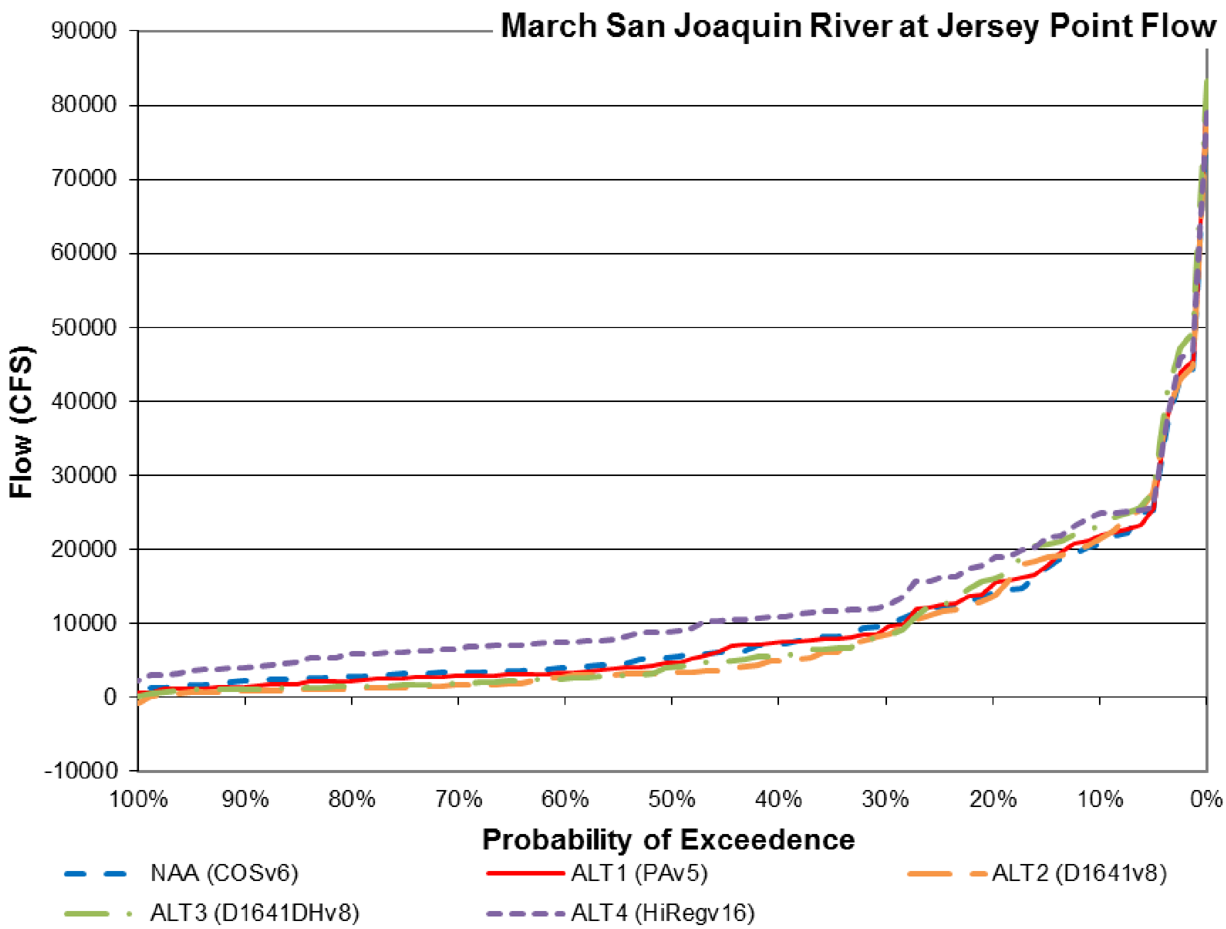

Figure O.3-79. DSM2-HYDRO-Modeled Probability of Exceedance of San Joaquin River Flow at Jersey Point, March

Potential changes to Longfin Smelt due to changes in Delta Cross Channel operations

There may be some differences in DCC operations effects under Alternative 1 relative to the No Action Alternative, although the effects would be expected to be limited given that Longfin Smelt occur downstream of the DCC. Hydrodynamic effects of water operations, including the DCC, e.g., on lower San Joaquin River flows and therefore potential south Delta entrainment risk, were discussed in the analysis of *Potential changes to Longfin Smelt due to OMR management*, which noted the low percentage of Longfin Smelt entrained historically under the D-1641 management framework included in Alternatives 2 and 3.

Potential changes in Longfin Smelt survival related to the Temporary Barriers Project

Although there may be the potential for greater Longfin Smelt occurrence in the south Delta as described under *Potential changes to Longfin Smelt due to OMR management* as a result of lower OMR flows under Alternative 1 compared to the No Action Alternative, and therefore greater potential for negative effects from the Temporary Barriers Project (e.g., near-field predation), the effects would be expected to be limited given the low frequency of occurrence of Longfin Smelt occurring in the south Delta (Merz et al. 2013).

Potential changes to Longfin Smelt from Contra Costa Water District operations

Contra Costa Water District operations under Alternative 1 would not change from the No Action Alternative and therefore would be expected to have similar effects to Longfin Smelt, i.e., negligible entrainment and hydrodynamic effects per analyses undertaken for Delta Smelt (Reclamation 2019).

Potential changes to Longfin Smelt from North Bay Aqueduct operations

There would be expected to be little difference in potential effects on Longfin Smelt from North Bay Aqueduct Operations water operations under Alternative 1 relative to the No Action Alternative, given that operations and protective criteria from the CDFG (2009) ITP (discussed under the No Action Alternative) would not differ. As with Delta Smelt, sediment removal and aquatic weed removal would be expected to have limited effects on Longfin Smelt, particularly in the case of summer and fall aquatic weed removal, given that Longfin Smelt would be expected to be downstream of the Delta at this time.

Potential changes to Longfin Smelt from water transfers

Although Alternative 1 includes an expanded water transfer window (July–November) relative to the No Action Alternative (July–September), this expanded window does not overlap the main period of south Delta entrainment vulnerability for Longfin Smelt (December–May; Grimaldo et al. 2009) and therefore would not be expected to increase south Delta entrainment risk under Alternative 1 relative to the No Action Alternative.

Potential changes to Longfin Smelt from Clifton Court aquatic weed and algal bloom management

Although Clifton Court aquatic weed and algal bloom management under Alternative 1 includes potential additional herbicides and an extended treatment period relative to the No Action Alternative, the timing of the action generally would avoid the main period of Longfin Smelt occurrence in Clifton Court Forebay, resulting in little or no effect to the species, consistent with the No Action Alternative. As previously described for Delta Smelt and as discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to Longfin Smelt due to changes from Tracy and Skinner fish facilities

Alternative 1 would include a new carbon dioxide injection device at the Tracy Fish Facility and therefore could have a positive effect on Longfin Smelt salvage efficiency relative to the No Action Alternative in this respect. Given the potential increase in entrainment from seasonal operations (as discussed for Alternative 2), the negative effects from salvage at the Tracy and Skinner fish facilities could outweigh any increases in salvage efficiency at Tracy. However, as previously discussed above in *Potential changes to Longfin Smelt due to OMR management*, the population-level effects may be limited given historically low entrainment loss of Longfin Smelt.

Potential changes to Longfin Smelt due to changes from Suisun Marsh facilities

During the period of Longfin Smelt potential occurrence near the Suisun Marsh facilities (i.e., winter/spring), Suisun Marsh facilities would not be operated differently under Alternative 1 than under the No Action Alternative and therefore the effects such as entrainment (CDFG 2009a) would be expected to be similar to the No Action Alternative.

Potential changes Longfin Smelt from actions for Delta Smelt summer-fall habitat

Delta Smelt habitat operations under Alternative 1 would be focused on the summer/fall period during which Longfin Smelt would not be expected to be affected given general distribution downstream of the potentially affected area.

Potential changes to Longfin Smelt due to the San Joaquin Basin Steelhead Telemetry Study

As discussed for Delta Smelt, the San Joaquin Steelhead telemetry study would not affect Longfin Smelt as it would be primarily in the San Joaquin River upstream of the areas where Longfin Smelt occur, and also does not involve trapping or other mechanisms to affect Longfin Smelt of any life stage.

Potential changes to Longfin Smelt due to the reintroduction by Fish Conservation and Culture Laboratory

Increased abundance of Delta Smelt from reintroduction of Delta Smelt under Alternative 1 potentially could have negative effects on Longfin Smelt if, for example, the rate of hybridization between the species increased from the current low levels (Fisch et al. 2014). There would be expected to be limited effects on Longfin Smelt from reintroduction of Delta Smelt given appropriate risk management strategies such as scaling and adjusting release numbers to optimize production while avoiding significant, density-related interspecific ecological risk (Lessard et al. 2018).

O.3.3.8.3 Sacramento River Winter-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Rearing Winter-Run Chinook Salmon are present in the Delta between October and May. Key habitat attributes relevant to seasonal operations in the Delta include out-migration cues and entrainment risk.

Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to adversely affect juvenile Chinook Salmon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, and 2) “far-field” mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team’s (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver-linkage-outcome (DLO) framework for specifying how water project operations (the “driver”) can influence juvenile salmonid behavior (the “linkage”) and potentially cause changes in survival or routing (the “outcome”). The SST concluded altered “Channel Velocity” and altered “Flow Direction” were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O.3-80 provides a simplified conceptual model of the DLO defined by the CAMT SST.

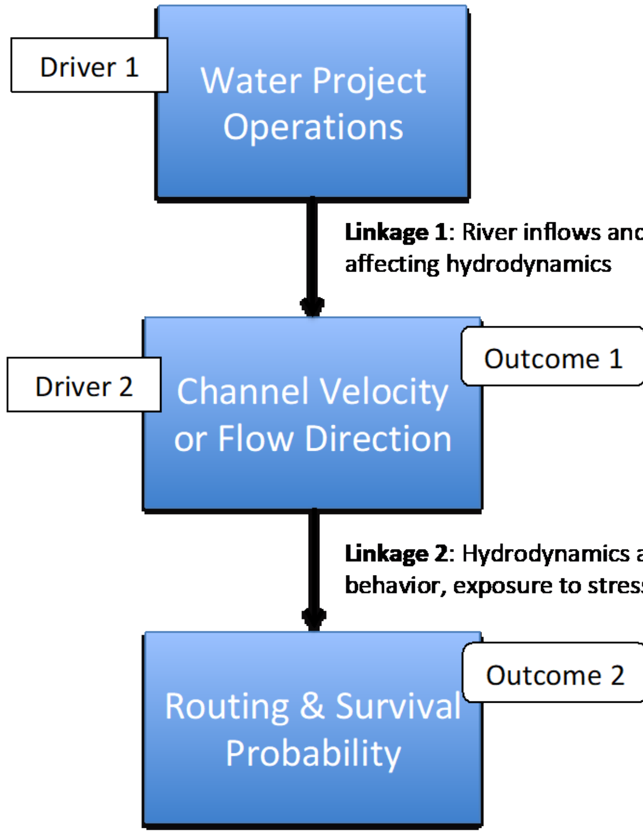

Figure O.3-80. Conceptual Model for Far-Field Effects of Water Project Operations on Juvenile Salmonids in the Delta. This CM is a Simplified Version of the Information Provided by the CAMT SST

In order to assess the potential for water project operations to influence survival and routing, Reclamation and DWR analyzed Delta hydrodynamic conditions by creating maps from DSM2 Hydro modeling. The maps are based on a comparative metric, proportion overlap (more below), to capture channel-level hydrodynamic details as a single number for color-scale mapping of Delta channels.

The objective of the comparative metric is to summarize the water velocity time series for each channel and scenario such the channel-level comparison is captured in a single number. For the proportion overlap metric, kernel density estimates are calculated on each time series. The kernel density estimates represent a non-parametric smoothing of the empirical distribution of time series values. The proportion overlap of two kernel density estimates is calculated with the following steps: 1) calculate the total area under the curve (AUC_t) as the sum of the AUC for each density estimate, 2) calculate the AUC of the overlapping portions (AUC_o) of the two density distributions being compared, and 3) calculate the overlapping proportion of the density distributions as AUC_o/AUC_t. Proportion overlap is naturally bound by zero and one; a value of zero indicates no overlap and a value of one indicates complete overlap. Lower values of proportion overlap identify channels demonstrating larger differences in a scenario comparison.

The proportion overlap metric is best applied over relatively short time periods because seasonal and annual variation in water velocity can overwhelm differences between scenarios. Thus, Reclamation calculated proportion overlap for every DSM2 channel for two seasons (Dec-Feb, Mar-May) in each water year (1922–2003). DSM2 output was excluded from water year 1921 to allow for an extensive burn-in period. The proportion overlap was calculated based on hourly DSM2 output. Because each season was roughly 90 days, each comparison involved roughly 4,300 DSM2 values (2 scenarios * 24 hours * 90 days) for each channel.

Because the proportion overlap was calculated for each channel in each water year, the proportion overlap values were summarized prior to mapping (i.e., not feasible to map proportion overlap for every comparison in every water year). To summarize, the minimum and median proportion overlap for each channel for each water year type for each comparison was found. The minimum values represent the maximum expected effect. The median values represent the average expected effect. Note that the year with the minimum (or median) proportion overlap for one channel might not be the same year as for another channel.

Entrainment

In the December through May period, the average total export rate, under Alternative 1, is slightly higher difference compared to the No Action Alternative. Therefore, slightly higher entrainment is expected compared to the No Action Alternative.

Zeug and Cavallo (2014) analyzed more than 1,000 release groups representing more than 28 million coded wire tagged juvenile fish including Winter-Run, Late Fall-Run and Fall-Run Chinook Salmon. This data represents large release groups of tagged smolts where the number of fish representing each release group lost to entrainment at the export facilities has been estimated. Cavallo (2016) provided a supplemental assessment of Winter-Run Chinook Salmon entrainment risk (building upon Zeug and Cavallo 2014) that showed total CVP and SWP exports described entrainment risk better than OMR or other flow metrics. Entrainment loss results as reported below represents the proportion of coded wire tagged Winter-Run Chinook Salmon released upstream of the Delta which were entrained at South Delta export facilities. This proportion accounts for and includes expansion for sampling effort at the salvage facilities and also prescreen mortality. With total exports of ≤ 6,500 cfs, entrainment loss rates for Winter-Run Chinook Salmon range between 0 and 1.5% (mean 0.1%) (Zeug and Cavallo 2014). With total exports greater than 6,500 cfs, entrainment losses range between 0 and 4% (mean 0.25%) (Zeug and Cavallo 2014). For December through February, Alternative 1 has an average total export rate similar to No Action Alternative (7,813 and 7,617 cfs respectively; Figure O1-1 in Appendix O, Attachment 1, Bay-Delta Aquatics Effects Figures), and will therefore have similar entrainment risk. In the March through June period, total exports for Alternative 1 increase entrainment risk relative to No Action Alternative (5,916 vs. 4,164 cfs, respectively; Figure O1-2 in Appendix O, Attachment 1), but entrainment losses should average 0.1% and not exceed 1.5%. While entrainment risk will increase under Alternative 1, compared to the No Action Alternative, Alternative 1 includes restrictions to OMR (-3,500 cfs and -2,500 cfs) when cumulative salvage of any species reaches 50% of the salvage threshold. CalSim modeling incorporates an assumption for this cumulative salvage restriction.

Routing

Routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 1 were evaluated using DSM2. Juvenile Winter-Run Chinook Salmon are present in the Sacramento River at Sherwood Harbor upstream of the first distributary junctions between November and March with peak abundance in February and March (Reclamation 2019).

In the December to February period, velocity overlap between Alternative 1 and No Action Alternative in the Sacramento River main stem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 75% in critically dry, dry, below normal and above normal years (Figure O1-3 in

Appendix O, Attachment 1). In wet years, velocity overlap in this reach was ≈50%. Velocities were higher under Alternative 1 in all water year types in December through February indicating routing into the interior Delta would be lower relative to No Action Alternative (Perry et al. 2015 described for the December to February period (Figure O1-11 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 1 was >75% in all water year types (Figure O1-4 in Appendix O, Attachment 1).

Abundance of juvenile Winter-Run Chinook Salmon at Chipps Island peaks in March and April but fish are collected between December and May (Reclamation 2019). During this time period, Winter-Run Chinook Salmon originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can potentially be exposed to hydrodynamic effects associated with the CVP and SWP that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December to February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 1 and the No Action Alternative (Figure O1-5 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative1 to the No Action Alternative in the March to May period (Figure O1-6 in Appendix O, Attachment 1).

Through-Delta Survival

Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. This study was performed with hatchery-origin Late Fall-Run and there is uncertainty regarding the applicability of those results to Winter-Run. However, this study represents the best information avaiable on survival of juvneile Chinook Salmon in the Delta.

To examine potential effects of Alternative 1, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, there are higher velocities under Alternative 1 than the No Action Alternative in wet, above normal, below normal and dry years. Velocities were lower in critically dry years but overlap was high (>95%) Figure O1-7 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period velocities were higher under Alternative 1 relative to the No Action Alternative in all but critically dry water years (Figure O1-8 in Appendix O, Attachment 1). In the March through May period at Walnut Grove, when Alternative 1 was compared to the No Action Alternative, velocity overlap ranged from 78.5-92.5% with higher velocities under Alternative 1 (Figure O1-9 in Appendix O, Attachment 1). Velocity overlap at Steamboat Slough in the March through May period ranged from 82.2% to 95.0% with higher velocities under Alternative 1 (Figure O1-10 in Appendix O, Attachment 1).

Overall, Alternative 1 results in higher velocities in the Delta in the spring than under No Action Alternative, during the outmigrating juvenile time period. Survival probabilities are non-linear; however, the higher discharge at Freeport in the spring under Alternative 1 results in higher survival in the transition reaches. Higher flows also lead to lower probability of routing into the interior Delta, which has the lowest survival probability regardless of flow.

Potential changes to aquatic resources due to OMR management

See section on seasonal operations above, which integrate OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

Under Alternative 1, the DCC may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Winter-Run Chinook Salmon in the Sacramento River at Sherwood Harbor, which is near the DCC, occurs from February through March (Reclamation 2019). Therefore, the DCC is closed for the majority of the juvenile Winter-Run Chinook Salmon migration period in the Sacramento River and as such the proportion of juvenile Winter-Run Chinook Salmon exposed to an open DCC would be negligible. Juvenile Chinook Salmon entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010; Perry et al. 2018).

Potential changes to aquatic resources due to the Temporary Barriers Project

Juvenile Winter-Run Chinook Salmon are not expected to co-occur in space or time with the agricultural barriers indicating no potential impacts.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 1 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; CDFG 1994; CDFG 2009a) and remain unchanged from the No Action Alternative.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory route for Winter-Run Chinook Salmon (NMFS 2017c), approximately 18 miles from the Sacramento River via the shortest route. Designated critical habitat for Winter-Run Chinook Salmon does not occur within Rock Slough, but is present further to the north in the Delta (NMFS 2017c, 2014). Salmonids are expected to avoid the area of the Rock Slough Intake during certain times of the year based on historical water temperatures.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Winter-Run Chinook Salmon presence near the Rock Slough Intake. Since 1994, fish monitoring has been conducted by CDFW and CCWD consistent with the separate biological opinions and permits that govern CCWD's operations. From 1994 through 1999, CDFW conducted fish monitoring at the Rock Slough Intake and in the Contra Costa Canal up to the first pumping plant. Over this 6-year period, CDFW captured a total of 13 juvenile Winter-Run Chinook Salmon from January through May (CDFG 2002c; NMFS 2017c). From 1999 to 2009, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected no juvenile or adult Winter-Run Chinook Salmon at the Rock Slough Headworks (Reclamation 2016; NMFS 2017c).

Since construction of the RSFS, operation of the hydraulic rake cleaning system has been shown to trap and kill adult Chinook Salmon and other non-listed fish (Reclamation 2016). From 2011–2018, 47 Salmon were recovered at the RSFS (Reclamation 2016, Appendix A; Tenera Environmental 2018a), but none of the captured fish were identified as Winter-Run Chinook Salmon (NMFS 2017c).

NMFS issued a biological opinion in 2017 (NMFS 2017c) that considered improvements to the RSFS facility including the hydraulic rake cleaning system, operations and maintenance (O&M) of the RSFS and associated appurtenances, and administrative actions such as the transfer of O&M activities from

Reclamation to CCWD. NMFS determined that the O&M of RSFS may result in the incidental take of juvenile Winter-Run Chinook Salmon and provided an incidental take limit based upon the number of listed fish collected in the pre and post-construction RSFS monitoring (NMFS 2017c). The incidental take provided in NMFS 2017c is five juvenile Winter-Run Chinook Salmon per year.

CCWD’s Fish Monitoring Program also samples behind the fish screens at CCWD’s other south Delta intakes. Since the intakes have been in operation, CCWD’s Fish Monitoring Program has never collected Winter-Run Chinook Salmon at CCWD’s Old River Intake or Middle River Intake (CCWD 2019).

CCWD’s operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD’s operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD’s operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Winter-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Salmon can be “drawn” into the south Delta under reverse flows and high CVP and SWP pumping rates. One indicator of reverse flows is the net flow in Old and Middle Rivers (OMR). Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect OMR, and any effect that diversions at Rock Slough Intake would have in the Old and Middle River corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants.

However, diversions at the Rock Slough Intake could affect flows in the San Joaquin River at Jersey Point, which is approximately 14 river miles from the Rock Slough Intake (via the shortest route through Franks Tract). Mean velocity in a river channel can be calculated by dividing the flow rate by the cross-sectional area of the channel. The maximum effect of Rock Slough diversions on the channel velocity would be the maximum diversion rate (350 cfs) divided by the minimum cross-sectional area of the channel. This calculation assumes that all water diverted at Rock Slough comes from the San Joaquin River at Jersey Point, which is a conservative assumption (i.e., overestimates the effect on velocity). The cross-sectional area of the San Joaquin River at Jersey Point is approximately 60,500 square feet (sf), but varies depending on the tidal stage from approximately 56,000 sf (at low tide and low San Joaquin River flow) to 68,000 sf (at high tide and high San Joaquin River flow) as shown in Figure O.3-81.

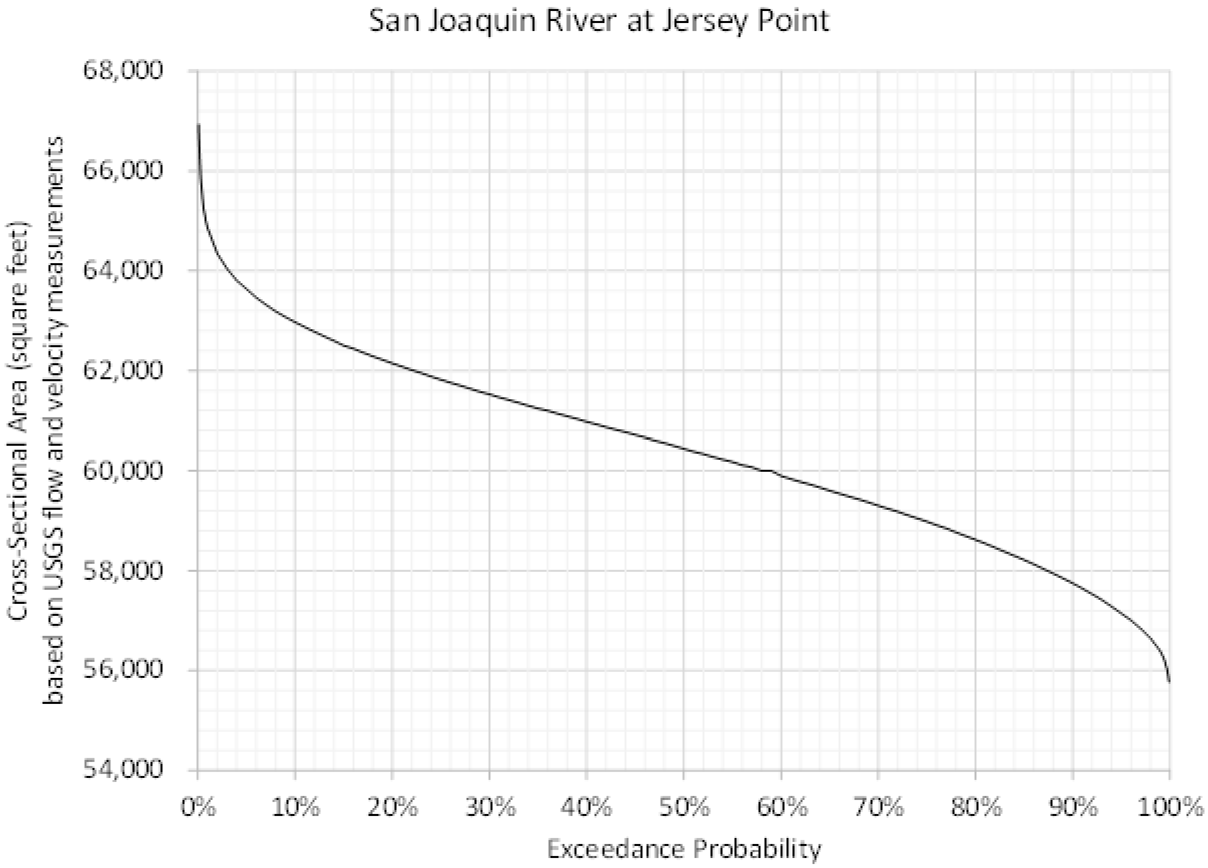

Figure O.3-81. Cross-Sectional Area of the San Joaquin River at Jersey Point (Station: 11337190) Calculated from USGS Measurements of Flow and Velocity every 15 Minutes for Water Years 2014 through 2018

The maximum effect of water diversions at Rock Slough Intake on velocity in the San Joaquin River at Jersey Point is calculated as 350 cfs divided by 56,000 square feet; resulting in 0.00625 feet per second (ft/sec). For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from Rock Slough diversions. Furthermore, the actual effect is likely to be much lower than 0.00625 ft/sec because the water diverted at the Rock Slough Intake does not all come from the San Joaquin River west of Jersey Point.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, the combined effect of all three intakes is examined. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Winter-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant

particles such as phytoplankton. To examine the effect on neutrally buoyant particles, the distance that a particle would travel due to the maximum permitted Rock Slough diversions over the course of a day is calculated. A change in velocity of 0.00625 ft/sec could move a neutrally buoyant particle approximately 540 ft over the course of the day (0.00625 ft/sec * 86,400 sec/day). For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is not significant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 1 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Alternative 1 includes the North Bay Aqueduct (NBA) intake in the North Delta and operation of the Barker Slough Pumping Plant. Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant (monitoring data is available at https://www.wildlife.ca.gov/Regions/3). There should be no discernable effect to the Winter-Run Chinook Salmon due to the operations of the Barker Slough Pumping Facility. This is due to the infrequent presence of Winter-Run Chinook Salmon in the monitoring surveys indicating a low risk of entrainment. Further, Barker Slough Pumping Facility fish screens are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment while greatly minimizing any impingement of fish against the screen.

Alternative 1 also includes sediment removal with a suction dredge that could entrain Winter Run individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Winter Run occurring near the removal. The low occurrence of Chinook Salmon in monitoring efforts suggest that any potantil imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

Under Alternative 1, Reclamation is extending the water transfer window until November, from the current July through September window. This extension could result in increased flows entering the Delta and increased pumping at Jones and Banks Pumping Plants.

Egg, alevin, and fry lifestages of Winter-Run Chinook Salmon do not occur in the Delta, and therefore would not be affected by this action. Winter-Run Chinook Salmon juveniles enter the Delta starting in December, and therefore would be unlikely to be exposed to increased pumping of water transfers through November. Adults returning from the ocean could possibly be in the Delta in July; however, they are strong swimmers, large fish that can avoid predators, and are unlikely to have impacts associated with direct entrainment of the pumping plants.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Winter-Run Chinook Salmon are present in the Delta between December and May with a peak in March and April (Reclamation 2019). The application of aquatic herbicide to the waters of CCF will occur between 28 June and 31 August 31, when tempertures exceed 25 ˚C, or when no protective actions have been triggered. Thus, the probability of exposing Winter-Run Chinook Salmon to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the water temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June. Mechanical harvesting would occur on an as-needed basis and, therefore, Winter-Run Chinook Salmon could be exposed to this action, if entrained into the CCF.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

A small proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility. Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements based on lack of observed salvage during the August to October in-water work window (see Figures F.2.7, F.2.8, and F.2.9 in Appendix F, *Juvenile Salmonid Monitoring, Sampling, and Salvage Summary from SacPAS*, from the ROC LTO BA). However, a few early migrants could occur during the in-water work window based on occurrence in the north Delta (see Figures WR_Seines and WR_Sherwood in Appendix F of the ROC LTO BA).

To the extent that the construction affects the ability of juvenile Winter-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Figure 5.6-44), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Chinook Salmon entrained into CCF. It is important to note that only small proportions of Winter-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014).

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May to meet salinity standards set by the State Water Resources Control Board and Suisun Marsh Preservation Agreement provides water quality benefits to Winter-Run Chinook Salmon habitat. This beneficial operation coincides with downstream migration of juvenile Winter-Run Chinook Salmon (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Winter-Run Chinook Salmon in Montezuma Slough thus, the proportion of the total run utilizing this route is unknown. Winter-Run Chinook Salmon typically migrate through the estuary several months before spawning, but an extended delay in the estuary may affect their ability to access their natal spawning streams. Winter-Run Chinook Salmon generally utilize high stream flow conditions to assist their upstream migration. Rapid upstream movement may be needed to take advantage of a short duration high stream flow event, particular in dry years when high flow events may be uncommon. NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.7 ft/s, so that juvenile Winter-Run Chinook Salmon would be excluded from entrainment.

The Morrow Island Distribution System (MIDS) diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, its unlikely juvenile Winter-Run Chinook Salmon will be entrained into the water distribution system, since Winter-Run Chinook Salmon have not be caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor Winter-Run Chinook Salmon.

Goodyear Slough Outfall improves water circulation in the marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Winter-Run Chinook Salmon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits juvenile Winter-Run Chinook Salmon in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat

No Winter-Run Chinook Salmon are detected in the Delta between June and September. Therefore, no effects would occur as a result of the Suisun Marsh Salinity Control Gate operation.

Potential changes to aquatic resources from Clifton Court predator management efforts

Clifton Court predator management efforts could reduce predation on listed fishes following entrainment into CCF, reducing pre-screen loss.

Potential changes to aquatic resources due to the San Joaquin Basin Steelhead Telemetry Study

No effect

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

Potential changes to aquatic resources from monitoring

No effect

A number of monitoring activities described in the ROC LTO BA (see Appendix C – Real Time Water Operations Charter, in section Routine Operations and Maintenance on CVP Activities) would have the potential to capture Winter-Run Chinook Salmon. Not all the existing IEP monitoring programs that target pelagic fish identify Chinook Salmon race. Of the programs that target and identify Winter-Run Chinook Salmon, collective catches are less than 1% of the Winter-Run JPE (Reclamation 2019). Because such a small percentage of the total JPE is captured in the monitoring programs, the effects of the monitoring programs are not likely to have effects to the Winter-Run Chinook Salmon population. These monitoring programs are important for understanding entry and residence time of Winter-Run Chinook Salmon into the Delta and San Francisco Estuary

O.3.3.8.4 Central Valley Spring-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Reclamation and DWR propose to operate the C.W. Bill Jones Pumping Plant and the Harvey O. Banks Pumping Plant. These pumping plants affect the hydrodynamics of the south and central Delta resulting in effects to Spring-Run Chinook Salmon entrainment, routing and through Delta survival. Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to negatively impact juvenile Chinook Salmon in two distinct ways: 1) "near-field" mortality associated with entrainment to the export facilities, 2) "far-field" mortality resulting from altered hydrodynamics. See Winter-Run Chinook Salmon effects section for more detail concerning "far-field" and "near-field."

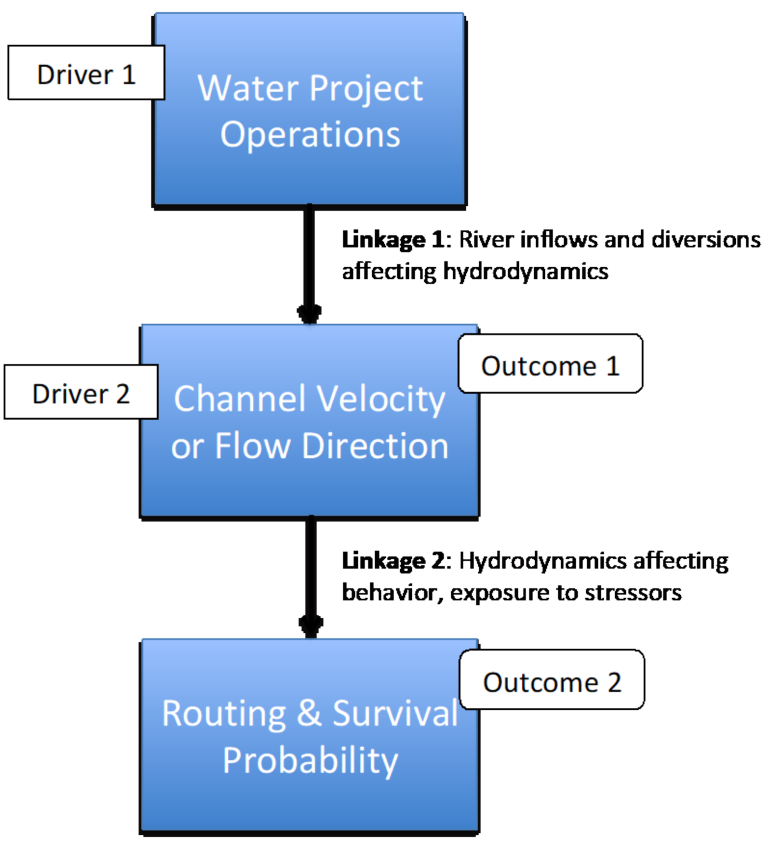

Figure O.3-82. Conceptual Model For Far-Field Effects of Water Project Operations on Juvenile Salmonids in the Delta. This CM Is a Simplified Version of the Information Provided by the CAMT SST

Entrainment

Among 6.8 million tagged natural origin and 2.8 million tagged hatchery origin Spring-Run Chinook Salmon juveniles, entrainment loss averaged less than 0.0005% (Zeug and Cavallo 2014). In the December through February, the average total export rate, under Alternative 1, is slightly higher difference compared to the No Action Alternative (366 cfs; Figure O1-1 in Appendix O, Attachment 1) and will therefore have a similar entrainment risk. Total exports proposed in March-June are 1,752 cfs higher than No Action Alternative (Figure O1-2 in Appendix O, Attachment 1) when juvenile Spring-Run Chinook Salmon are most abundant in the Delta.

Although data for juvenile Spring-Run Chinook Salmon originating from the San Joaquin River are limited, Zeug and Cavallo (2014) analyzed salvage of San Joaquin River-origin Fall-Run juvenile Chinook Salmon that are found in the Delta at a similar time as Spring-Run Chinook Salmon. Salvage of Fall-Run Chinook Salmon originating from the San Joaquin River averaged 1.4% and increased with export rate at the CVP and SWP (Zeug and Cavallo 2014). However, there were few observations at export rates greater than 3,000 cfs. Average mortality at the facilities represents < 5% total juvenile mortality for San Joaquin River-origin populations but can range as high as 17.5% (Zeug and Cavallo 2014).

In the December through February period, Alternative 1 proposes an average total export rate slightly higher than No Action Alternative (196 cfs; Figure O11) and will, therefore, have a similar entrainment risk. Total exports proposed for Alternative 1 in March-June (1,752 cfs higher than No Action Alternative; O1-2 in Appendix O, Attachment 1) when juvenile Spring-Run Chinook Salmon are most abundant in the Delta, will increase entrainment risk relative to No Action Alternative. Recent acoustic studies of juvenile Fall-Run Chinook Salmon in the San Joaquin River revealed that when the Head of Old River Barrier is out, >60% of fish detected at Chipps Island came through CVP, indicating that salvage is a higher survival route than volitional migration.

Routing

As stated in the Sacramento Winter-Run Chinook effects section, routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Juvenile Spring-Run Chinook Salmon are present in the Delta between November and early June with a peak in April (Reclamation 2019). In the December through February period, velocity overlap between Alternative 1 and No Action Alternative in the Sacramento River main stem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was >75% in critically dry, dry, below normal and above normal years (Figure O1-3 in Appendix O, Attachment 1). In wet years, velocity overlap in this reach was ≤ 50%. Velocities were higher under Alternative 1 in all water year types indicating routing into the interior Delta would be lower relative to No Action Alternative (Perry et al. 2015). In the March to May period, comparison of Alternative 1 and No Action Alternative revealed similar patterns of velocity overlap as described for the December to February period (Figure O1-4 in Appendix O, Attachment 1) indicating routing into the interior Delta would be lower under Alternative 1 in the March to May period.

Spring-Run Chinook Salmon originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can be exposed to hydrodynamic project effects that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December to February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 1 and both the No Action Alternative scenarios (Figure O1-5 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 1 to No Action Alternative in the March to May period (Figure O1-6 in Appendix O, Attachment 1).

Juvenile Spring-Run Chinook Salmon are present in the Delta between November and early June with a peak in April (Reclamation 2019). Early studies using coded wire tags indicated that survival of San Joaquin River-origin juvenile Chinook Salmon was lower in the Old River Route relative to the San Joaquin main stem (Newman 2008). This finding led to strategies designed to keep larger proportions of fish in the San Joaquin River main stem including the Head of Old River rock barrier and non-physical barriers. Recent studies using acoustic technology have indicated that differences in survival among the two routes are not significant (Buchanan et al. 2013; Buchanan et al. 2018). Thus, fish that enter Old River are unlikely to experience reduced survival.

Spring-Run Chinook Salmon originating from the San Joaquin River that remain in the San Joaquin River main stem at the Head of Old River are exposed to additional junctions that lead into the interior Delta including; Turner Cut, Columbia Cut, Middle River, Old River, Fisherman's Cut and False River. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junctions with San Joaquin Rivers between Alternative 1 and No Action Alternative scenarios (Figure O1-5 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 1 to No Action Alternative in the March to May period (Figures O1-6 in Appendix O, Attachment 1).

In the December through February period, velocity overlap between Alternative 1 and No Action Alternative at the Head of Old River was high in critically dry water years and moderate in dry, below normal and wet years (Figure O1-5 in Appendix O, Attachment 1). The lowest overlap occurred in above normal years (Figure O1-5 in Appendix O, Attachment 1). In the March to May period, velocity overlap patterns were similar to comparisons in the December through February period (Figure O1-6 in Appendix O, Attachment 1).

Through-Delta Survival

To examine potential effects of Alternative 1, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this "transitional" region. During the December to February period at Walnut Grove, velocity distributions for Alternative 1 relative to No Action Alternative were most different in wet years (70.9%) with higher velocities in Alternative 1. Velocities were also greater for Alternative 1 relative to No Action Alternative in dry, below normal and above normal years although overlap was greater (≥79%; Figure O1-7 in Appendix O, Attachment 1). In critically dry years, velocity distributions were almost identical (95.4%; Figure O1-7 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, there was a similar pattern where velocities under Alternative 1 were higher than No Action Alternative in wet, above normal and below normal years and similar in dry and critically dry years (Figure O1-8 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 1 and No Action Alternative was ≥78% across all water year types with greater velocities under Alternative 1 (Figure O1-9 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between

Alternative 1 and No Action Alternative scenarios was high with all values ≥82% and greater velocities under Alternative 1 (Figure O1-10 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. This study was performed with hatchery-origin Late Fall-Run Chinook Salmon and there is uncertainty regarding the applicability of those results to Spring-Run Chinook Salmon. However, this study represents the best information avaiable on survival of juvneile Chinook Salmon in the Delta.To examine potential effects of Alternative 1, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the “transitional” region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 1 relative to No Action Alternative exhibited high overlap in all water year types (≥84.3%; Figure O1-11 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 1 and No Action Alternative in critically dry, dry and below normal water years (≥90.1%) and moderate in wet and above normal years (53.6-75.1%; Figure O1-12 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 1 and No Action Alternative (≥83.2%; Figure O1-13 in Appendix O, Attachment 1). Velocities were lower under Alternative 1 in dry, below normal and wet year and higher in above normal years (Figure O1-23 in Appendix O, Attachment 1). At the Head of Middle River in the March –May period, overlap between Alternative 1 and No Action Alternative was moderate in above normal years (57.7%) and higher in all other water year types ≥ 73% (Figure O1-14 in Appendix O, Attachment 1). In above normal years, velocities were higher under Alternative 1 and lower in all other water year types (Figure O1-14 in Appendix O, Attachment 1).

Potential changes to aquatic resources due to OMR management

See section on seasonal operation above, which integrates OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

The Delta Cross Channel may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. Significant amounts of flow and many juvenile Spring-Run Chinook Salmon enter the DCC (when the gates are open) and Georgiana Slough, especially during increased Delta pumping. Mortality of juvenile Salmon entering the central Delta is higher than for those continuing downstream in the Sacramento River. Juvenile Chinook Salmon that are entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010) The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Spring-Run Chinook Salmon in the Sacramento River past Knights Landing, which is upstream of the DCC, occurs from March-April (Reclamation 2019). Therefore, the DCC is closed to protect the majority of the juvenile Spring-Run Chinook Salmon migration period in the Sacramento River and reduce the proportion of fish exposed to an open DCC.

Potential changes to aquatic resources due to the Temporary Barriers Project

The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30.

The proportion of juvenile Spring-Run Chinook Salmon exposed to the agricultural barriers (Temporary Barrier Program, TBP) depends on their annual timing of installation and removal. Due to their location, primarily migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Spring-Run Chinook Salmon in the Delta is March and April (Reclamation 2019). If the agricultural barriers are operating as early as April 15 then they have the potential to expose a large proportion of the juvenile Spring-Run Chinook Salmon migrating down the San Joaquin River. When the Head of Old River barrier is not in place, acoustically tagged juvenile Chinook Salmon have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). Flap gates tied up on agricultural barriers from May 16 to May 31 would help to reduce the negative effect of the barriers during this period. However, juveniles migrating before or after this period could be exposed to the agricultural barriers with flaps down which apparently decreases passage success and survival (DWR 2018).

Potential changes to aquatic resources due to Contra Costa Water District operations

As discussed in Chapter 3, CCWD’s operations in Alternative 1 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD’s operations, including operation of the Rock Slough Intake, for Alternative 1 remain unchanged from the current operations.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory route for Central Valley Spring-Run Chinook Salmon (NMFS 2017c), approximately 18 miles from the Sacramento River and 10 miles from the San Joaquin River via the shortest routes. Designated critical habitat for Spring-Run Chinook Salmon does not occur within Rock Slough, but is present further to the north in the Delta (NMFS 2017c, 2014). Salmonids are expected to avoid the area of the Rock Slough Intake during certain times of the year based on historical water temperatures, which range from lows of about 45°F in winter (December and January) to over 70°F beginning in May and continuing to October (Reclamation 2016).

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Central Valley Spring-Run Chinook Salmon presence near the Rock Slough Intake. Since 1994, fish monitoring has been conducted by CDFW and CCWD consistent with the separate biological opinions and permits that govern CCWD’s operations. From 1994 through 1999, CDFW conducted fish monitoring at the Rock Slough Intake and in the Contra Costa Canal up to the first pumping plant. Over this 6-year period, CDFW captured a total of 108 juvenile Central Valley Spring-Run Chinook Salmon from March through May (CDFG 2002c; NMFS 2017c). From 1999 to 2009, the 11 years prior to construction of the RSFS, CCWD’s Fish Monitoring Program collected a total of 11 juvenile Central Valley Spring-Run Chinook Salmon from March through May at the Rock Slough Headworks (Reclamation 2016; NMFS 2017c) and 4 juvenile Central Valley Spring-Run at Pumping Plant #1 (CCWD 2019). No adult Spring-Run Chinook Salmon were collected in the vicinity of the Rock Slough Intake from 1994 through 2009 (CDFG 2002c; Reclamation 2016; NMFS 2017c). No juvenile or adult

Central Valley Spring-Run Chinook Salmon have been collected in CCWD's Fish Monitoring Program at the Rock Slough Intake since 2008.

Since construction of the RSFS, operation of the hydraulic rake cleaning system has been shown to trap and kill adult Chinook Salmon and other non-listed fish (Reclamation 2016). From 2011-2018, 47 Salmon were recovered at the RSFS (Reclamation 2016, Appendix A; Tenera Environmental 2018a), but none of the captured fish were identified as Spring-Run Chinook Salmon (NMFS 2017c).

CCWD's Fish Monitoring Program also samples behind the fish screens at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD's operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes (i.e., 10 miles from the San Joaquin River and 18 miles from the Sacramento River), juvenile Spring-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Spring-Run Chinook Salmon can be "drawn" into the south Delta under reverse flows and high CVP and SWP pumping rates.

One indicator of reverse flows is the net flow in OMR. Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect net reverse flow in OMR, and any effect that diversions at Rock Slough Intake would have in the OMR corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the OMR corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstem of the Sacramento River or the San Joaquin River and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run Chinook Salmon. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, we examine the combined effect of all three intakes. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Spring-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is insignificant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 1 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Alternative 1 includes the North Bay Aqueduct (NBA) intake in the North Delta and operation of the Barker Slough Pumping Plant. Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant (monitoring data is available at https://www.wildlife.ca.gov/Regions/3). The NBA is located within designated critical habitat for Spring-Run Chinook Salmon. There should be no discernable effect to the Spring-Run Chinook Salmon due to the operations of the Barker Slough Pumping Facility. This is due to the infrequent presence of Spring-Run Chinook Salmon in the monitoring surveys indicating a low risk of entrainment. Further, Barker Slough Pumping Facility fish screens are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment while greatly minimizing any impingement of fish against the screen.

Alternative 1 also includes sediment removal with a suction dredge that could entrain Spring Run individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Spring Run occurring near the removal. The low occurrence of Chinook Salmon in monitoring efforts suggest that any potantil imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

Under Alternative 1, Reclamation is expanding the transfer window to November from the current July to September. Expanding the transfer window could lead to increased pumping at Jones and Banks Pumping Plants, when capacity is available. The Figures below show when capacity is available under Alternative 1 and the No Action Alternative, in terms of exceedances, years in the model period of record, and average by water year types. These values are total available, and are not filtered for the pattern on which water might be acquired for transfer. The pattern of acquisition could decrease these values, as well as reoperation of storage that might be required, or the water cost of meeting D-1641. Prior estimates indicate that approximately 50% of the capacity in the figures below would be useful for water transfers given these timing and upstream considerations. In addition, a 20-30% surcharge on acquisition might be necessary to accommodate the salinity related inefficiencies that arise in operations. Based on the figures below and these additional estimates, expanding the water transfer window could result in an additional approximately 50 TAF of pumping in most yeartypes. As more stored water is available from CVP and SWP reservoirs to pump in wetter yeartypes, most of the available capacity for transfers is in drier yeartypes (Figures O.3-83 through O.3-85).

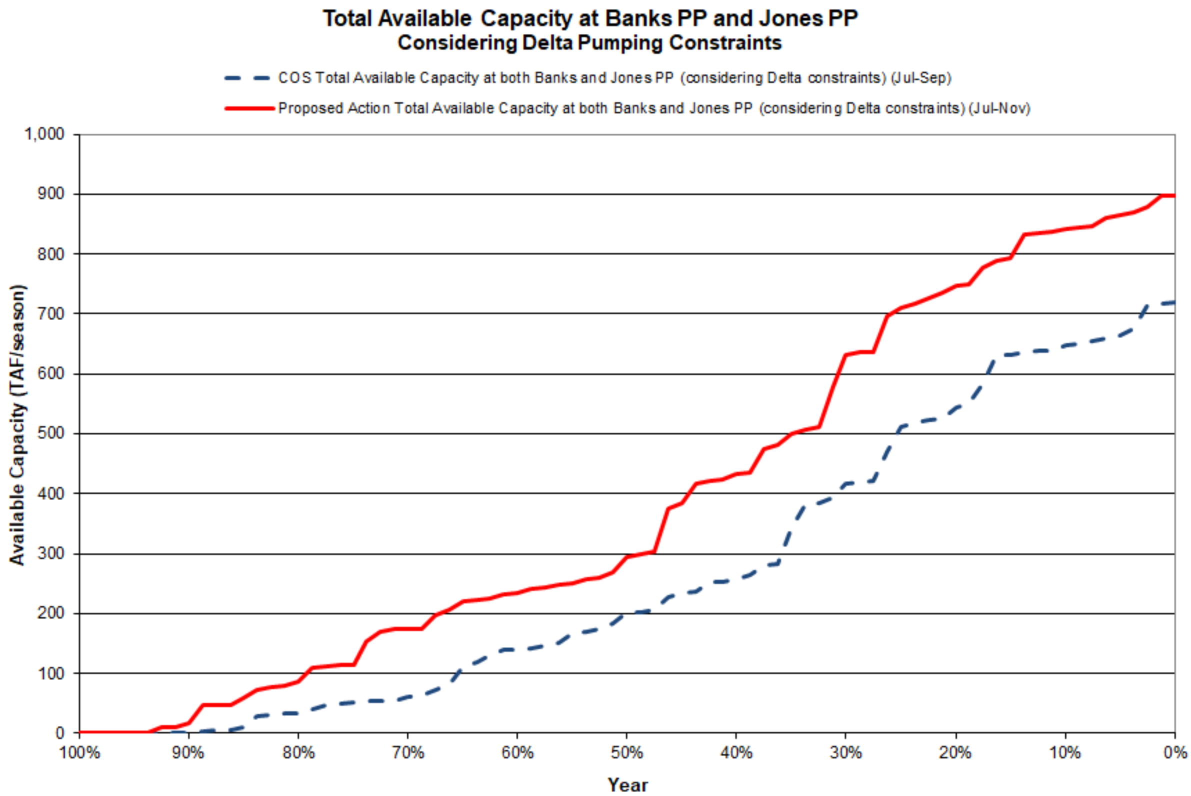

Figure O.3-83. Exceedance of Available Capacity for Transfers at Jones and Banks under the Alternative 1 and No Action Alternative

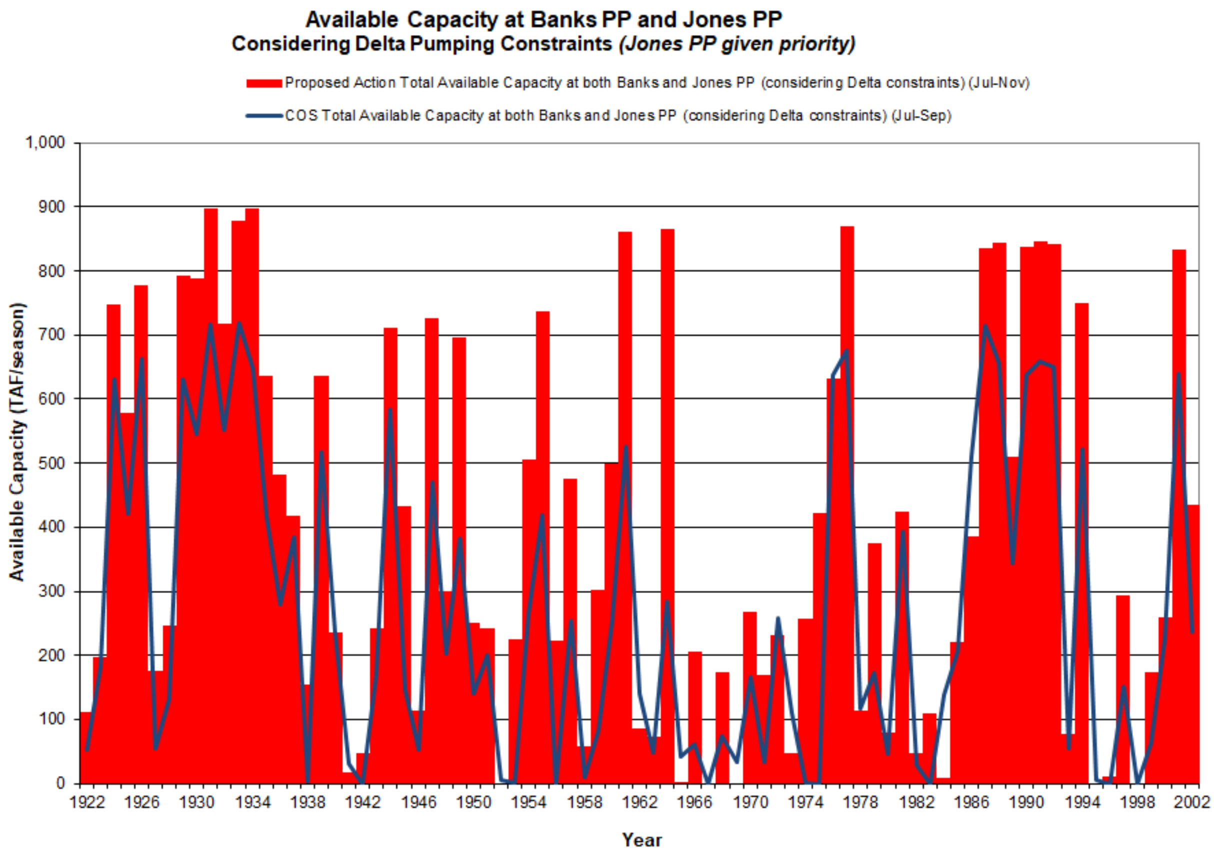

Figure O.3-84. Modeled Annual Maximum Available Capacity for Transfers under Alternative 1 and No Action Alternative, CalSim Period of Record (1922–2003)

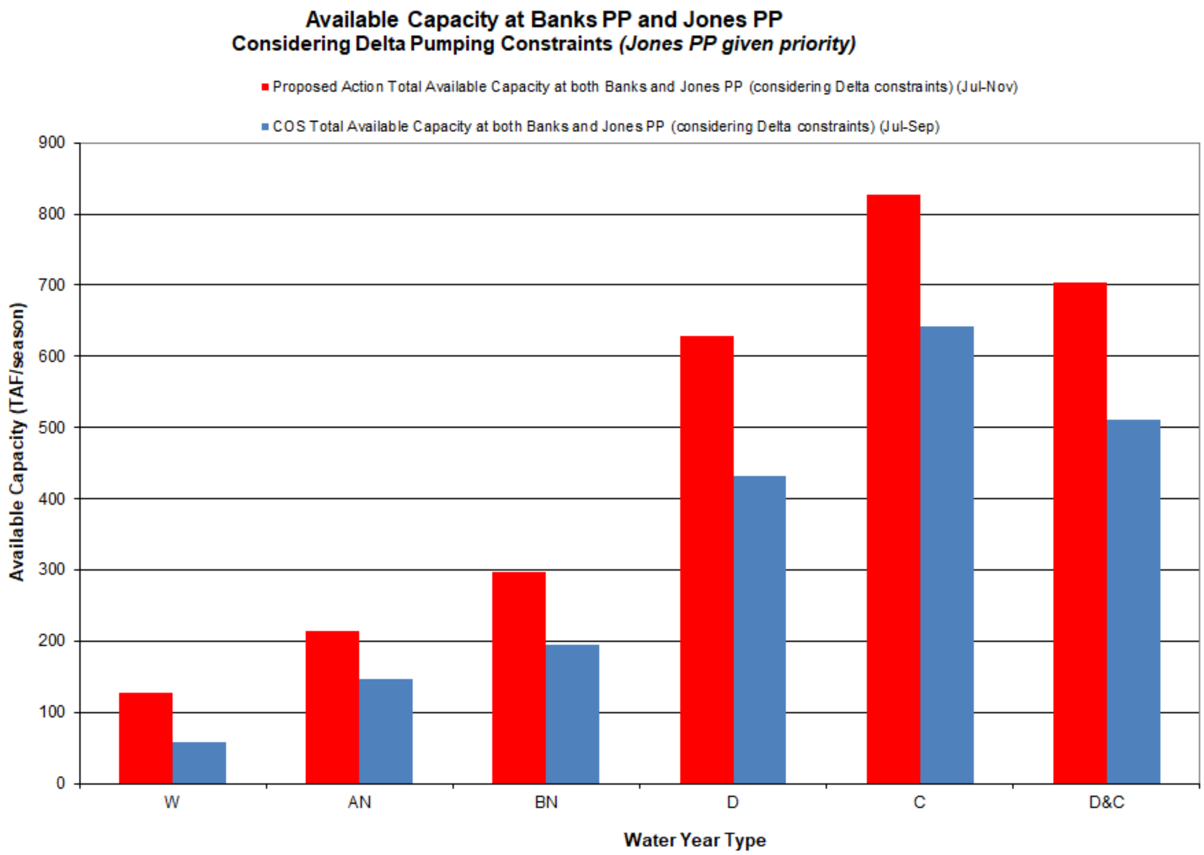

Figure O.3-85. Water Year Type Average Available Capacity at Jones and Banks Pumping Plants

Egg, aelvin, fry, and adult lifestages of Spring-Run Chinook Salmon would not be exposed to the effects of increased water transfers as they do not occur in the Delta during July through November. Juvenile Central Valley Steelhead are detected at Chipps Island between December and July with the highest abundance in March to May (Reclamation 2019). Thus, only the very early or late migrants could potential be exposed to water transfers that occur during this time. These early or late migrant uvenile Spring-Run Chinook Salmon could be exposed to increased effects of entrainment, routing, and decreased Delta survival (see OMR management section) as a result of the expanded water transfer window. Increased flows during conveyance in the Sacramento River could provide small survival benefits to migrating juveniles (Perry et al. 2018).

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Spring-Run Chinook Salmon are present in the Delta between mid-November and early June with a peak in April (Reclamation 2019). The application of aquatic herbicide to the waters of Clifton Court Forebay will occur during the summer months between 28 June and 31 August. Herbicide application can occur before 28 June if tempertures are ≥ 25˚C but Spring-Run Chinook Salmon are unlikley to be present at these temperature. Thus, the probability of exposing

Spring-Run Chinook Salmon to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

A number of programmatic actions are proposed to improve salvage efficiency of TFCF, including installing a carbon dioxide injection device to allow remote controlled anesthetization of predators in the secondary channels of the Tracy Fish Facility. These actions could potentially benefit juvenile Spring-Run Chinook Salmon through greater salvage efficiency.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see figures in Appendix F of the ROC LTO BA: WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race). Risks to these few individuals would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*), the selected in-water work window, and the small scale of the in-water construction. For juvenile Spring-Run Chinook Salmon that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Predator control efforts at Skinner Fish Facility under Alternative 1 to reduce predation on listed fishes following entrainment intopre Clifton Court Forebay could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. A small number of juvenile Spring-Run Chinook Salmon could be impacted by predtor removal activies depending on the technique employed. However, increases in survival may offset any loss due to removal activities.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May to meet salinity standards set by the State Water Resources Control Board and Suisun Marsh Preservation Agreement provides water quality benefits to Spring-Run Chinook Salmon habitat. This beneficial operation coincides with downstream migration of juvenile Spring-Run Chinook Salmon (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Spring-Run Chinook Salmon in Montezuma Slough thus, the proportion of the total run utilizing this route is unknown. Spring-Run Chinook Salmon typically migrate through the estuary several months before spawning, but an extended delay in the estuary may affect their ability to access their natal spawning streams. Spring-Run Chinook Salmon generally utilize high stream flow conditions during the spring snowmelt to assist their upstream migration. Rapid upstream movement may be needed to take advantage of a short duration high stream flow event, particular in dry years when high flow events may be uncommon. If the destination of a pre-spawning adult Salmon is among the smaller tributaries of the Central Valley, it may be important for migration to be unimpeded, since access to a spawning area could diminish with receding flows. However NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.7 ft/s, so that juvenile Spring-Run Chinook Salmon would be excluded from entrainment.

The Morrow Island Distribution System (MIDS) diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, its unlikely juvenile Central Valley Spring-Run Chinook Salmon will be entrained into the water distribution system, since Spring-Run Chinook Salmon have not be caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor Spring-Run Chinook Salmon.

Goodyear Slough Outfall improves water circulation in the marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Spring-Run Chinook Salmon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits juvenile Spring-Run Chinook Salmon in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat No Spring-Run Chinook Salmon are detected in the Delta between June and September. Therefore, no effects would occur as a result of the Suisun Marsh Salinity Control Gate operation.

Potential changes to aquatic resources from Clifton Court predator management efforts

Predator control efforts at Clifton Court Forebay under Alternative 1 could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts during the summer in-water work window.

Potential changes to aquatic resources from San Joaquin Basin Steelhead Telemetry Study

Potential changes to aquatic resources due to reintroduction changes from Fish Conservation and Culture Laboratory

Potential changes to aquatic resources from monitoring

Less than 2% of the estimated Spring-Run Chinook Salmon population, as indexed by the Red Bluff Rotary Screw Trap data, is collectively captured by the salmonid monitoring programs that support CVP operations (Reclamation 2019). Because such a small percentage of the estimated Spring-Run Chinook Salmon juvenile production is captured in the monitoring programs, the effects of the monitoring programs are not likely to have effects to the Spring-Run population.

O.3.3.8.5 Central Valley Fall-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Hydrodynamic changes associated with river inflows and South Delta exports have been hypothesized to adversely affect juvenile Chinook Salmon in two distinct ways: 1) "near-field" mortality associated with entrainment to the export facilities, 2) "far-field" mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be most appropriately assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team's (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver- linkage-outcome (DLO) framework for specifying how water project operations (the "driver") can influence juvenile salmonid behavior (the "linkage") and potentially cause changes in survival or routing (the "outcome"). The SST concluded altered "Channel Velocity" and altered "Flow Direction" were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O.3-86 provides a simplified conceptual model of the DLO defined by the CAMT SST.

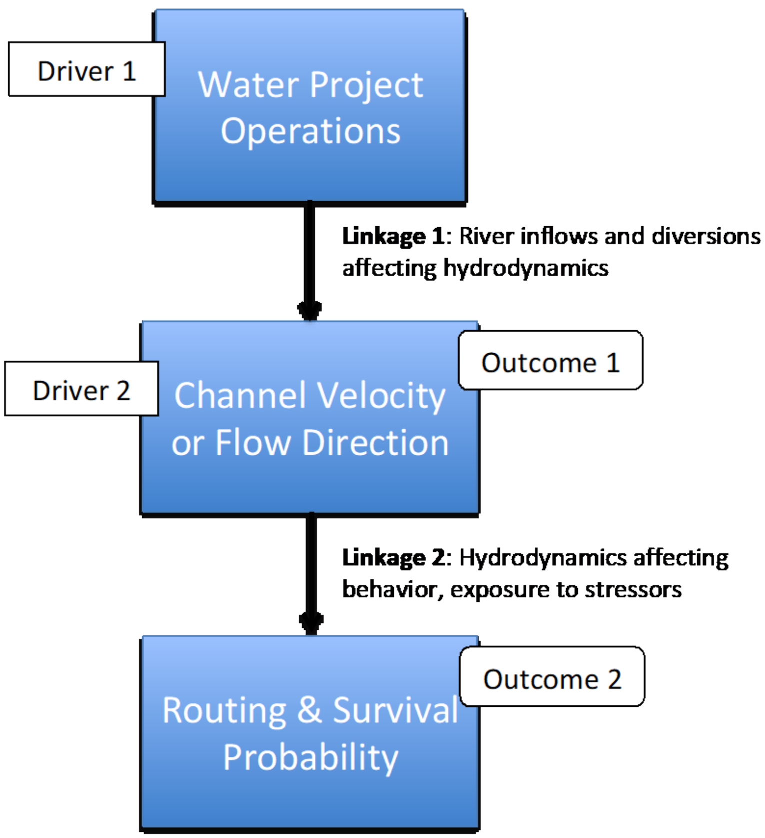

Figure O.3-86. Conceptual Model for Far-Field Effects of Water Project Operations on Juvenile Salmonids in the Delta. This CM Is a Simplified Version of the Information Provided by the CAMT SST

Though many juvenile salmonid tagging studies have been conducted in the Delta, the focus has primarily been on estimating reach survival and routing- not assessing export-related hydrodynamic mechanisms defined by the SST's DLO. In fact, most tagging studies have targeted areas of the Delta where "Channel Velocity" and "Flow Direction" may not be appreciably affected by exports (e.g., Newman and Brandes 2010; Perry et al. 2010; 2012; 2015; Michel et al. 2013).

In order to assess the potential for water project operations to influence survival and routing, we analyzed Delta hydrodynamic conditions by utilizing outputs from DSM2 Hydro modeling. Our analysis of DSM2 output is based on our previous work creating map-based visualizations of spatial hydrodynamic patterns at the scale of the Delta. The map-based approach allows us to identify a ‘footprint’ of the hydrodynamic differences between scenarios. The maps are based on a comparative metric, proportion overlap (more below), to capture channel-level hydrodynamic details as a single number for color-scaled mapping of Delta channels. Our previous work made clear that spatial patterns were more easily discerned by mapping comparative metrics than by mapping descriptive metrics in multiple panels.

The objective of the comparative metric is to summarize the water velocity time series for each channel and scenario such the channel-level comparison is captured in a single number. For the proportion overlap metric, kernel density estimates are calculated on each time series. The kernel density estimates represent a non-parametric smoothing of the empirical distribution of time series values. The proportion overlap of two kernel density estimates is calculated with the following steps: 1) calculate the total area under the curve (AUC_t) as the sum of the AUC for each density estimate, 2) calculate the AUC of the overlapping portions (AUC_o) of the two density distributions being compared, and 3) calculate the overlapping proportion of the density distributions as AUC_o/AUC_t. Proportion overlap is naturally bound by zero and one; a value of zero indicates no overlap and a value of one indicates complete overlap. Lower values of proportion overlap identify channels demonstrating larger differences in a scenario comparison.

The proportion overlap metric is best applied over relatively short time periods because seasonal and annual variation in water velocity can overwhelm differences between scenarios. Thus, we calculated proportion overlap for every DSM2 channel for two seasons (Dec-Feb, May-Mar) in each water year (1922–2003). We excluded DSM2 output from water year 1921 to allow for an extensive burn-in period. We calculated proportion overlap based on hourly DSM2 output. Because each season was roughly 90 days, each comparison involved roughly 4,300 DSM2 values (2 scenarios * 24 hours * 90 days) for each channel.

Because we calculated proportion overlap for each channel in each water year, we summarized the proportion overlap values prior to mapping (i.e., not feasible to map proportion overlap for every comparison in every water year). To summarize, we found the minimum and median proportion overlap for each channel for each water year type for each comparison. The minimum values represent the maximum expected effect. The median values represent the average expected effect. Note that the year with the minimum (or median) proportion overlap for one channel might not be the same year as for another channel.

O.3.3.8.6 Entrainment

Zeug and Cavallo (2014) analyzed > 1000 release groups representing, more than 28 million coded wire tagged juvenile fish including winter, Late Fall-Run and Fall-Run Chinook Salmon. This data is extremely useful because it represents large release groups of tagged smolts where the number of fish representing each release group lost to entrainment at the export facilities has been estimated. Estimating loss from “raw” salvage is problematic because the actual stock or basin of origin is often unknown (e.g., poor performance of length-at-date curves). Furthermore, with “raw” salvage, the number of smolts produced and potentially exposed to entrainment is unknown. The CWT salvage data analyzed by Zeug and Cavallo (2014) overcomes these deficiencies and provides the most appropriate basis for defining stock-specific categories of entrainment risk.

The average proportion Sacramento River-origin Fall-Run Chinook salvaged over a 15-year period was 0.0001 and the proportion of mortality accounted for by entrainment averaged 0.0003 (Zeug and Cavallo 2014). Salvage increased with increasing exports but loss never exceeded 1% regardless of export rate. Late Fall-Run Chinook Salmon juveniles were salvaged at a higher rate than any other race (0.02% of each release group) and entrainment related mortality accounted for almost 1% of total mortality on average (Zeug and Cavallo 2014). Proportional loss of Late-Fall remained low until exports exceeded ~9,000 cfs when proportional loss could approach 8% (Zeug and Cavallo 2014). In the December through February period when Late Fall-Run Chinook Salmon are most abundant, Alternative 1 proposes an average total export rate slightly higher than No Action Alternative (196 cfs; Figure O1-1 in Appendix O, Attachment 1) and will therefore have a similar entrainment risk. Total exports proposed for Alternative 1 in March-June (1,752 cfs higher than No Action Alternative; Figure O1-2 in Appendix O, Attachment 1) when juvenile Fall-Run Chinook Salmon are most abundant in the Delta, will increase entrainment risk relative to No Action Alternative, but entrainment losses for Fall-Run Chinook Salmon will be extremely low. Entrainment risk will also increase for Late Fall-Run Chinook Salmon and losses will likely be higher relative to Fall-Run.

Routing

Routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 1 were evaluated using DSM2 as described above. Juvenile Fall-Run Chinook Salmon abundance in the Delta is greatest between February and May and Late Fall-Run Chinook Salmon are present in the Delta between November and July with peaks in January through February and April through May (Table FR_1, LFR_1). In the December through February period, velocity overlap between Alternative 1 and No Action Alternative in the Sacramento River main stem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was >75% in critically dry, dry, below normal and above normal years (Figure O1-3 in Appendix O, Attachment 1). In wet years, velocity overlap in this reach was ≤ 50%. Velocities were higher under Alternative 1 in all water year types indicating routing into the interior Delta would be lower relative to No Action Alternative (Perry et al. 2015). In the March to May period, comparison of Alternative 1 and No Action Alternative revealed similar patterns of velocity overlap as described for the December through February period (Figure O1-4 in Appendix O, Attachment 1) indicating routing into the interior Delta would be lower under Alternative 1 during March to May.

Fall-Run and Late Fall-Run juveniles originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can be exposed to hydrodynamic project effects that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 1 and No Action Alternative scenarios (Figure O1-5 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 1 to No Action Alternative in the March to May period (Figure O1-6 in Appendix O, Attachment 1).

O.3.3.8.7 Through-Delta Survival

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. This study was performed with hatchery-origin Late Fall-Run Chinook Salmon and there is uncertainty regarding the applicability of those results to Fall-Run. However, this study represents the best information avaiable on survival of juvneile Chinook Salmon in the Delta.To examine potential effects of the proposed project, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, velocity distributions for Alternative 1 relative to No Action Alternative were most different in wet years (70.9%) with higher velocities in Alternative 1. Velocities were also greater for Alternative 1 relative to No Action Alternative in dry, below normal and above normal years although overlap was greater (≥79%; Figure O1-7 in Appendix O, Attachment 1). In critically dry years, velocity distributions were almost identical (95.4%; Figure O1-7 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, there was a similar pattern where velocities under Alternative 1 were higher than No Action Alternative in wet, above normal and below normal years and similar in dry and critically dry years (Figure O1-8 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 1 and No Action Alternative was ≥78% across all water year types with greater velocities under Alternative 1 (Figure O1-9 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 1 and No Action Alternative scenarios was high with all values ≥82% and greater velocities under Alternative 1 (Figure O1-10 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 1, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the "transitional" region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 1 relative to No Action Alternative exhibited high overlap in all water year types (≥84.3%; Figure O1-11 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 1 and No Action Alternative in critically dry, dry and below normal water years (≥90.1%) and moderate in wet and above normal years (53.6-75.1%; Figure O1-12 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 1 and No Action Alternative (≥83.2%; Figure O1-13 in Appendix O, Attachment 1). Velocities were lower under Alternative 1 in dry, below normal and wet year and higher in above normal years (Figure O1-23 in Appendix O, Attachment 1). At the Head of Middle River in the March to May period, overlap between Alternative 1 and No Action Alternative was moderate in above normal years (57.7%) and higher in all other water year types ≥ 73% (Figure O1-14 in Appendix O, Attachment 1). In above normal years, velocities were higher under Alternative 1 and lower in all other water year types (Figure O1-14 in Appendix O, Attachment 1).

Potential changes to aquatic resources due to OMR management

See section on seasonal operations, which includes OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

The Delta Cross Channel may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Fall-Run Chinook Salmon in the Sacramento River past West Sacramento, which is near the DCC, occurs from February through May (Table FR_1). Therefore, the DCC is closed for the majority of the juvenile Fall-Run Chinook Salmon migration period in the Sacramento River and as such the proportion of fish exposed to an open DCC would be low. Juvenile

Fall-Run Chinook Salmon that are entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010).

Potential changes to aquatic resources due to the Temporary Barriers Project

The Temporary Barriers Project (TBP) consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions and one rock barrier to improve San Joaquin River salmonid migration in the south Delta. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, Grant Line Canal near Tracy Boulevard Bridge, and the head of Old River. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30. The head of Old River Barrier is only installed from September 16 to November 30 to improve flow and dissolved oxygenconditions in the San Joaquin River for the immigration of adult Fall-Run Chinook Salmon.

The proportion of juvenile Fall-Run Chinook Salmon exposed to the TBP depends on their annual timing of installation and removal. Due to their location, primarily migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Fall-Run Chinook Salmon in the Delta at Mossdale is February through May (seeTable FR_1 of the ROC LTO BA). The Head of Old River Barrier would have no effect on juvenile Fall-Run Chinook Salmon if installed from September 16 to November 30 as juvenile Fall-Run Chinook Salmon are largely absent from this section of the San Joaquin River during this time period (see Table FR_1 of the ROC LTO BA). If the agricultural barriers are operating as early as April 15 then they have the potential to expose a large proportion of the juvenile Fall-Run Chinook Salmon migrating down the San Joaquin River. When the Head of Old River barrier is not in place, acoustically tagged juvenile Chinook Salmon have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). Flap gates tied up on agricultural barriers from May 16 to May 31 would help to reduce the negative effect of the barriers during this period. However, juveniles migrating before or after this period could be exposed to the agricultural barriers with flaps down which apparently decreases passage success and survival (DWR 2018). Therefore, the potential negative effects of the agricultural barriers depends on when they are installed and whether the flap gates are down or tied up but overall would be medium to high.

Potential changes to aquatic resources due to Contra Costa Water District operations

As discussed in Chapter 3, CCWD’s operations in Alternative 1 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994; 2009a). Therefore, CCWD’s operations, including operation of the Rock Slough Intake, under Alternative 1 would remain unchanged from the current operations.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Fall-Run/Late presence near the Rock Slough Intake. From 1999 to 2011, the 11 years prior to construction of the RSFS, CCWD’s Fish Monitoring Program collected 23 juvenile Fall-Run/Late Fall-Run Chinook Salmon at the Rock Slough Headworks and Contra Costa Pumping Plant #1. Since construction of the Rock Slough Fish Screen in 2012, no Fall-Run/Late Fall-Run Chinook Salmon have been collected behind the fish screen. CCWD's Fish Monitoring Program also samples at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Fall-Run/Late Fall-Run Chinook Salmon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD's operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Central Valley Fall-Run /Late Fall-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Salmon can be "drawn" into the south Delta under reverse flows and high CVP and SWP pumping rates.

One indicator of reverse flows is the net flow in Old and Middle Rivers (OMR). Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect net reverse flow in Old and Middle Rivers (OMR), and any effect that diversions at Rock Slough Intake would have in the Old and Middle River corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the Old and Middle River corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstems of the Sacramento River or the San Joaquin River and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, we examine the combined effect of all three intakes. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Central Valley Fall-Run/Late Fall-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is not significant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 1 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant, however several years of monitoring have failed to consistently capture any salmonids during the winter Delta Smelt surveys (1996 to 2004) in Lindsey Slough or Barker Slough. Captures of Chinook Salmon have usually occurred in the months of February and March and typically are only a single fish per net haul (http://www.delta.dfg.ca.goc/data/nba). Most Chinook Salmon captured have come from Miner Slough, which is a direct distributary from the Sacramento River via Steamboat and Sutter Sloughs. Few if any San Joaquin River-origin Fall-Run Chinook Salmon are expected to be exposed to the North Bay aqueduct because it is not on the migration route of this species.

Alternative 1 also includes sediment removal with a suction dredge that could entrain Fall Run individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Fall Run occurring near the removal. The low occurrence of Chinook Salmon in monitoring efforts suggest that any potantil imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Potential Effects from Clifton Court Aquatic Weed Removal

Few if any juvenile Fall-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Fall-Run Chinook Salmon are present in the Delta between mid-November and early June with a peak in April (See Table_WR1 of the ROC LTO BA). The application of aquatic herbicide to the waters of Clifton Court Forebay will occur during the summer months between 28 June and 31 August. Treatment could occur before 28 June if tempertures exceed 25 ˚C; however, Fall-Run Chinook Salmon are not expected to occure at that temperature. Thus, the probability of exposing Fall-Run Chinook Salmon to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June. The overall effect of this action is low.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Although actions at the Tracy facility could positively affect juvenile Fall-Run Chinook Salmon through greater salvage efficiency, only small proportions of Fall-Run Chinook Salmon are lost at the CVP (Zeug and Cavallo 2014).

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Chinook Salmon entrined into Clifton Cout Forebay. However, given that only small proportions of Fall-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014), the population-level positive effect of this action would be low. Larger proportions of Late Fall-Run Chinook Salmon are lost at the facilities and this action would have a larger effect for this run.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May coincides with downstream migration of juvenile Fall-Run Chinook Salmon (Reclamation 2019). NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.2 ft/s (for Delta Smelt protection), so that juvenile Fall-Run Chinook Salmon would be excluded from entrainment.

NMFS (2009: 438) considered it unlikely that juvenile Winter-Run Chinook Salmon, would be entrained by the three unscreened 48-inch culverts that form the Morrow Island Distribution System (MIDS) water intake, as a result of their larger size and better swimming ability relative to the size of Fall-Run Chinook Salmon observed to have been entrained (<45 mm), and also because the location of the MIDS intake on Goodyear Slough is not on a migratory corridor for listed juvenile salmonids. Although Fall-Run Chinook Salmon have been entrained at this facility, only a small proportion of total migrants are likely to encounter it.

NMFS (2009: 438) concluded that it would be unlikely that Chinook Salmon would encounter or be negatively affected by the Goodyear Slough outfall given its location and design, which is intended to improve water circulation in Suisun Marsh and therefore was felt by NMFS (2009: 438) to likely be of benefit to juvenile salmonids by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat Juvenile Fall-Run Chinook Salmon are abundant in the Delta in December and January and April and May (Reclamation 2019). Late Fall-Run Chinook Salmon are most abundant from January through April. Small fractions of each run could be exposed to Fall Delta Smelt habitat actions. For fish that are exposed, increased turbidity may reduce susceptibility to predation and increase through-Delta survival.

Potential changes to aquatic resources from Clifton Court predator management efforts

Pre-screen survival of juvenile Chinook Salmon has been shown to be low (Gingras 1997) and predation is thought to be a major source of mortality. Analyses by Zeug and Cavallo (2014) indicate that only small proportions of Sacramento River-origin Fall-Run Chinook Salmon arrive at the facilities. However, moderte proportions of San Joaquin River-origin Fall-Run Chinook Salmon arrive at the facilities. For fish that are entrained into Clifton Cout Forebay, predator control may increase pre-screen survival. There is potential for San Joaquin River- and Mokelumne River-origin adult Fall-Run Chinook Salmon to be impacted by predator capture activities. Survival benefits of predator management may offset impacts to the occasional capture of adult Fall-Run. The overall effect of the action is low for Sacramento River-Origin fish and moderte for San Joaquin River and Mokelumne River-origin fish.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from Fish Conservation and Culture Laboratory

O.3.3.8.8 Central Valley Steelhead

Potential changes to aquatic resources due to seasonal operations

Entrainment

ICF (2018) analyzed salvage of Central Valley Steelhead at the CVP and SWP between 2003 and 2017 and found that salvage increased with export rate and decreased with San Joaquin River flow. Salvage also decreased with OMR flow. However, OMR is a metric comprised of both exports and San Joaquin River flow which complicates attempts to understand individual effects.

In the December through February period, Alternative 1 proposes an average total export rate slightly higher than the No Action Alternative (196 cfs; Figure O1-1 in Appendix O, Attachment 1) and will therefore have a similar entrainment risk. Total exports proposed for Alternative 1 in March-June (1,752 cfs higher than No Action Alternative; Figure O1-2 in Appendix O, Attachment 1) when juvenile Central Valley Steelhead are most abundant in the Delta at Chipps Island (Reclamation 2019), will increase entrainment risk relative to No Action Alternative.

Routing

Routing of juvenile Central Valley Steelhead into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 1 were evaluated using DSM2. Juvenile Central Valley Steelhead are present in the Sacramento River at Hood upstream of the first distributary junctions between November and early June with peak abundance from February to early June (Reclamation 2019). In the December through February period, velocity overlap between Alternative 1 and No Action Alternative in the Sacramento River main stem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was >75% in critically dry, dry, below normal and above normal years (Figure O1-3 in Appendix O, Attachment 1). In wet years, velocity overlap in this reach was ≈ 50%.

In the March to May period Comparison of Alternative 1 and No Action Alternative revealed similar patterns of velocity overlap as described for the December through February period (Figure O1-4 in Appendix O, Attachment 1) indicating routing into the interior Delta would be lower under Alternative 1 during March to May.

Through-Delta Survival

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. This study was performed with hatchery-origin Late Fall-Run Chinook Salmon and there is uncertainty regarding the applicability of those results to steelhead. However, this study represents the best information avaiable on survival of juvneile salmonids in the Delta.To examine potential effects of Alternative 1, changes in velocity distributions were examined assuming a positive correlation between discharge and mean water column velocity for the Sacramento River at Walnut Grove and Steamboat Slough, which are both in this “transitional” region. During the December to February period at Walnut Grove, velocity distributions for Alternative 1 relative to No Action Alternative were most different in wet years (70.9%) with higher velocities in Alternative 1. Velocities were also greater for Alternative 1 relative to No Action Alternative in dry, below normal and above normal years although overlap was greater (≥79%; Figure O1-7 in Appendix O, Attachment 1). In critically dry years, velocity distributions were almost identical (95.4%; Figure O1-7 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, there was a similar pattern where velocities under Alternative 1 were higher than No Action Alternative in wet, above normal and below normal years and similar in dry and critically dry years (Figure O1-8 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 1 and No Action Alternative was ≥78% across all water year types with greater velocities under Alternative 1 (Figure O1-9 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 1 and No Action Alternative scenarios was high with all values ≥82% and greater velocities under Alternative 1 (Figure O1-10 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 1, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the “transitional” region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 1 relative to No Action Alternative exhibited high overlap in all water year types (≥84.3%; Figure O1-11 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 1 and No Action Alternative in critically dry, dry and below normal water years (≥90.1%) and moderate in wet and above normal years (53.6-75.1%; Figure O1-12 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 1 and No Action Alternative (≥83.2%; Figure O1-13 in Appendix O, Attachment 1). Velocities were lower under Alternative 1 in dry, below normal and wet year and higher in above normal years (Figure O1-23 in Appendix O, Attachment 1). At the Head of Middle River in the March to May period, overlap between Alternative 1 and No Action Alternative was moderate in above normal years (57.7%) and higher in all other water year types ≥ 73% (Figure O1-14 in Appendix O, Attachment 1). In above normal years, velocities were higher under Alternative 1 and lower in all other water year types (Figure O1-14 in Appendix O, Attachment 1).

Potential changes to aquatic resources due to OMR management

See section on Seasonal Operations, which includes OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

Significant flow and many juvenile Central Valley Steelhead enter the central Delta when the DCC gates are open. Mortality of juvenile Central Valley Steelhead entering the central Delta is higher than for those continuing downstream in the Sacramento River. The peak migration of juvenile Central Valley Steelhead in the Sacramento River past Knights Landing, which is upstream of the DCC, occurs from January through February (Reclamation 2019). Therefore under Alternative 1, the continued operation of the DCC to protect the majority of the juvenile Central Valley Steelhead during their migration period in the Sacramento River would reduce the proportion of fish exposed to an open DCC and result in beneficial impacts to this life stage when compared to the No Action Alternative.

Potential changes to aquatic resources due to the Temporary Barriers Project

The Temporary Barriers Project (TBP) consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions and one rock barrier to improve San Joaquin River salmonid migration in the south Delta. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, Grant Line Canal near Tracy Boulevard Bridge, and the head of Old River. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30. The Head of Old River Barrier is only installed from September 16 to November 30 to improve flow and dissolved oxygenconditions in the San Joaquin River for the immigration of adult Fall-Run Chinook Salmon.

The proportion of juvenile Central Valley Steelhead exposed to the TBP depends on their annual timing of installation and removal. Due to their location, primarily juvenile Central Valley Steelhead migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Central Valley Steelhead in the San Joaquin River in the vicinity of the TBP (Mossdale) occurs in April and May (Reclamation 2019). If the agricultural barriers are operating as early as April 15, there is potential exposure to a large proportion of the juvenile Central Valley Steelhead migrating down the San Joaquin River.

When the Head of Old River barrier is not in place, acoustically tagged juvenile Central Valley Steelhead have demonstrated a high probability of selecting the Old River route (Buchanan 2018[PC1]), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Central Valley Steelhead migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Central Valley Steelhead passage past the agricultural barrier was improved (DWR 2018). Therefore, although Alternative 1 does not include HORB, which could result in negative impacts to Central Valley Steelhead juvenile migration, the improvements to the agricultural barriers (including flap gates tied up from May 16 to May 31) would help to reduce the negative effect of the barriers on migrating juvenile Central Valley Steelhead during this period relative to No Action Alternative. However, juvenile Central Valley Steelhead migrating before or after this period could be exposed to the agricultural barriers with flaps down, which apparently decreases passage success and survival (DWR 2018). Therefore, the potential negative effects of the agricultural barriers under Alternative 1 on juvenile Central Valley Steelhead depends on when they are installed and whether or not the flap gates are down.

Potential changes to aquatic resources due to Contra Costa Water District operations

As discussed in Chapter 3, CCWD's operations in Alternative 1 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD's operations, including operation of the Rock Slough Intake, under Alternative 1 would remain unchanged from the current operations and the No Action Alternative.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Central Valley Steelhead presence near the Rock Slough Intake. From 1999 to 2011, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected 15 juveniles at the Rock Slough Headworks and Pumping Plant #1. Since construction of the Rock Slough Fish Screen, no Central Valley Steelhead have been collected behind the fish screen. CCWD's Fish Monitoring Program also samples at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Central Valley Steelhead at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD's operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Central Valley Steelhead are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile salmonids can be "drawn" into the south Delta under reverse flows and high CVP and SWP pumping rates. One indicator of reverse flows is the net flow in OMR. Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect OMR, and any effect that diversions at Rock Slough Intake under Alternative 1 would have in the OMR corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the Old and Middle River corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstems of the Sacramento or San Joaquin Rivers and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, the combined effect of all three intakes was examined. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Central Valley Steelhead.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is insignificant in comparison to the tidal excursion and mixing at this location. Although the diversions at Rock Slough Intake are not likely to impact juvenile Central Valley Steelhead, the aggregate effect of all water diversions in the Delta, including exports at Jones and Banks Pumping Plants can affect channel velocity.

In summary, CCWD's operations under Alternative 1 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Under Alternative 1, there would be no changes to operational criteria at the NBA's BSPP relative to current op. Juvenile Central Valley Steelhead could occur in the vicinity of the BSPP; however, the fish screens used at the facility are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment and greatly minimize impingement of fish against the screen itself (NMFS 2009). In addition, the location of the facility is well off the typical migration corridor of juvenile Central Valley Steelhead (NMFS 2009: 417). No juvenile Central Valley Steelhead have been captured during CDFW monitoring surveys from 1996 to 2004 (http://www.delta.dfg.ca.goc/data/nba).

Alternative 1 also includes sediment removal with a suction dredge that could entrain steelhead individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb steelhead occurring near the removal. The low occurrence of steelhead in monitoring efforts suggest that any potential imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

Central Valley Steelhead juveniles could be exposed to increased entrainment, predation, and decreased through-Delta survival as a result of the expanded transfer window under Alternative 1, but as the peak of the juvenile out-migration is in the spring, effects are anticipated to be minimal. No other lifestages of Central Valley Steelhead would co-occur in time and space with water transfers from the Delta.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Under Alternative 1, the application of aquatic herbicide to the waters of CCF will occur between 28 June and 31 August. Treatment could occur prior to 28 June at tempertures $\geq 25^{\circ}$C; however, steelhead would not be expected to occur at these temperatures. Treatment could also occur after 31 August if protective measures have not been triggered but few if any steelhead would be expected in the Delta during that time period. Juvenile Central Valley Steelhead abundance in the Delta peaks between March and May (Reclamation 2019). Based on typical water temperatures in the vicinity of the salvage facilities during this period, the water temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June. As such, it is unlikely that juvenile Central Valley Steelhead would be rearing near this location after mid-June and the potential application of aquatic herbicide would only occur well after the peak out-migration period (Reclamation 2019) and therefore Central Valley Steelhead are not expected to be exposed to herbicide application activities.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Small proportions of Sacramento River-origin Central Valley Steelhead and moderate proportions of Mokelumne River and San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the Tracy Fish Facility. However, for fish that arrive at the facility, the proposed improvements resulting in greater salvage efficiency under Alternative 1 are likely to increase survival of juvenile Central Valley Steelhead.

As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, none to a few late migrants or early migrants have the potential to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements. Risks of decreased Central Valley Steelhead juvenile salvage during construction would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, Mitigation Measures). Steelhead may be impacted by operation of CO_2 injection device but this would likely be offset by reduced predation at the facility.

Skinner Fish Facility improvements under Alternative 1 to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead. Steelhead may be impacted by predator control activities but this would likely be offset by reduced predation at the facility.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May under Alternative 1 coincides with downstream migration of juvenile Central Valley Steelhead (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Central Valley Steelhead thus, the proportion of the total run utilizing this route is unknown. However NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

Under Alternative 1, the Roaring River Distribution System water diversion intake is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.2 ft/s (for Delta Smelt protection), excluding juvenile Central Valley Steelhead from entrainment (NMFS 2009: 437).

The MIDS diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, it is unlikely juvenile Central Valley Steelhead will be entrained into the water distribution system because Central Valley Steelhead have not been caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor for Central Valley Steelhead. The operation of the MIDS under Alternative 1 would not impact Central Valley Steelhead.

Goodyear Slough Outfall improves water circulation in the Suisun Marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Central Valley Steelhead are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits Central Valley Steelhead in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat Central Valley Steelhead juveniles are in the Delta in the spring. Reclamation proposes to conduct actions for Fall Delta Smelt Habitat in the fall, as adult Central Valley Steelhead are migrating upstream. Fall Delta Smelt Habitat actions are unlikely to affect adult Central Valley Steelhead.

Potential changes to aquatic resources from Clifton Court predator management efforts

Clifton Court predator management under Alternative 1 could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead. Some steelhead may be impacted by predator control activities but this would likely be offset by reduced predation at the facility.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from Fish Conservation and Culture Laboratory

Potential changes to aquatic resources from monitoring

Population estimates for wild Steelhead remain outstanding in the Central Valley, therefore it is difficult to quantify the effects of the monitoring on Steelhead populations. However, most existing monitoring programs in the Central Valley and Delta/SF Estuary are not designed to capture Steelhead, which are much larger than Chinook Salmon upon river and Delta entry. Existing programs likely have poor capture efficiency for collecting and retaining Steelhead. Therefore, it is unlikely the monitoring programs have any effects to the population.

O.3.3.8.9 North American Green Sturgeon Souther DPS

Potential changes to aquatic resources due to seasonal operations

Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to negatively impact southern DPS Green Sturgeon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, 2) “far-field” mortality resulting from altered hydrodynamics. The SST completed a thorough review of this subject and defined a driver- linkage-outcome (DLO) framework for specifying how water project operations (the “driver”) can influence juvenile salmonid behavior (the “linkage”) and potentially cause changes in survival or routing (the “outcome”). A similar analysis is not available for southern DPS Green Sturgeon.

Entrainment

As described by NMFS (2009: 386), impacts to the migratory corridor function of juvenile and subadult Green Sturgeon critical habitat from south Delta exports are less clear than for juvenile salmonids because Green Sturgeon spend 1 to 3 years rearing in the Delta environment before transitioning to their marine life history stage. During this Delta rearing phase, Green Sturgeon are free to migrate throughout the Delta. In the conceptual model, it is hypothesized that higher rates of exports may result in higher rates of entrainment. However, estimating entrainment risk from raw salvage data is not possible due to a lack of information on the number of juvenile Green Sturgeon potentially exposed to salvage.

Juvenile southern DPS Green Sturgeon (> 5 mo) are present in the Delta all year and subadults are most abundant from June through November. In the June through September period under Alternative 1 Reclamation proposes an average total export rate slightly higher than No Action Alternative (188 cfs; Figure O1-15 in Appendix O, Attachment 1) and will, therefore, have a similar entrainment risk. Total exports proposed for Alternative 1 in September-November (776 cfs higher than No Action Alternative; Figure O1-16 in Appendix O, Attachment 1) are unlikely to measurably increase entrainment risk relative to No Action Alternative.

Juvenile White and Green Sturgeon are infrequent at the TFCF, but may occur in the facility salvage year-round. Salvage is expected to be similar and slightly higher than No Action Alternative under Alternative 1.

Routing

Juvenile Green Sturgeon (>5 mo) are present in the Delta all year and subadults are most abundant from June to November (Reclamation 2019). Juvenile Green Sturgeon swim and behave quite differently and have distinct body morphologies and habitat associations in the Delta compared to outmigrating salmonids, so it is hypothesized that juvenile Green Sturgeon have different routing-hydrology survival relationships. Per NMFS (2009: 338), Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways. It is highly uncertain how Green Sturgeon routing would change with Alternative 1.

Through-Delta Survival

Little is known about the relationship between survival of juvenile Green Sturgeon and Delta hydrology. Green Sturgeon reside in the Delta for 1 to 3 years suggesting they encounter a variety of daily, seasonal, and annual hydrological conditions. The majority of Green Sturgeon in the Delta are likely not surviving through the Delta per se, but using these habitats for rearing and foraging. Per NMFS (2009: 338), Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways. For juvenile outmigrating Green Sturgeon present in these regions, increasing negative velocities under Alternative 1 may result in lower survival. However, as described above, there is a lower probability of juvenile Green Sturgeon residing in this area.

Potential changes to aquatic resources due to OMR management

See section above on Seasonal operations, which includes OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

Delta Cross Channel operations under Alternative 1 are changed to allow Reclamation to predict water quality exceedances and open the DCC if D-1641 criteria are predicted to be exceeded. This results in greater opening times of the DCC.

Little is known about the migratory behavior of juvenile Green Sturgeon in the Sacramento River basin. It is likely that juvenile Green Sturgeon (larger than the 75 mm) will not enter the Delta prior to their first winter and thus would not be exposed to the open DCC gates. If juvenile Green Sturgeon are exposed to the open DCC gates, they could be entrained into the central / south Delta and exposed to biological and physical conditions in this area, including potentially greater predation. It is likely that these fish will enter the Delta sometime in the winter or spring following their hatching upriver and encounter both types of gate configurations as they enter the Delta.

Potential changes to aquatic resources due to the Temporary Barriers Project

Agricultural Barriers (Temporary Barrier Project, TBP) are included in Alternative 1 and consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, and Grant Line Canal near Tracy Boulevard Bridge. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30.

Juvenile Green Sturgeon are present in the Delta in all months of the year. However, little is known about their spatial distribution. When the south Delta agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up (May 16 to May 31), outmigrating Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). It could be inferred that passage of outmigrating juvenile Green Sturgeon may also be improved when flap gates are tied up. Therefore, the potential negative effects of the agricultural barriers under Alternative 1 depends on when they are installed and whether the flap gates are down or tied up.

Potential changes to aquatic resources due to Contra Costa Water District operations

As discussed in Chapter 3, CCWD’s operations in Alternative 1 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD operations, includingoperation of the Rock Slough Intake, under Alternative 1 remain unchanged from current conditions and the No Action Alternative.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory routes for southern DPS Green Sturgeon (NMFS 2017c), approximately 18 miles from the Sacramento River and 10 miles from the San Joaquin River via the shortest routes. Water temperatures in Rock Slough range from lows of about 40 degrees F in winter (December and January) to over 70 degrees F beginning in May and continuing through October (NMFS 2017c).

A review of the 24 years of fish monitoring data (1994–2018) near the Rock Slough Intake both pre- and post-construction of the Rock Slough Fish Screen (RSFS) showed that southern DPS Green Sturgeon have never been observed in Rock Slough (CDFG 2002c; Reclamation 2016; NMFS 2017c; Tenera Environmental 2018b, ICF 2018). CCWD's Fish Monitoring Program also samples at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never observed southern DPS Green Sturgeon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

It is unlikely that juvenile, subadult, or adult Green Sturgeon would be present in Rock Slough due to the shallow depth, warm water temperatures, and low dissolved oxygen, which make the area unsuitable habitat during most of the year. Therefore, it is unlikely that Green Sturgeon will be entrained at Rock Slough Intake and unlikely that would be impacted by CCWD operations.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Overall, the modeled exports in Alternative 1 represent a significant increase in export levels and, thus, a greater risk to Green Sturgeon in the waters adjacent to the pumping facility compared to their historical vulnerability (NOAA 2009). However, Green Sturgeon are expected to be fully screened out of the facilities by the positive barrier fish screen in place at the pumping facility.

Alternative 1 also includes sediment removal with a suction dredge that could entrain juvenile Green Stugeon individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Green Sturgeon occurring near the removal. The low occurrence of Green Sturgeon in monitoring efforts suggest that any potential imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

As discussed under the Spring-Run Chinook Salmon water transfer section, under Alternative 1 Reclamation proposes to expand the transfer window to November. This extended transfer window could result in approximately 50 TAF of additional pumping per year in most years, with associated entrainment, routing, and through-Delta survival impacts. Please see the OMR management section for a discussion of the effects of pumping.

Juveniles older than 5 months, subadults, and adult Green Sturgeon could be exposed to the effects of increased pumping due to water transfers. Although southern DPS Green Sturgeon are present in the Delta in all months of the year, Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways (NMFS 2009:338). Therefore, there are no negative impacts of increased pumping at Jones and Banks Pumping Plants due to water transfers under Alternative 1.

Juvenile southern DPS Green Sturgeon are present in the Delta in every month of the year (Reclamation 2019). Thus, some portion of the population would be exposed to this action. Increases in Delta inflow during water transfers may have benefits for juvenile Green Sturgeon. However, there is no information on relationships between flow and juvenile Green Sturgeon ecology.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few southern DPS juvenile Green Sturgeon Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program as part of Alternative 1. Although southern DPS juvenile Green

Sturgeon are present in the Delta in all months of the year, Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways (NMFS 2009:338). The application of aquatic herbicide to the waters of Clifton Court Forebay will occurbetween 28 June and 31 August. Treatment could occur prior to 28 June at tempertures ≥ 25˚C; however, Green Sturgeon would not be expected to occur at these temperatures. Thus, the likelihood of exposing juvenile Green Sturgeon to the herbicide is very low.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Upgrades to the TFCF under Alternative 1 will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish, and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

Upgrades to the TFCF will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

As previously described, juvenile Green Sturgeon can occur in the Delta year-round (Reclamation 2019) and, therefore, have the potential to be exposed to the effects of construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements. If construction affects the efficiency of Green Sturgeon salvage (which is an element of entrainment risk; Figure 5.12-3), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures (Appendix E, *Mitigation Measures*).

Skinner Fish Facility improvements under Alternative 1, which involve predator control efforts, can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently. Thus, Alternative 1 is not likely to negatively impact juvenile Green Sturgeon. There is potential for Green Sturgeon to be impacted by predator control activities. However, Green Sturgeon are rarely encountered at the facilities suggesting few fish would be impacted.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from June through September under Alternative 1 coincides with a portion of the downstream migration of juvenile southern DPS Green Sturgeon, as well as adult southern DPS Green Sturgeon. Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. During full gate operation, the flashboards are installed and the radial gates open and close twice each tidal day. Green Sturgeon are thought to successfully pass through either the boat lock or through the gates during periods when the gates are open. NMFS (2009) determined that operation of the SWSCG is unlikely to produce conditions that support unusually high numbers of predators, change habitat suitability or availability for rearing or migration of juvenile and adult Green Sturgeon. Green

Sturgeon are strong swimmers and therefore the operation of the Suisun Marsh Salinity Control Gate will have no impact on adults or juvenile Green Sturgeon.

The low screen velocity at the intake culverts combined with a small screen mesh size are expected to successfully prevent Green Sturgeon from being entrained into the RRDS under Alternative 1. (NOAA 2009).

The MIDS intakes under Alternative 1 do not currently have fish screens, and juvenile Green Sturgeon are more prone to entrainment than other species such as White Sturgeon (Poletto et al. 2014). However, fisheries monitoring performed in 2004-05 and 2005-06 identified entrainment of 20 fish species, none of which were Green Sturgeon (NOAA 2009). Presence of Green Sturgeon in the area of the MIDS intake is not well studied or documented, but it if Green Sturgeon are present they may potentially avoid entrainment as they do not typically swim along the surface where the diversion is located.

Due to its location and design, Green Sturgeon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall under Alternative 1 likely benefits juvenile Green Sturgeon in Suisun Marsh by improving water quality and increasing foraging opportunities (NOAA 2009).

Potential changes to aquatic resources from Clifton Court predator management efforts

Predator control efforts under Alternative 1 can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from Fish Conservation and Culture Laboratory

Potential changes to aquatic resources from monitoring

Population estimates for Green Sturgeon also remain outstanding in the Central Valley. Similar to Steelhead, the existing monitoring programs very rarely catch Green Sturgeon because most monitoring programs are not designed to capture them. Similar to Steelhead, it is unlikely the monitoring programs have an effect to the population.

O.3.3.9 *Nearshore Pacific Ocean on the California Coast*

O.3.3.9.1 <u>Southern Resident Killer Whale</u>

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

As previously described in Section O.3.2.9, *Nearshore Pacific Ocean on the California Coast*, and described in more detail in the ROC LTO BA, potential effects to Southern Resident Killer Whale as a result of SWP/CVP operations could occur as a result of effects to Chinook Salmon prey abundance. The ROC LTO BA concluded that there may be positive and negative effects of Alternative 1 (the ROC LTO proposed action), with the former including operation of the south Delta export facilities and the latter including flow and temperature management. Overall, it was concluded that given the medium priority of Central Valley Chinook Salmon stocks and the contribution of hatchery-origin Chinook Salmon released downstream of the potential proposed action influence, the proposed action (Alternative 1) would not be expected to have population-level effects to Southern Resident Killer Whale Chinook Salmon prey. This suggests limited effects of Alternative 1 on Southern Resident Killer Whale.

O.3.4 Alternative 1 – Program-Level Effects

O.3.4.1 *Sacramento River*

Potential changes to aquatic resources from Battle Creek restoration

Under Alternative 1, Reclamation would accelerate implementation of the Battle Creek Salmon and Steelhead Restoration Project, which is intended to reestablish approximately 42 miles of prime salmon and steelhead habitat on Battle Creek and an additional 6 miles on its tributaries. Winter-Run Chinook Salmon are currently limited to a single population that spawns in a 5-mile stretch of the Sacramento River, but they are being reintroduced to Battle Creek (around 200,000 juveniles were released in Battle Creek in 2018). This new population would benefit from the restoration efforts. An additional population of Winter-Run Chinook Salmon on Battle Creek would provide temperature compliance flexibility. This intervention measure would benefit Winter-Run Chinook Salmon and other anadromous salmonids.

Potential adverse construction impacts of this measure are being minimized and mitigated by the Battle Creek Salmon and Steelhead Restoration Program, as described in the program's Final EIR (Reclamation 2005).

Potential changes to aquatic resources from lower intakes near Wilkins Slough

The conservation of Shasta storage to satisfy Winter-Run Chinook Salmon cold water needs would benefit from a reduction in Sacramento River flows at certain times of year. The river near Wilkins Slough used to have a 5,000 cfs minimum navigational flow set by Congress, but this is no longer required. However, as many of the fish screens at diversions in this region were designed to meet the 5,000 cfs minimum, they may not function properly at the lower flows and as a result may not meet state and federal fish screening requirements during the lower flows (NCWA 2014). This could result in take of state-protected and federally protected species that use this section of the river. This action would provide grants to water users within this area to install new diversions and screens that would properly operate at lower flows, thereby allowing Reclamation greater flexibility in managing Sacramento River flows and temperatures for both water users and wildlife, including listed salmonids (NCWA 2014).

Any fish present during the June 1 through October 1 in-water work window could be exposed to temporary disturbances associated with the construction of a cofferdam for this project. Water quality may be temporarily disturbed, in addition to noise associated with construction of the cofferdam. Additionally, fish rescue operations may need be conducted during the period when water within the coffered area needs to be pumped. However, implementation of AMM's identified in Appendix E, *Avoidance and Minimization Measures* would further minimize those effects.

This intervention measure is expected to benefit incubating Winter-Run and Spring-Run Chinook Salmon eggs and alevins by reducing risk of depleting the coldwater pool and to benefit juvenile fish of all species by reducing entrainment.

Potential changes to aquatic resources due to Shasta TCD Improvements

Reclamation would study the feasibility of infrastructure improvements to enhance Shasta TCD performance, including reducing the leakage of warm water into the structure. The leakage increases the temperature of cold water released to maintain suitable temperatures for Winter-Run Chinook Salmon that spawn in the upper Sacramento River from May through August. Fry emergence occurs up to two months after eggs are spawned, so effects of water temperature and flow in the upper Sacramento River on Winter-Run Chinook Salmon fry and alevins potentially occur from May through October, but occur primarily during June through September. The ability to better manage the coldwater pool and cold water releases would result in increased probability of maintaining suitable spawning, incubating, and rearing temperatures throughout the season in all but the driest years.

This intervention measure would potentially benefit Winter-Run and Spring-Run Chinook Salmon and would have no impact on other species.

Potential changes to aquatic resources from operation of the Livingston-Stone National Fish Hatchery (Winter-Run Chinook Salmon)

Expansion of Livingston-Stone National Fish Hatchery would allow increased operation to sustain Winter-Run Chinook Salmon, particularly during drought years. The purpose would be to provide artificial rearing and spawning habitat when in-river environmental conditions (low flow and high temperatures) are not suitable for egg or fry life stages. It will be important to couple other conservation measures together with increased production to ensure that the measure addresses losses of natural production. For example, if in-river conditions are not conducive to migration downriver, fish produced at the hatchery may need to be trucked to a point with higher downstream survival.

Minimizing potential adverse effects of increased hatchery production would depend on complex interactions between hatchery and natural-origin fish and their environment. Livingston-Stone National Fish Hatchery operates an “integrated” hatchery program with the intention of minimizing genetic divergence between hatchery and natural components of the population by exchanging spawners between them (Paquet et al. 2011). A natural consequence of expanding numbers of hatchery fish is an increase of hatchery origin fish on in-river spawning grounds. This coupled with low survival of natural-origin fish may influence the genetic management criteria to include hatchery-origin spawners and variable numbers of males and females under drought conditions.

This intervention measure would potentially benefit the Winter-Run Chinoook Salmon population by reducing the risk of its extinction, but would do so at the risk of reducing its genetic fitness.

Potential changes to aquatic resources from small screen program installation

Installation of fish screens on small irrigation diversions in the Sacramento River has the potential to benefit fish species with life stages that are vulnerable to entrainment by the diversions (e.g., floating eggs, larvae, fry, juveniles, smolts). However, the benefits would be realized only for species with a large proportion of their vulnerable life stages present when the diversions operate. The small diversions in the Sacramento River operate primarily during April to September. The focal fish species with vulnerable life stages present during this period include Central Valley Steelhead, Green Sturgeon, White Sturgeon, Splittail, Pacific and River Lamprey, Hardhead, Striped Bass, American Shad, and Largemouth, Smallmouth, and Spotted Bass. All of these species would potentially benefit from the small screen program. Central Valley Steelhead and Green Sturgeon are federally protected, so their protection is the most critical. Steelhead fry and juveniles and Green Sturgeon larvae and juveniles may be present in the Sacramento River and vulnerable to agricultural diversions throughout the diversion period, so screening the diversions would likely benefit both species. However, benefit of the screens to sturgeon is more uncertain than the benefit to steelhead because the screens would be designed to meet NMFS and CDFW fish screen criteria designed to reduce entrainment of juvenile salmonids, and the effectiveness of such fish screens in reducing larval and juvenile sturgeon entrainment is poorly understood.

Green sturgeon juveniles are believed to be highly susceptible to entrainment in unscreened diversions and impingement on screened diversions (Mussen et al. 2014, NMFS 2018b). Risks of entrainment and impingement in the Sacramento River are increased because the period of juvenile presence in the river (May through December) coincides with peak period of irrigation diversions (April to September). Green sturgeon larvae may be particularly susceptible to entrainment, impingment, and injury at water diversions. The larvae are present in areas where substantial water volumes are diverted, such as the Red Bluff Diversion Dam and Glen-Colusa Irrigation District (GCID) facilities, and these diversion may entrain larval and juvenile sturgeon (Mussen et al. 2014). Due to their small size and relatively poor swimming performance, it is highly likely that entrainment affects larval survival (Heublein et al. 2017a; Verhille et al. 2014). Many small-scale unscreened diversions are present near larval habitat of Green Sturgeon throughout the mainstem Sacramento River.

Focal fish species may be exposed to the effects of construction of screens on water diversion intakes if their vulnerable life stages are present in the river during the typical timing of in-water construction (July 15–October 15). However, the work area for these projects is small, limiting exposure to construction. Potential short-term adverse effects may include temporary degradation of water quality, including increased turbidity and suspended sediments and sediment deposition in the direct vicinity of the work area, and the temporary displacement of individual fish in the work area. If fish are present in the work area, flowing water will be isolated and fish captured and relocated to an appropriate location in an effort to minimize possible mortality. Juveniles would likely experience increased levels of stress and injury during handling, which could be exacerbated by poor water quality (i.e., increased temperatures, low dissolved oxygen saturation), and prolonged periods of holding between capture and release. There may be a minor effect to a small number of individuals, although the risk from these potential effects would be minimized through the implementation of mitigation measures for aquatic resources (Appendix E, Mitigation Measures). In addition, the appropriate conservation measures and handling techniques will be employed to ensure that the stress resulting from handling and transport is short-lived and minor.

This intervention measure is expected to benefit Central Valley Steelhead, Green Sturgeon, White Sturgeon, Splittail, Pacific and River Lamprey, Hardhead, Striped Bass, American Shad, Largemouth Bass, Smallmouth Bass, and Spotted Bass.

Potential changes to aquatic resources from spawning habitat restoration

Reclamation would create additional spawning habitat by injecting approximately 15,000 to 40,000 tons of gravel annually into the Sacramento River to 2030, using the following sites: Keswick Dam Gravel Injection Site, Market Street Injection Site, Redding Riffle, Turtle Bay, Tobiasson Island, Shea Levee sites, and Kapusta. This intervention measure is likely to benefit all Chinook Salmon runs that spawn in the Sacramento River, as well as Central Valley Steelhead and Green Sturgeon.

Adults, eggs, alevins, larvae and juveniles of all the species that occur in the upper Sacramento River would be subject to potential adverse effects from proposed spawning (e.g, gravel augmentation) restoration projects in the upper Sacramento River associated with the proposed measure. Construction activities could result in mortality of eggs and alevins by crushing if heavy equipment enters the stream channel or otherwise disturbs existing redds during in-water activities. Eggs and alevins and other life stages could also be negatively impacted by increases in suspended sediment, turbidity, and contaminant exposure risk, leading to indirect impacts on individuals from reductions in habitat quality (e.g., reduced flow and dissolved oxygen in redds from increases in sediment deposition) or direct impacts from sublethal and lethal exposures to contaminants. Although these potential effects may be unavoidable, exposure of the fish populations to construction effects would be low based on the limited extent of proposed restoration projects relative to the overall distribution of the fish, and the implementation of other mitigation measures for aquatic resources described in Appendix E, *Mitigation Measures*. These measures include MM-AQUA-1, which requires worker awareness training, MM-AQUA-4, erosion and sediment control, and MM-AQUA-5, spill prevention and containment.

Potential changes to aquatic resources from rearing habitat restoration

Reclamation, in coordination with Sacramento River Settlement Contractors, would create 40 to 60 acres of side channel and floodplain habitat at 10 sites in the Sacramento River by 2030. Creation of this additional 40 to 60 acres of rearing habitat would help increase the quantity and quality of Winter-Run, Spring-Run, and Fall-/Late Fall-Run Chinook Salmon and Central Valley Steelhead juvenile rearing habitat in the Upper Sacramento River. Reclamation estimates that this additional 50 acres of rearing habitat could support the progeny of 5,600 returning adult salmonids (see Reclamation 2019).

Adults, eggs, alevins, larvae and juveniles of all the species that occur in the upper Sacramento River would be subject to potential adverse effects from proposed rearing habitat (e.g., side channel) restoration projects in the upper Sacramento River associated with the proposed action. Construction activities could result in mortality of eggs and alevins by crushing if heavy equipment enters the stream channel or otherwise disturbs existing redds during in-water activities. Eggs and alevins and other life stages could also be negatively impacted by increases in suspended sediment, turbidity, and contaminant exposure risk, leading to indirect impacts on individuals from reductions in habitat quality (e.g., reduced flow and dissolved oxygen in redds from increases in sediment deposition) or direct impacts from sublethal and lethal exposures to contaminants. Although these potential effects may be unavoidable, exposure of the fish populations to construction effects would be low based on the limited extent of proposed restoration projects relative to the overall distribution of the fish, and the implementation of other mitigation measures for aquatic resources described in Appendix E, Mitigation Measures. These measures include MM-AQUA-1, which requires worker awareness training, MM-AQUA-4, erosion and sediment control, and MM-AQUA-5, spill prevention and containment.

Potential changes to aquatic resources due to adult rescue activities

O.3.4.1.1 Winter-Run Chinook Salmon

The Fremont Weir fish ladder and Wallace Weir fish rescue facility have improved fish passage in the Yolo Bypass and between the bypass and the river. However, the potential for stranding in isolated pools remains when hydrologic connectivity is not present during droughts or after periods of bypass flooding. Reclamation proposes to trap and haul adult salmonids and sturgeon from Yolo and Sutter bypasses during droughts and after periods of bypass flooding, when flows from the bypasses are most likely to attract upstream migrating adults but prohibit passage to upstream spawning grounds, and move them up the Sacramento River toward spawning grounds. CDFW initiated fish trapping and rescue efforts at the Wallace Weir in 2014 and at Fremont Weir in 2017 to return anadromous fish to the Sacramento River (CDFW 2016, 2017). This measure would continue these actions. This trap and haul program is in addition to weir fish passage projects within the proposed action and would improve survival of adults.

Under Alternative 1, stranded adult Sacramento Winter-Run Chinook Salmon that are blocked from upstream migration would be captured at the Fremont, Wallace, and Tisdale weirs and hauled closer to spawning grounds upstream in the Sacramento River. Adults migrating in-river or that do not become stranded in the Yolo and Sutter bypasses would be unaffected by Alternative 1. The rescue and transport of adult Sacramento Winter-Run Chinook Salmon closer to spawning grounds would result in an increased number of adults returning to spawn in the Sacramento River. Potential adverse effects of adult rescue activities to individual adult Winter-Run Chinook Salmon include increased risk of stress, injury, and/or mortality associated with capture, handling, and transport, which may affect survival of affected individuals after release; however, survival is estimated to be much higher following capture/transport than if left trapped in bypasses. Any adverse effects related to rescue activities would be minimized through the application of AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Alternative 1 may adversely affect juvenile Winter-Run Chinook Salmon when Sacramento River flows overtop the Fremont and/or Tisdale Weirs if they become stranded with adults that are targeted by adult rescue activities and are incidentally captured. Potential adverse effects of Alternative 1 on juvenile Winter-Run Chinook Salmon include increased risk of stress, injury, and/or mortality during handling and transport. Risk of these potential effects would be minimized through the application of AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Any potential negative population-level effects of Alternative 1 would be expected to be offset by the benefits associated with increased numbers of adult Winter-Run Chinook Salmon returning to spawning grounds. Under the No Action Alternative there is no rescue and transport of stranded adult Winter-Run Chinook Salmon to upstream spawning grounds; therefore, the overall population-level effects of Alternative 1 are expected to be positive relative to the No Action Alternative.

O.3.4.1.2 Spring-Run Chinook Salmon

Under Alternative 1, adult Spring-Run Chinook Salmon that become trapped in the Yolo and Sutter bypasses during droughts and after periods of bypass flooding would be captured and released further upstream in the Sacramento River. CDFW initiated fish trapping and rescue efforts at the Wallace Weir in 2014 and at Fremont Weir in 2017 to return anadromous fish to the Sacramento River (CDFW 2016, 2017). This component would continue these actions. Adults migrating in-river or that do not become stranded in the Yolo and Sutter bypasses would be unaffected by Alternative 1. The rescue and transport of adult Spring-Run Chinook closer to spawning grounds would result in an increased number of adults returning to spawn in the Sacramento River. Potential adverse effects of adult rescue activities to individual adult Spring-Run Chinook Salmon include increased risk of stress, injury, and/or mortality associated with capture, handling, and transport, which may affect survival of individuals after release; however, survival is estimated to be much higher following capture/transport than if left trapped in bypasses. Any adverse effects related to rescue activities would be minimized through the application of AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Alternative 1 may adversely affect juvenile Spring-Run Chinook Salmon when Sacramento River flows overtop the Fremont and/or Tisdale Weirs if they become stranded with adults that are targeted by adult rescue activities and are incidentally captured. Potential adverse effects of Alternative 1 on juvenile Spring-Run Chinook include increased risk of stress, injury, and/or mortality during handling and transport. Risk of these potential effects would be minimized through the application of AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Any potential negative population-level effects of Alternative 1 would be expected to be offset by the benefits associated with increased numbers of adult Central Valley Spring-Run Chinook Salmon returning to spawning grounds. Under the No Action Alternative there is no rescue and transport of stranded adult Spring-Run Chinook to upstream spawning grounds; therefore, the overall population-level effects of Alternative 1 are expected to be positive relative to the No Action Alternative.

O.3.4.1.3 Fall- /Late Fall-Run Chinook Salmon

Under Alternative 1, adult Fall- /Late Fall-Run Chinook Salmon that become stranded in the Yolo and Sutter bypasses during droughts and after periods of bypass flooding would be captured and released further upstream in the Sacramento River. CDFW initiated fish trapping and rescue efforts at the Wallace Weir in 2014 and at Fremont Weir in 2017 to return anadromous fish to the Sacramento River (CDFW 2016, 2017). This component would continue these actions. Adults migrating in-river or that do not become stranded in the Yolo and Sutter bypasses would be unaffected by Alternative 1. The rescue and transport of adult Fall- /Late Fall-Run Chinook Salmon closer to spawning grounds would result in an increased number of adults returning to spawn in the Sacramento River. Potential adverse effects of adult rescue activities to individual Fall- /Late Fall-Run Chinook Salmon include increased risk of stress, injury, and/or mortality associated with capture, handling, and transport, which may affect survival of individuals after release; however, survival is estimated to be much higher following capture/transport than if left trapped in bypasses. Any adverse effects related to rescue activities would be minimized through the application of AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Alternative 1 may adversely affect juvenile Fall- /Late Fall-Run Chinook Salmon when Sacramento River flows overtop the Fremont and/or Tisdale weirs if they become stranded with adults that are targeted by adult rescue activities and are incidentally captured. Potential adverse effects of Alternative 1 on juvenile Fall- /Late Fall-Run Chinook Salmon could therefore include increased risk of stress, injury, and/or mortality during handling and transport. Risk of these potential effects would be minimized through AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities

Any potential adverse population-level effects of Alternative 1 would be expected to be offset by the benefits associated with increased numbers of adult Fall- /Late Fall-Run Chinook Salmon returning to spawning grounds. Under the No Action Alternative there is no rescue and transport of stranded adult Fall- /Late Fall-Run Chinook Salmon to upstream spawning grounds; therefore, the overall population-level effects of Alternative 1 are expected to be positive relative to the No Action Alternative.

O.3.4.1.4 Central Valley Steelhead

Under Alternative 1, adult California Central Valley Steelhead trapped in the Yolo and Sutter bypasses would be captured and transported further upstream to release sites in the Sacramento River. CDFW initiated fish trapping and rescue efforts at the Wallace Weir in 2014 and at Fremont Weir in 2017 to return anadromous fish to the Sacramento River (CDFW 2016, 2017). This component would continue these actions. While California Central Valley Steelhead are less likely than Chinook Salmon to utilize floodplain habitat such as the Yolo and Sutter bypasses, there is the potential for adults and juveniles to occur in the bypasses when Sacramento River flows overtop the Fremont and/or Tisdale Weirs. Exposure of adult California Central Valley Steelhead to rescue effects would be restricted to only those adult Steelhead which become stranded in the Yolo and Sutter bypasses and are subsequently rescued and released in the Sacramento River; in-river migrating adults and those that do not become stranded in the bypasses would be unaffected by Alternative 1. The rescue and transport of adult Central Valley Steelhead closer to spawning grounds would result in an increased number of adults returning to spawn in the Sacramento River. Potential adverse effects of adult rescue activities to individual Central Valley Steelhead include increased risk of stress, injury, and/or mortality associated with capture, handling, and transport, which may affect survival of individuals after release; however, survival is estimated to be much higher following capture/transport than if left trapped in bypasses. Any adverse effects related to rescue activities would be minimized through the application of AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Juvenile California Central Valley Steelhead could be exposed to the effects of Alternative 1 if they become stranded with adults targeted by adult rescue activities and are incidentally captured. Potential adverse effects of Alternative 1 on juvenile Central Valley Steelhead include increased risk of stress, injury, and/or mortality associated with capture, handling, and transport during adult rescue activities, which could affect survival of individuals after release. However, any adverse effects related to rescue activities would be minimized through the application of AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Any potential adverse population-level effects of Alternative 1 would be expected to be offset by the benefits associated with increased numbers of adult California Central Valley Steelhead returning to spawning grounds. Under the No Action Alternative there is no rescue and transport of stranded adult California Central Valley Steelhead to upstream spawning grounds; therefore, the overall population-level effects of Alternative 1 are expected to be positive relative to the No Action Alternative.

O.3.4.1.5 Green Sturgeon

Under Alternative 1, adult Southern DPS North American Green Sturgeon trapped in the Yolo and Sutter bypasses would be captured and transported upstream to release sites in the Sacramento River. Exposure of adult Green Sturgeon to rescue effects would be restricted to only those that become stranded in the Yolo and Sutter bypasses and are subsequently rescued and released to the Sacramento River; in-river migrating adults and those that do not become stranded in the bypasses would be unaffected. CDFW initiated fish trapping and rescue efforts at the Wallace Weir in 2014 and at Fremont Weir in 2017 to return anadromous fish to the Sacramento River (CDFW 2016, 2017). This component would continue these actions. The rescue and transport of adult Green Sturgeon closer to spawning grounds would result in an increased number of adults returning to spawn in the Sacramento River. Potential adverse effects of adult rescue activities to individual Green Sturgeon include increased risk of stress, injury, and/or mortality associated with capture, handling, and transport, which may affect survival of individuals after release; however, survival is estimated to be much higher following capture/transport than if left trapped in bypasses. Any adverse effects related to rescue activities would be minimized through the application of AMM8 *Fish Rescue and Salvage Plan* (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Juvenile Green Sturgeon could be exposed to the effects of Alternative 1 if they become stranded with adults targeted by adult rescue activities and are incidentally captured. Potential adverse effects of

Alternative 1 include increased risk of stress, injury, and/or mortality associated with capture, handling, and transport during adult rescue activities, which could affect survival of individuals after release; however, survival is estimated to be much higher following capture/transport than if left trapped on bypasses. Any adverse effects related to rescue activities would be minimized through the application of AMM8 Fish Rescue and Salvage Plan (Reclamation 2019), which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of rescue activities.

Any potential adverse population-level effects of Alternative 1 would be expected to be offset by the benefits associated with increased numbers of adult Green Sturgeon returning to spawning grounds. Under the No Action Alternative, there is no rescue and transport of stranded adult Green Sturgeon to upstream spawning grounds; therefore, the overall population-level effects of Alternative 1 are expected to be positive relative to the No Action Alternative.

Potential changes to aquatic resources due to trap and haul activities

Under Alternative 1, if a Tier 4 year is predicted (i.e., a year with less than 2.5 MAF of storage at the beginning of May), Reclamation would implement a downstream trap and haul strategy for the capture and transport of juvenile Winter-Run Chinook Salmon, Spring-Run Chinook Salmon, Fall- /Late Fall-Run Chinook Salmon, and Central Valley Steelhead in the Sacramento River watershed. In Tier 4 years, low flows and resulting high water temperatures are typically unsuitable for volitional downstream migration and survival. Reclamation would place temporary juvenile collection weirs at key feasible locations downstream of spawning areas in the Sacramento River. Reclamation would transport collected fish to a safe release location or locations in the Delta upstream of Chipps Island. Juvenile trap and haul activities would occur from December 1 through May 31, consistent with the migration period for juvenile Chinook Salmon and Steelhead (NMFS 2014a), depending on hydrologic conditions. In the event of high river flows or potential flooding, the fish weirs would be removed. Under the No Action Alternative, there is no capture and transport of juvenile fish.

O.3.4.1.6 <u>Winter-Run Chinook Salmon</u>

Alternative 1 would increase the number of out-migrating juvenile Winter-Run Chinook Salmon during Tier 4 years relative to the No Action Alternative. Under the No Action Alternative, juveniles could be exposed to low flows and high water temperatures in Tier 4 years, but such exposure would be lessened under Alternative 1 as juveniles are transported around unfavorable conditions to downstream locations where their migrations can continue (Reclamation 2014d: 3–2). Potential adverse effects of Alternative 1 on juvenile Winter-Run Chinook Salmon include increased risk of stress during transport, making juveniles more vulnerable to predation, impaired auditory function, earlier ocean entry, reduced growth rates, and decreased homing ability as adults (Lusardi and Moyle 2017: 479–480). The risk of these negative effects would be reduced through the application of AMM8, *Fish Rescue and Salvage Plan,* which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of trapping. Although there are negative effects associated with trap and haul, implementation of Alternative 1 could provide benefits to Winter-Run Chinook Salmon relative to the No Action Alternative, where trapping and hauling of juveniles during Tier 4 years would not occur.

O.3.4.1.7 <u>Spring-Run Chinook Salmon</u>

Alternative 1 would increase the number of out-migrating juvenile Spring-Run Chinook Salmon during Tier 4 years relative to the No Action Alternative. Under the No Action Alternative, juveniles could be exposed to low flows and high water temperatures in Tier 4 years, but such exposure would be lessened under Alternative 1 as juveniles are transported around unfavorable conditions to downstream locations where their migrations can continue (Reclamation 2014d: 3–2). Potential adverse effects of Alternative 1 on juvenile Spring-Run Chinook Salmon include increased stress during transport, making juveniles more vulnerable to predation, impaired auditory function, earlier ocean entry, reduced growth rates, and decreased homing ability as adults (Lusardi and Moyle 2017: 479–480). The risk of these potential negative effects would be reduced through the application of AMM8, *Fish Rescue and Salvage Plan,* which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of trapping. Although there are negative effects associated with trap and haul, implementation of Alternative 1 could provide benefits to Spring-Run Chinook Salmon relative to the No Action Alternative, where trapping and hauling of juveniles during Tier 4 years would not occur.

O.3.4.1.8 Fall- /Late Fall-Run Chinook Salmon

Alternative 1 would increase the number of out-migrating juvenile Fall- /Late Fall-Run Chinook Salmon relative to the No Action Alternative. Under the No Action Alternative, juveniles could be exposed to low flows and high water temperatures in Tier 4 years, but such exposure would be lessened under Alternative 1 as juveniles are transported around unfavorable conditions to downstream locations where their migrations can continue (Reclamation 2014d: 3-2). Potential adverse effects of Alternative 1 on juvenile Fall-Run/Late Fall-Run Chinook Salmon include increased stress during transport, making juveniles more vulnerable to predation, impaired auditory function, earlier ocean entry, reduced growth rates, and decreased homing ability as adults (Lusardi and Moyle 2017: 479–480). The risk of these potential negative effects would be reduced through the application of AMM8, *Fish Rescue and Salvage Plan,* which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of trapping. Although there are negative effects associated with trap and haul, implementation of Alternative 1 could provide benefits to Fall- /Late Fall-Run Chinook Salmon relative to the No Action Alternative, where trapping and hauling of juveniles during Tier 4 years would not occur.

O.3.4.1.9 Central Valley Steelhead

Alternative 1 would increase the number of out-migrating juvenile California Central Valley Steelhead during Tier 4 years relative to the No Action Alternative. Under the No Action Alternative, juveniles could be exposed to low flows and high water temperatures in Tier 4 years, but such exposure would be lessened under Alternative 1 as juveniles are transported around unfavorable conditions to downstream locations where their migrations can continue (Reclamation 2014d: 3-2). Potential adverse effects of Alternative 1 on juvenile California Central Valley Steelhead include increased stress during transport, making juveniles more vulnerable to predation, impaired auditory function, earlier ocean entry, reduced growth rates, and decreased homing ability as adults (Lusardi and Moyle 2017: 479–480). The risk of these potential negative effects would be reduced through the application of AMM8, *Fish Rescue and Salvage Plan,* which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of trapping. Although there are negative effects associated with trap and haul, implementation of Alternative 1 could provide benefits to California Central Valley Steelhead relative to the No Action Alternative, where trapping and hauling of juveniles during Tier 4 years would not occur.

O.3.4.1.10 Green Sturgeon

Juvenile trap and haul activities are targeted at salmonids; however, larval and juvenile Green Sturgeon could be affected by the trap and haul program under Alternative 1. Larger Green Sturgeon larvae, as well as juveniles, could be incidentally captured by gear used to trap juvenile salmonids during implementation of Alternative 1. However, because juvenile trap and haul activities would be focused on trapping juvenile salmonids, few Green Sturgeon larvae and juveniles would be expected to be collected; adult Green Sturgeon are not expected to be vulnerable to trapping because of their large size and benthic behavior. Effects on larval and juvenile Green Sturgeon exposed to trapping activities could include increased stress, injury, and/or mortality during capture and handling. Risk of these potential effects would be reduced through application of AMM8, *Fish Rescue and Salvage Plan*, which establishes detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to the adverse effects of trapping. Through the implementation of AMM8 and the return of trapped larval and juvenile Green Sturgeon to the Sacramento River, any adverse effects on Green Sturgeon from implementation of Alternative 1 are expected to be minimal.

O.3.4.2 *Stanislaus River*

Potential changes to salmonid habitat in the Stanislaus River related to habitat restoration

Alternatives 1 and 3 include spawning and habitat restoration activities in the Stanislaus River that would result in construction-related temporary disturbance to habitat and may expose nearby fish to stressful conditions. Construction activities may result in a temporary elevation of turbidity, noise and exclusion. However, through coordination with the regulatory agencies and implementation of avoidance and minimization measures, including the implementation of an in-water work window from July 15 through October 15, effects to the particular life stages would be minimized or avoided.

The majority of species and life stages would be unaffected by construction activities due to timing of in-water construction within the in-water work window of July 15 through October. However, some life stages are present during this time, and may be temporarily affected. Implementation of mitigation measures for aquatic resources (Appendix E, Mitigation Measures) would minimize those effects. The species that the avoidance and minimization measures would benefit due to the presence of their life stage during the in-water work window would include holding Spring-Run Chinook Salmon depending on location of in-water work related to the restoration, rearing Central Valley Steelhead that may be present year-round, outmigrating Fall-Run Chinook Salmon.

Although construction may temporarily affect certain fish species and their habitat, restoration of spawning and rearing habitat will result in long-term improvements to the habitat and aquatic inhabitants including increase in riparian vegetation providing Instream object and overhanging object cover, new shaded riverine habitat, and additional areas for food source. Habitat complexity and diversity would also occur resulting in additional cover for predator avoidance and refuge for salmonids or other native fishes.

Restoration activities have the potential to increase growth and survival of juvenile Chinook Salmon, Steelhead, and other native fish by providing increased seasonal access to productive foraging and high quality rearing habitat.

O.3.4.3 *Bay-Delta*

O.3.4.3.1 Delta Smelt

Potential changes to Delta Smelt from food subsidies (Sacramento Deepwater Ship Channel food study; North Delta food subsidies/Colusa Basin drain study; Suisun Marsh Roaring River Distribution System food subsidies study)

As previously noted in the discussion of *Potential changes to Delta Smelt from actions for Delta Smelt summer-fall habitat,* Alternative 1 includes Delta Smelt food subsidy studies in the Sacramento Deepwater Ship Channel, North Delta/Colusa Basin Drain, and Suisun Marsh/RRDS. These studies will allow assessment of the extent to which operating these actions will provide Delta Smelt with additional food relative to the No Action AlternativeNo Action Alternative. This is discussed further in the ROC LTO Ba, where it is also noted that there could be negative effects from sediment mobilization in the Sacramento Deepwater Ship Channel, potentially increasing contaminant exposure. Additional food could allow offsetting of potential negative effects from the previously described differences in seasonal operations (i.e., less spring Delta outflow under Alternative 1 potentially affecting *E. affinis*; less summer/fall outflow affecting *P. forbesi* transport to the low salinity zone).

Potential changes to Delta Smelt from tidal habitat restoration

As described in the ROC LTO BAand as noted for the No Action Alternative, completion of the approximately 6,000 acres of remaining tidal habitat restoration required by the USFWS (2008) BO has the potential to provide positive effects on Delta Smelt as a result of increased food availability, as well as habitat for occupation depending on habitat features. Potential negative effects from contaminants (e.g., methylmercury) would be addressed with minimization measures. As previously discussed, food and habitat effects of tidal habitat restoration have the potential to offset negative effects from seasonal operations (i.e., less spring outflow affecting *E. affinis* abundance; less low salinity zone habitat as a result of less fall Delta outflow), although the offsetting from the same restoration acreage potentially would be less than under the No Action Alternative because the operational effects under Alternative 1 would be greater (see *Potential changes to Delta Smelt due to seasonal operations*).

Potential changes to Delta Smelt from the predator hot spot removal program

The predator hot spot removal program proposed under Alternative 1 has the potential to have limited positive effects on Delta Smelt relative to the No Action Alternative. As explained by Reclamation (2019) in the ROC LTO BA, the potential effects probably would be limited because the hot spot removal program likely would be focused on areas of importance to downstream-migrating juvenile salmonids, which tend to be at the periphery of the Delta Smelt range, and are spatially limited in extent.

Potential changes to Delta Smelt from Delta Cross Channel gate improvements

Programmatic improvements to the DCC under Alternative 1 to allow, for example, diurnal operations for protection of juvenile salmonids, may have limited effects on Delta Smelt (see previous discussion in *Potential changes to Delta Smelt due to changes in Delta Cross Channel operations*; see also ROC LTO BA).

Potential changes to Delta Smelt due to changes from Tracy and Skinner fish facility improvements

The various Tracy and Skinner facility improvements summarized in Section 4.3.6.10, *Intervention Components,* of Appendix D have the potential to provide small positive effects to Delta by improving salvage efficiency relative to the No Action Alternative. However, these improvements would be limited because OMR management would limit the potential for Delta Smelt to be entrained at the south Delta facilities.

Potential changes to Delta Smelt from the small screen program

As described in the ROC LTO BA, the small screen program proposed under Alternative 1 has the potential to have limited positive effects relative to the No Action Alternative on Delta Smelt through reductions in entrainment. The potential is limited to Delta Smelt sufficiently large (>20 mm or so) to be screened, and is limited in effect because entrainment by small diversions is posited to be of minimal importance to Delta Smelt.

Potential changes to Delta Smelt from the Delta fish species conservation hatchery

As described in the ROC LTO BA, the Delta Fish Species Conservation Hatchery has the potential to provide appreciable positive effects to Delta Smelt through breeding and releasing fish to supplement the wild population. The potential positive effect depends on the implementation of various risk reduction strategies to address ecological, demographic, genetic, and uncertainty risks. The conservation hatchery could have negative effects such as discharge of effluent and construction, but these would be limited by application of appropriate measures such as offsite habitat mitigation and treatment of discharged water.

O.3.4.3.2 Longfin Smelt

Potential changes to Longfin Smelt from food subsidies (Sacramento Deepwater Ship Channel food study; North Delta food subsidies/Colusa Basin drain study; Suisun Marsh Roaring River Distribution System food subsidies study)

The timing of food subsidy actions under Alternative 1 is focused on providing Delta Smelt benefits in summer/fall and therefore would be expected to result in limited effects to Longfin Smelt, given their distribution mostly downstream of the potential area of effect.

Potential changes to Longfin Smelt from tidal habitat restoration

As described for the No Action Alternative, there may be some potential positive (greater food availability and habitat for occupancy) and negative (contaminants) effects from completion of 8,000 acres of restoration under Alternative 1, but these effects would be relatively limited because most Longfin Smelt occur downstream of likely restoration areas in the north Delta.

Potential changes to Longfin Smelt from predator hot spot removal program

As described for Delta Smelt, the predator hot spot removal program proposed under Alternative 1 has the potential to have limited positive effects on Longfin Smelt relative to the No Action Alternative, but the potential effects probably would be limited because the hot spot removal program likely would be focused on areas of importance to downstream-migrating juvenile salmonids, which tend to be at the periphery of the Longfin Smelt range (even more so than for Delta Smelt), and are spatially limited in extent.

Potential changes to Longfin Smelt from Delta Cross Channel gate improvements

Programmatic improvements to the DCC under Alternative 1 to allow diurnal operations for protection of juvenile salmonids, for example, may have limited effects on Longfin Smelt (see previous discussion in *Potential changes to Longfin Smelt due to changes in Delta Cross Channel operations*).

Potential changes to Longfin Smelt due to changes from Tracy and Skinner fish facility improvements

Alternative 1 would include a carbon dioxide injection device for predator removal at the Tracy Fish Facility and therefore could have a positive effect on Longfin Smelt salvage efficiency relative to the No Action Alternative in this respect. Given the potential increase in entrainment from seasonal operations, the negative effects from salvage at the Tracy and Skinner fish facilities could outweigh any increases in salvage efficiency at Tracy. However, as previously discussed in *Potential changes to Longfin Smelt due to OMR management*, the population-level effects may be limited given the low entrainment loss observed historically.

Potential changes to Longfin Smelt from the small screen program

As previously described for Delta Smelt, the small screen program proposed under Alternative 1 has the potential to have limited positive effects relative to the No Action Alternative on Longfin Smelt through reductions in entrainment. The potential is limited to Longfin Smelt sufficiently large (>20 mm or so) to be screened, and is limited in effect because entrainment by small diversions may be of minimal importance to Longfin Smelt, by analogy to Delta Smelt, which is more likely to occur in areas with small diversions than Longfin Smelt and for which entrainment by small diversions is posited to be of minimal importance.

Potential changes to Longfin Smelt from the Delta fish species conservation hatchery

Similar to the previously discussed potential effects from reintroduction of Delta Smelt by the Fish Conservation and Culture Laboratory, reintroduction of Delta Smelt from the Delta Fish Species Conservation Hatchery under Alternative 1 could negatively affect Longfin Smelt if, for example, increased hybridization occurred; risk management strategies would be needed to limit such potential negative effects. As previously described for Delta Smelt, the conservation hatchery could have negative effects such as discharge of effluent and construction, but these would be limited by application of appropriate measures such as offsite habitat mitigation and treatment of discharged water.

O.3.4.3.3 Sacramento River Winter-Run Chinook Salmon

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

This action would hydrologically connect the Sacramento River with the Sacramento Deepwater Ship Channel (SDWSC) via the Stone Lock facility from mid-spring to late fall. Juvenile Winter-Run Chinook Salmon may be exposed to the Sacramento Deepwater Ship Channel (SDWSC) component of Alternative 1. This action would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018) to provide food web benefits to Delta Smelt. Juvenile Winter-Run Chinook Salmon abundance downstream of Stone Lock at Sherwood Harbor is highest in February and March, declines in April, and is moderate in November (Reclamation 2019). Juvenile Winter-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be routed into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, if survival rates are similar, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit associated with Alternative 1. A hydrologically connected SDWSC could potentially attract adult Winter-Run Chinook

Salmon. If the connection is maintained there would likely not be impacts to adults. However, if the connection is not maintained there could be migratory delays and stranding.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and therefore would have limited effects on Winter-Run Chinook Salmon, who are in the Delta between December and May for juveniles, and December to July for adults.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 1, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Winter-Run Chinook Salmon, who are in the Delta between December and May for juveniles, and December to July for adults.

Potential changes to aquatic resources due to tidal habitat restoration

Although migration through the Delta represents a short period, a large proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to 8,000 acres of tidal habitat restoration in the Delta. Tidal habitat restoration is expected to benefit juvenile Winter-Run Chinook Salmon in several aspects represented by the Winter-Run Chinook Salmon conceptual model, (Reclamation 2019) including increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta. Reclamation and DWR will consult on future tidal habitat restoration with USFWS and NMFS on potential effects to fish from construction-related effects.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Winter-Run Chinook Salmon. Although Alternative 1 would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Winter-Run Chinook Salmon. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile Salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016). Winter-Run Chinook Salmon juveniles in the Bay-Delta are unlikely to be exposed to the effects of construction at predator hot spot removal locations in the Sacramento River, as the in-water work window is in the summer / fall when Winter-Run Chinook Salmon juveniles are generally in the upper river.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Winter-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. Few Winter-Run Chinook Salmon are expected to be exposed to improvements to the Delta Cross Channel. Seasonal closure periods would still be in place to protect migrating salmonids. Potential diurnal operation during closure periods could increase exposure of Winter-Run Chinook Salmon juveniles to entrainment into the interior Delta. Improved biological and physical monitoring associated with improvements would likely minimize potentially increased routing into the interior Delta and subsequent entrainment. Greater operational flexibility and increased gate reliability resulting from improvements would reduce the risk of gate failure that could result in higher rates of entrainment.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

A small proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility. Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements based on lack of observed salvage during the August to October in-water work window (see Figures F.2.7, F.2.8, and F.2.9 in Appendix Fof the ROC LTO BA). However, a few early migrants could occur during the in-water work window based on occurrence in the north Delta (see Figures WR_Seines and WR_Sherwood in Appendix Fof the ROC LTO BA).

To the extent that the construction affects the ability of juvenile Winter-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Reclamation 2019), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures, including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12 (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measuress, and the small scale of the in-water construction.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Chinook Salmon entrained into CCF. It is important to note that only small proportions of Winter-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014).

Potential changes to aquatic resources from the small screen program

There may be some overlap Winter-Run Chinook Salmon with the main late spring-fall irrigation period for small diversions. Diversion screening could reduce entrainment of late migrating individuals. It is important to note that only a small proportion of the population would be exposed.

Few if any juvenile Winter-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Winter-Run Chinook Salmon primarily migrate from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

The operation of the Delta Fish Species Conservation Hatchery would not provide benefits to any life stage of Winter-Run Chinook Salmon. Potential negative effects of the Delta Fish Species Conservation Hatchery include inadvertent propagation and spread of invasive or nuisance species, which could affect juvenile Winter-Run Chinook Salmon through changes in food web structure, for example, in the case of invasive quagga and zebra mussels (Fera et al. 2017). Additional impacts could include reduced water quality resulting from hatchery discharge. Potential negative effects from discharged water are expected to be minimal due to the water treatment and the very small size of the discharge compared to flows in the Sacramento River near the hatchery location. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Winter-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Bay-Delta, few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of early migrants to in-water and shoreline construction of the hatchery intake and outfall, as illustrated by timing of occurrence in Sacramento seines and trawls (see Figures F.2.4 and F.2.5 in Appendix Fof the ROC LTO BA). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of construction of the Delta Fish Species Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

O.3.4.3.4 Central Valley Spring-Run Chinook Salmon

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

This action would hydrologically connect the Sacramento River with the Sacramento Deepwater Ship Channel (SDWSC) via the Stone Lock facility from mid-spring to late fall. Juvenile Spring-Run Chinook Salmon abundance in the Delta is moderate in March and peaks in April (Reclamation 2019). Juvenile Spring-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be enter into the SDWSC. There are potential benefits to Spring-Run Chinook Salmon from this action. Fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar. However, estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. Also, there is potential for decreased migration time to the ocean and exposure to larger food sources of Liberty Island, but this is currently uncertain.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and therefore would have limited effects on Spring-Run Chinook Salmon, who are in the Delta between January and February for adults, and November through June for juveniles, with a peak of juvenile migration from March to April.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 1, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Spring-Run Chinook Salmon, that are in the Delta from January through February for adults, and November through June for juveniles, with a peak of juvenile migration from March to April.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Spring-Run Chinook Salmon are expected to benefit from continuing to construct the 8,000 acres of tidal habitat restoration in the Delta under Alternative 1. Benefits include increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of yearling migrants that enter the Delta in the fall. Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes the following: temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance, indirect impairment of aquatic ecosystem productivity, loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. Many of these are elements highlighted in the SAIL conceptual model (Reclamation 2019). The risk from these potential effects would be minimized through application of mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14 (Appendix E, *Mitigation Measures*).

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 1 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Spring-Run Chinook Salmon. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Spring-Run Chinook. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile Salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016).

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Greater operational flexibility and increased gate reliability resulting from improvements to the Delta Cross Channel under Alternative 1 would reduce the risk of gate failure that could result in higher rates of entrainment of Spring-Run Chinook Salmon, if left open. Few Spring-Run Chinook Salmon are expected to be exposed to in-water construction related improvements to the Delta Cross Channel due to observance of species protective work windows. Seasonal closure periods would still be in place to protect Spring-Run Chinook Salmon. The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Spring-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. However, improved biological and physical monitoring associated with improvements would likely minimize potentially increased entrainment.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

A number of programmatic actions are proposed to improve salvage efficiency of TFCF, including installing a carbon dioxide injection device to allow remote controlled anesthetization of predators in the secondary channels of the Tracy Fish Facility. These actions could potentially benefit juvenile Spring-Run Chinook Salmon through greater salvage efficiency.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see figures in Appendix F of the ROC LTO BA*:* WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race). Risks to these few individuals would be minimized through appropriate mitigation measures, including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 AND MM-AQUA-12(Appendix E, *Mitigation Measures*), the selected in-water work window, and the small scale of the in-water construction. For juvenile Spring-Run Chinook Salmon that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Predator control efforts at Skinner Fish Facility under Alternative 1 to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts.

Potential changes to aquatic resources from the small screen program

Few if any juvenile Spring-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Sacramento River Spring-Run Chinook Salmon primarily from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

The operation of the Delta Fish Species Conservation Hatchery would not provide benefits to any life stage of Winter-Run Chinook Salmon. Potential negative effects of the Delta Fish Species Conservation Hatchery include inadvertent propagation and spread of invasive or nuisance species, which could affect juvenile Winter-Run Chinook Salmon through changes in food web structure, for example, in the case of invasive quagga and zebra mussels (Fera et al. 2017). Additional impacts could include reduced water quality resulting from hatchery discharge. Potential negative effects from discharged water are expected to be minimal due to the water treatment and the very small size of the discharge compared to flows in the Sacramento River near the hatchery location. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Winter-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Bay-Delta, few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of early migrants to in-water and shoreline construction of the hatchery intake and outfall, as illustrated by timing of occurrence in Sacramento seines and trawls (Reclamation 2019). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, and MM-AQUA-4 through MM-AQUA-14. (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of construction of the Delta Fish Species Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

O.3.4.3.5 Central Valley Fall-Run Chinook Salmon

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

Moderate to high proportions of juvenile Fall-Run Chinook Salmon are expected to be exposed to the Sacramento Deepwater Ship Channel (SDWSC) action. This action would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018). Juvenile Fall-Run Chinook Salmon abundance in the Delta is moderate in peaks in April and May (Table FR_1). Juvenile Fall-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be entrained into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough, which would provide a benefit if survival rates are similar. The effect of this action on juvenile Fall-Run Chinook Salmon is moderate.

No San Joaquin River-origin Fall-Run Chinook Salmon are expected to be exposed to the Sacramento Deepwater Ship Channel.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

This action is proposed to occur in July or September which is largely outside of the migration period for juvenile Fall-Run and Late Fall-Run Chinook Salmon in the Delta (Reclamation 2019). For fish that are exposed, increased food production could potentially enhance growth. The effect of this action is expected to be low.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

This action is proposed to occur in July or September which is largely outside of the migration period for juvenile Fall-Run and Late Fall-Run Chinook Salmon in the Delta (Reclamation 2019). For fish that are exposed, increased food production could potentially enhance growth. The effect of this action is expected to be low.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Fall-Run and Late Fall-Run Chinook Salmon are expected to be exposed to 8,000 acres of tidal habitat restoration in the Delta. Tidal habitat restoration is expected to benefit juvenile Chinook Salmon in several aspects represented by the Winter-Run Chinook Salmon conceptual model (Reclamation 2019) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta. Migration through the Delta represents a short period in the migration of juvenile Fall-Run and Late Fall-Run Chinook Salmon. Thus the total effect of this action is moderate.

Few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance (e.g., gill damage and reduced ability to take in oxygen, increasing metabolic cost), indirect impairment of aquatic ecosystem productivity (e.g., reduction in benthic macroinvertebrate production and availability), loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. Many of these are elements highlighted in the SAIL conceptual model (Reclamation 2019). The risk from these potential effects would be minimized through application of mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14 (Appendix E, *Mitigation Measures*).

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Fall-Run and Late Fall-Run Chinook Salmon. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Spring-Run Chinook. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile Salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016).

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Greater operational flexibility and increased gate reliability resulting from improvements to the Delta Cross Channel under Alternative 1 would reduce the risk of gate failure that could result in higher rates of entrainment of Fall-Run and Late Fall-Run Chinook Salmon, if left open. Few Fall-Run or Late Fall-Run Chinook Salmon are expected to be exposed to in-water construction related improvements to the Delta Cross Channel due to observance of species protective work windows. Seasonal closure periods would still be in place to protect Chinook Salmon. The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating

Fall- and Late Fall-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. However, improved biological and physical monitoring associated with improvements would likely minimize potentially increased entrainment.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

A small proportion of juvenile Fall-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see Figures WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race in - in Appendix F of the ROC LTO BA). To the extent that the construction affects the ability of juvenile Fall-Run, and Late Fall-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Reclamation 2019), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12 (Appendix E, *Mitigation Measures*). Given the low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction, it is concluded that the negative population-level effects of Tracy Fish Facility Improvements construction would be low on this life stage.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Chinook Salmon entrined into Clifton Cout Forebay. However, given that only small proportions of Fall-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014), the population-level positive effect of this action would be low. Larger proportions of Late Fall-Run Chinook Salmon are lost at the facilities and this action would have a larger effect for this run.

Potential changes to aquatic resources from the small screen program

Although there may be moderate overlap Fall-Late Fall-Run Chinook Salmon with the main late spring to fall irrigation period for small diversions, and small diversion screening could reduce entrainment of late migraing individuals, the potential population-level positive effect would be low because only a small proportion of the population would be exposed.

Few if any juvenile Fall- /Late-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Sacramento River Fall- /Late Fall-Run Chinook Salmon primarily migrate from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

Potential effects of the Delta Fishes Conservation Hatchery include inadvertent propagation and release of nuisance species and reduced water quality resulting from hatchery discharge. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Fall-Run Chinook

Salmon would be restricted to a small spatial area within the primary migration route. The overall impact of the operation of this facility is low.

As with the other proposed construction activities in the Bay-Delta, few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, and MM-AQUA-4 through MM-AQUA-14 (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures will reduce effects, and the in-water construction is of a small scale.

O.3.4.3.6 Central Valley Steelhead

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

Moderate to high proportions of Central Valley Steelhead are expected to be exposed to the Sacramento Deepwater Ship Channel (SDWSC) conservation measure under Alternative 1. This conservation measure would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018), allowing food to enter the Delta and an alternate migration pathway. Juvenile Central Valley Steelhead abundance in the Delta peaks in February through May (Reclamation 2019). Juvenile Central Valley Steelhead passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be entrained into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar.

No Central Valley Steelhead are expected to be exposed to the Sacramento Deepwater Ship Channel construction, as the in-water work window does not overlap with their occurrence in the Delta.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall, and does not overlap in time or space with juvenile Central Valley Steelhead occurrence in the Delta. There would not be any effect to Central Valley Steelhead adults.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 1, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Central Valley Steelhead juveniles, who are in the Delta between December and July. The action is not expected to have any effect on Central Valley Steelhead adults.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Central Valley Steelhead are expected to benefit from 8,000 acres of tidal habitat restoration in the Delta under Alternative 1. Tidal habitat restoration is expected to benefit juvenile Central Valley Steelhead in several aspects represented by the Winter-Run Chinook Salmon conceptual model (Reclamation 2019) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta; however, the Delta only represents a small fraction of the total migration route.

Few if any juvenile Central Valley Steelhead would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be exposure of a few late migrants, as illustrated by timing of occurrence in Chipps mid-water trawls (Reclamation 2019). Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance (e.g., gill damage and reduced ability to take in oxygen, increasing metabolic cost), indirect impairment of aquatic ecosystem productivity (e.g., reduction in benthic macroinvertebrate production and availability), loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 1 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids, including Central Valley Steelhead. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of Central Valley Steelhead. All hotspots are limited in scale relative to overall available habitat, and previous research has not found a consistent positive effect of predator removal on juvenile Salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016). However, implementation of this action would likely improve conditions for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Completion of DCC gate improvements would benefit Central Valley Steelhead of all life stages within the CVP watershed systems. The peak migration of juvenile Central Valley Steelhead in the Sacramento River past Hood, which is near the DCC, occurs from February through mid-June (Reclamation 2019). No San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the DCC. As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, few late migrants or early migrants have the potential to be exposed to potential construction from improvements to the DCC under Alternative 1.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements

Small proportions of Sacramento River-origin Central Valley Steelhead and moderate proportions of Mokelumne River and San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the Tracy Fish Facility. However, for fish that arrive at the facility, the proposed improvements resulting in greater salvage efficiency under Alternative 1 are likely to increase survival of juvenile Central Valley Steelhead.

As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, none to a few late migrants or early migrants have the potential to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements. Risks of decrease Central Valley Steelhead juvenile salvage during construction would be minimized through appropriate mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10, and MM-AQUA-12..

Skinner Fish Facility improvements under Alternative 1 to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources from the small screen program

Fish screens under Alternative 1 would also benefit this lifestage in the same ways described above. Juvenile Central Valley Steelhead outmigrating in the Bay-Delta may be exposed to the effects of construction of screens since they migrate downstream during most months of the year, with a peak emigration period in the spring and a smaller peak in the fall (Hallock et al. 1961). Juvenile Central Valley Steelhead may be found in the work area of these projects; however, MM-AQUA-7 would minimize impacts.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

Potential effects of the Delta Fishes Conservation Hatchery include inadvertent propagation and release of nuisance species and reduced water quality resulting from hatchery discharge. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Central Valley Steelhead would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Delta under Alternative 1, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) which means that none to a few late or early migrants of this life stage could be exposed to Delta Fishes Conservation Hatchery construction. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risk from these potential effects would be minimized through application of mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-14 (Appendix E, *Mitigation Measures*).

O.3.4.3.7 North American Green Sturgeon Southern DPS

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

As described above, juvenile Green Sturgeon may potentially be entrained into the SDWSC. Fish entering the SDWSC would not, however, be exposed to entrainment into the interior Delta through the DCC or

Georgiana Slough which would provide a benefit if survival rates are similar between the SDWSC and the Sacramento main stem.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta or Suisun Marsh food subsidies by routing drain water would occur in summer/fall and therefore could provide food benefits to Green Sturgeon juveniles, who are in the Delta in the fall.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Provision of north Delta or Suisun Marsh food subsidies by routing drain water would occur in summer/fall and therefore could provide food benefits to Green Sturgeon juveniles, who are in the Delta in the fall.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile southern DPS Green Sturgeon are expected to be exposed to continuing to implement the 8,000 acres of tidal habitat restoration in the Delta under Alternative 1. Tidal habitat restoration is expected to benefit juvenile Green Sturgeon in several aspects represented by the Green Sturgeon juvenile conceptual model (Reclamation 2019) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 1 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids. It is currently unknown if predation on juvenile Green Sturgeon in the Delta is limiting their productivity. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the rearing and migratory corridors of juvenile Green Sturgeon.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Little is known about the migratory behavior of juvenile Green Sturgeon in the Sacramento River basin. It is likely that juvenile Green Sturgeon (larger than the 75 mm) will not enter the Delta prior to their first winter and thus would not be exposed to the open DCC gates. It is likely that these fish will enter the Delta sometime in the winter or spring following their hatching upriver and encounter both types of gate configurations as they enter the Delta. More information is required to accurately assess the migratory movements of juvenile Green Sturgeon in the river system, as well as their movements within the Delta during their rearing phase in estuarine/Delta waters. Greater operational flexibility and increased gate reliability resulting from improvements would reduce the risk of gate failure that could result in higher rates of entrainment.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

Upgrades to the TFCF will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

As previously described, juvenile Green Sturgeon can occur in the Delta year-round (Reclamation 2019) and, therefore, have the potential to be exposed to the effects of construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements. If construction affects the efficiency of Green Sturgeon salvage (which is an element of entrainment risk; Reclamation 2019), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12 (Appendix E, *Mitigation Measures*).

Skinner Fish Facility improvements under Alternative 1, which involve predator control efforts, can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently. Thus, Alternative 1 is not likely to negatively impact juvenile Green Sturgeon.

Potential changes to aquatic resources from the small screen program

Southern DPS Green Sturgeon are expected to be present in the Delta during the main irrigation period for small diversions (late spring to fall). Diversion screening under Alternative 1 could reduce entrainment of individual Green Sturgeon. However, there is currently no information on the proportion of juvenile Green Sturgeon that are entrained into small unscreened diversions. North American Green Sturgeon in the juvenile to subadult/adult life stage may be exposed to the effects of construction of screens since they are present in the Sacramento River year-round (Reclamation 2019). Effects are the same as described above for juveniles. MM-AQUA-7 would minimize risk.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

None of the Green Sturgeon life stages would benefit from the Delta Fish Species Conservation Hatchery under Alternative 1. As with the other proposed construction activities in the Delta, the year-round occurrence of juvenile Green Sturgeon in the Delta (Reclamation 2019) means that this life stage, as well as the timing of the adult Green Sturgeon occurring in the Delta during May to October, could be exposed to Delta Fish Species Conservation Hatchery construction under Alternative 1. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risks from these potential effects would be minimized with through the application of mitigation measures including MM-AQUA-1, MM-AQUA-2 and MM-AQUA-4 through MM-AQUA-14 (Appendix E, *Mitigation Measures*).

O.3.4.4 *Nearshore Pacific Ocean on the California Coast*

O.3.4.4.1 <u>Southern Resident Killer Whale</u>

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

As previously described in Section O.3.3.1.9, *Nearshore Pacific Ocean on the California Coast,* relative to project-level effects, given the medium priority of Central Valley Chinook Salmon stocks and the contribution of hatchery-origin Chinook Salmon released downstream of the potential proposed action influence, the proposed action (Alternative 1) would not be expected to have population-level effects to

Southern Resident Killer Whale Chinook Salmon prey. This suggests limited effects of Alternative 1 programmatic activities on Southern Resident Killer Whale.

O.3.5 Alternative 2 – Project-Level Effects

O.3.5.1 *Trinity River*

O.3.5.1.1 Seasonal Operations

As described in the No Action Alternative and Alternative 1, the Trinity River system would be operated according to the Trinity River ROD with lower Klamath River augmentation flows.

Potential changes to aquatic resources from changes in reservoir storage

Under Alternative 2, storage volume in Trinity Lake would remain the same as under the No Action Alternative in most water year types. On average, storage is expected to increase by 7 TAF under Alternative 2 compared to the No Action Alternative. The effects of changes in reservoir storage conditions as they relate to water temperature can be assessed by looking at temperatures in the Trinity River downstream of Trinity Dam. Under Alternative 2, average monthly water temperatures in the Trinity River downstream of Trinity Dam would remain similar compared to the No Action Alternative (Figure O.3-87). Maximum modeled water temperatures in the Trinity River downstream of Trinity Dam are generally similar under Alternative 2 compared to the No Action Alternative except in August when temperatures are approximately 5°F higher, in September when temperatures are approximately 2°F higher, and in October when temperatures are approximately 4°F lower under Alternative 2 compared to the No Action Alternative.

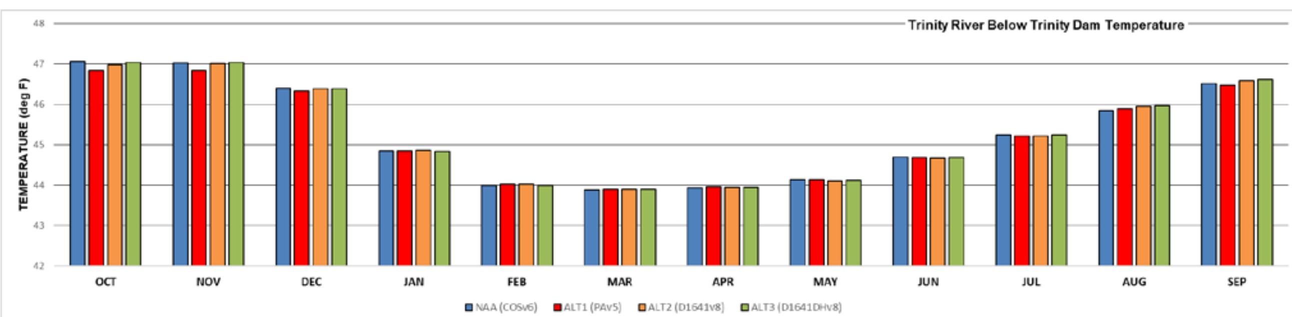

Figure O.3-87. Average Trinity River Water Temperatures below Trinity Dam for the Period October to September, Average of All Water Year Types

No focal fish species occur in Trinity Lake or in the Trinity River downstream of Trinity Dam. Effects of Trinity Reservoir storage on fish in the Trinity River downstream of Lewiston Dam are described below.

Potential changes to aquatic resources from variation in flow

Under Alternative 2 environmental conditions in the Trinity River downstream of Lewiston Dam would be similar to flows under the No Action Alternative in most months and water year types. However, in wet years flows would increase in December under Alternative 2 compared to the No Action Alternative (1,295 cfs versus 1,192 cfs). In above normal years flows under Alternative 2 would decrease in November compared to the No Action Alternative (565 cfs versus 678 cfs) and increase in February compared to the No Action Alternative (801 cfs versus 528 cfs). In critically dry years, flows under Alternative 2 would decrease compared to the No Action Alternative in September and October from 870 cfs to 818 cfs and from 342 cfs to 311 cfs, respectively, and flows would increase in November from 275 cfs to 300 cfs compared to the No Action Alternative.

Coho Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 2 compared to the No Action Alternative. Minor differences (<10%) in November and December of some water year types and a larger difference (17%) in November of above normal water years may affect spawning and juvenile rearing habitat for Coho Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these differences in flow are not expected to result in a detectable effect on Coho Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in above normal water years in February would increase by approximately 52% under Alternative 2 (801 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Coho Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Spring-Run Chinook Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 2 compared to the No Action Alternative. Minor differences (<10%) in November and December of some water year types and a larger difference (17%) in November of above normal water years may affect spawning and juvenile rearing habitat for Spring-Run Chinook Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these differences in flow are not expected to result in a detectable effect on Spring-Run Chinook Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in above normal water years in February would increase by approximately 52% under Alternative 2 (801 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Spring-Run Chinook Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Fall-Run Chinook Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 2 compared to the No Action Alternative. Minor differences (<10%) in November and December of some water year types and a larger difference (17%) in November of above normal water years may affect spawning habitat for Fall-Run Chinook Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these differences in flow are not expected to result in a detectable effect on Fall-Run Chinook Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in above normal water years in February would increase by approximately 52% under Alternative 2 (801 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Fall-Run Chinook Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Steelhead (Winter- and Summer-Run)

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 2 compared to the No Action Alternative. Flow under Alternative 2 in February of above normal water years would increase by approximately 52% (801 cfs) compared to the No Action Alternative (528 cfs). This increase in flow may reduce the amount of spawning habitat for Steelhead. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999: 123), increasing flows from 500 cfs to 800 cfs showed little change in the amount of spawning habitat for Steelhead in the Trinity River from downstream of Lewiston Dam to the confluence with Dutch Creek.

Green Sturgeon

Green Sturgeon occur within the lower 43 miles of the Trinity River, approximately 70 miles downstream of Lewiston Dam. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in flow under Alternative 2 would not affect Green Sturgeon.

White Sturgeon

White Sturgeon are not likely to be affected by changes in reservoir operations under Alternative 2 compared to the No Action Alternative due to their limited distribution in the lower Klamath River, primarily in the estuary.

Pacific Lamprey

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 2 compared to the No Action Alternative. However, minor changes (<10%) to flow would occur under Alternative 2 in November and December of some water year types and a larger change to flow in November (565 cfs compared to 678 cfs under the No Action Alternative) and February (801 cfs compared to 528 cfs under the No Action Alternative) of above normal water years. Increased flows in February overlap with the Pacific Lamprey adult migration period but are not expected to affect migration because Pacific Lamprey migration spans multiple seasons and associated flows. Although previous flow habitat relationship studies in the Trinity River (USFWS 1999) did not focus on Pacific Lamprey, results for salmonids suggest that changes in flow under Alternative 2 would not result in a detectable effect on juvenile rearing or adult holding habitat for Pacific Lamprey compared to the No Action Alternative.

American Shad

American Shad are primarily found in the Lower Klamath River but may occur in the lower sections of the Trinity River up to approximately RM 24 at the town of Willow Creek. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in flow under Alternative 2 would not affect American Shad.

Potential changes to aquatic resources due to variation in temperature

Modeling results indicate that changes in monthly average water temperature in the Trinity River downstream of Lewiston Dam would be similar between Alternative 2 and the No Action Alternative. Differences in monthly average temperature between Alternative 2 and the No Action Alternative are less than 0.5°F for all months of the year (Figure O.3-88). Modeled maximum temperatures in the Trinity River are lower under Alternative 2 compared to the No Action Alternative in July and October and higher in August, September, and December, with similar maximum temperatures in the remaining months (Figure O.3-89 and Table O.3-24).

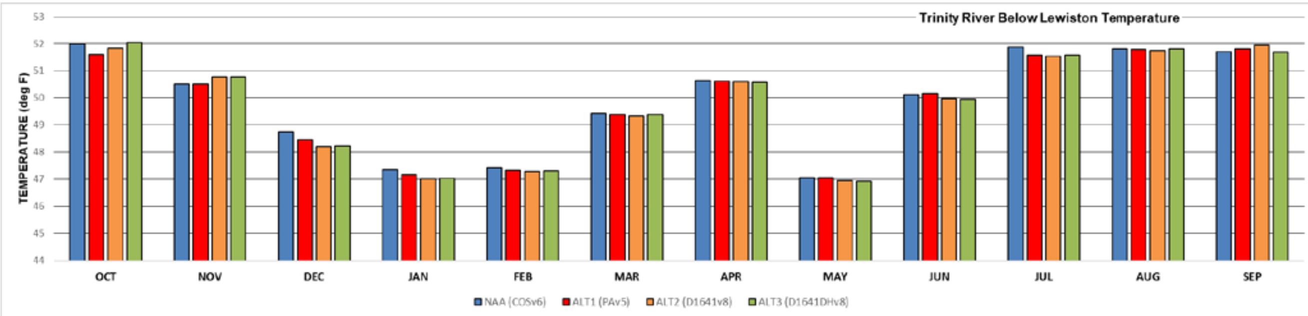

Figure O.3-88. Average Trinity River Water Temperatures below Lewiston Dam for the Period October to September, Average of All Water Year Types

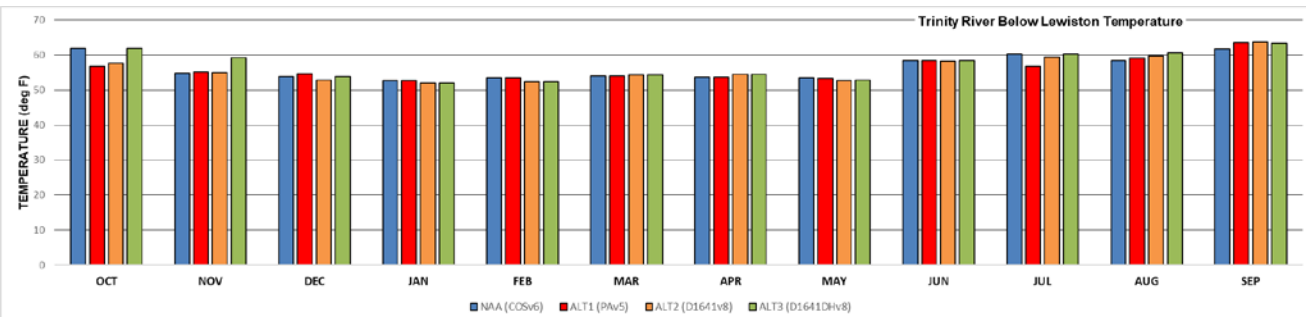

Figure O.3-89. Maximum Trinity River Water Temperatures below Lewiston Dam for the Period October to September, Average of All Water Year Types

Table O.3-24. Maximum Trinity River Water Temperatures below Trinity Dam for the Period October–September, Average of All Water Year Types (Differences >1°F Are Highlighted)

Alt	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
No Action Alternative	61.8	54.8	53.8	52.7	53.4	54.1	53.7	53.5	58.4	60.3	58.4	61.8
ALT 1	56.7	55.2	54.6	52.6	53.5	54.0	53.7	53.4	58.4	56.9	59.1	63.5
ALT 2	57.6	55.1	52.8	52.0	52.4	54.4	54.5	52.7	58.4	59.4	59.7	63.8
ALT 3	61.9	59.3	53.9	52.0	52.4	54.4	54.5	52.9	58.4	60.3	60.6	63.4

In a previous study that looked at flow and water temperatures in the Trinity River (USFWS 1999), results indicated that flows do not have a significant influence on water temperatures from mid-October through early April when cooler air temperatures help maintain cold water temperatures even when flow releases drop below 150 cfs. Once tributary influence begins to decrease and meteorological conditions warm from May to mid-July, flow releases become more influential on downstream temperatures, particularly in hot-dry conditions. Maintaining a flow of 450 cfs in the summer and early fall was found to meet the water temperature objectives for the Trinity River when water released from Lewiston Dam was 53°F or less (USFWS 1999: 203). Water temperatures are most influenced by flow releases from May through mid-October. Flows from May to October would be similar under Alternative 2 compared to the No Action Alternative in most water year types, with the exception of critically dry years. In critically dry years, flows in September and October would decrease by approximately 6% to 9% under Alternative

2 compared to the No Action Alternative from 870 cfs to 818 cfs and from 342 cfs to 311 cfs, respectively. Based on modeling results, changes in flow under Alternative 2 are not likely to have a detectable change in water temperature in the Trinity River downstream of Lewiston Dam in all but critically dry years.

Coho Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 2 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 2 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-88). Modeled maximum temperatures in the Trinity River in July and October would be approximately 1°F to 4°F lower under Alternative 2 compared to the No Action Alternative and approximately 1°F to 2°F higher in August, September, December, and February with similar maximum temperatures in the remaining months (Figure O.3-89). Maximum temperatures under Alternative 2 increase in August and September and exceed the NCRWQCB (2018) objectives for the Trinity River. Under both the No Action Alternative and Alternative 2, water temperatures exceed the NCRWQCB objectives during this time; however, further increases in temperature that would occur under Alternative 2 may reduce juvenile Coho Salmon rearing success. Conversely, the decreased maximum temperatures under Alternative 2 that occur in July would meet the NCRWQCB (2018) objectives for the Trinity River, and the cooler October water temperatures may improve juvenile rearing conditions compared to conditions under the No Action Alternative.

Spring-Run Chinook Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 2 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 2 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-88). Modeled maximum temperatures in the Trinity River in July and October would be approximately 1°F to 4°F lower under Alternative 2 compared to the No Action Alternative and approximately 1°F to 2°F higher in August, September, December, and February with similar maximum temperatures in the remaining months (Figure O.3-89). Spring-Run Chinook Salmon spawning usually peaks in October but typically ranges from the third week of September through November. Maximum August and September temperatures under Alternative 2 would exceed the NCRWQCB (2018) objectives for the Trinity River. Under both the No Action Alternative and Alternative 2 water temperatures exceed the NCRWQCB objectives during this time. However, the further increases in temperature predicted under Alternative 2 may limit the success of adult migration, spawning, and juvenile rearing of Spring-Run Chinook Salmon. Conversely, the reduced temperatures under Alternative 2 that occur in July would meet the NCRWQCB (2018) objectives for the Trinity River, and the cooler temperatures in October may improve spawning and juvenile rearing conditions compared to conditions under the No Action Alternative

Fall-Run Chinook Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 2 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 2 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-88). Modeled maximum temperatures in the Trinity River in July and October would be approximately 1°F to 4°F lower under Alternative 2 compared to the No Action Alternative and approximately 1°F to 2°F higher in August, September, December, and February, with similar maximum temperatures in the remaining months (Figure O.3-89). Fall-Run Chinook Salmon spawning usually occurs between October and December with peak spawning activity occurring in November. Maximum August and September temperatures would exceed the NCRWQCB (2018) objectives for the Trinity River and may affect adult migration for Fall-Run Chinook Salmon compared to the No Action Alternative; however, the reduced temperatures under Alternative 2 in October would improve spawning conditions compared to the No Action Alternative.

Steelhead (Winter- and Summer-Run)

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 2 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 2 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-88). Modeled maximum temperatures in the Trinity River in July and October would be approximately 1°F to 4°F lower under Alternative 2 compared to the No Action Alternative and approximately 1°F to 2°F higher in August, September, December, and February, with similar maximum temperatures in the remaining months (Figure O.3-89). Maximum temperatures under Alt 2 would increase in August and September with temperatures exceeding the NCRWQCB (2018) objectives for the Trinity River. Under both the No Action Alternative and Alt 2 water temperatures would exceed the NCRWQCB objectives during this time. However, larger increases in temperature that would occur under Alternative 2 may further reduce juvenile Steelhead rearing success. Conversely, the reduced maximum temperatures under Alternative 2 that would occur in July meet the NCRWQCB (2018) objectives for the Trinity River, and the cooler temperatures in October would improve juvenile rearing conditions compared to the No Action Alternative.

Green Sturgeon

Green Sturgeon occur within the lower 43 miles of the Trinity River, approximately 70 miles downstream of Lewiston Dam. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Results of previous water temperature modeling for the Trinity River (USFWS 1999) predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43 with smaller temperature differences expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers. Therefore, changes in water temperature under Alternative 2 would not affect Green Sturgeon.

White Sturgeon

White Sturgeon would not be affected by changes in reservoir operations under Alternative 2 compared to the No Action Alternative due to their limited distribution in the lower Klamath River, primarily in the estuary.

Pacific Lamprey

Model results predict that water temperatures in the Trinity River below Lewiston Dam would be similar under Alternative 2 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 2 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-88). Modeled maximum temperatures in the Trinity River in July and October would be approximately 1°F to 4°F lower under Alternative 2 compared to the No Action Alternative and approximately 1°F to 2°F higher in August, September, December, and February, with similar maximum temperatures in the remaining months (Figure O.3-89). Maximum temperatures under Alternative 2 increase in August and September with temperatures exceeding the NCRWQCB (2018) objectives for the Trinity River. Under both the No Action Alternative and Alternative 2 water temperatures exceed the NCRWQCB objectives during this time. However, larger increases in temperature that would occur under Alternative 2 may further reduce Pacific Lamprey juvenile rearing success. Conversely, the decreased maximum temperatures under Alternative 2 that would occur in July meet the NCRWQCB (2018) objectives for the Trinity River, and the cooler temperatures in October may improve Pacific Lamprey juvenile rearing conditions compared to the No Action Alternative.

American Shad

American Shad are primarily found in the Lower Klamath River but may occur in the lower sections of the Trinity River up to approximately RM 24 at the town of Willow Creek. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in water temperature under Alternative 2 would not affect American Shad.

O.3.5.1.2 Trinity River Record of Decision

The Trinity River ROD is being implemented under both Alternative 2 and the No Action Alternative. Therefore, implementation of the variable annual flow regime, restoration actions, and monitoring and adaptive management, per the Trinity River ROD under Alternative 2 would have similar effects as the No Action Alternative on Coho Salmon, Chinook Salmon (Spring- and Fall-Run), Steelhead (Winter- and Summer-Run), Green Sturgeon, White Sturgeon, Pacific Lamprey, and American Shad.

O.3.5.2 *Sacramento River*

Potential changes to aquatic resources in the Sacramento River from seasonal operations

Under all the Project alternatives, flows in the upper Sacramento River result from controlled releases from Shasta and Keswick reservoirs, as well as transfers from the Trinity River and natural accretions. Dry hydrologic conditions often lead to inadequate storage in Shasta Reservoir for operators to provide suitable conditions for salmonids and other native species in the upper Sacramento River. In most cases, water temperature rather than flow is the limiting factor creating unsuitable conditions, as discussed below. The primary differences between the No Action Alternative and Alternative 2 for the Sacramento River upstream of the Delta is that the No Action Alternative includes NMFS's 2009 BO RPAs to operate Shasta Reservoir for management of cold water in the reservoir and river to protect anadromous salmonids, and requirements for Fall X2 flow releases, but Alternative 2 does not include either requirement. A minimum flow of 3,250 cfs is required from Keswick Dam to the RBDD during October through March under the No Action Alternative and during October through February under Alternative 2 (NCWA 2014).

CalSim II modeling indicates that average flow released at Keswick Dam under Alternative 2 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 2 flows would be substantially lower than the No Action Alternative flows (Table O.3-25). The higher September and November flows under the No Action Alternative result from Fall X2 releases, which are not included in Alternative 2. Table O.3-25 shows that the highest mean monthly flows for both alternatives occur primarily during winter of wet and above normal water years and during summer of all water year types. Flow releases are high during summer to satisfy downstream demands of water users and Delta water quality and to meet water temperature requirements of incubating Winter-Run Chinook Salmon eggs and alevins downstream of Keswick Dam.

Table O.3-25. CalSim II Monthly Average Flow (cfs) by Water Year Type and Month below Keswick Dam for No Action Alternative, Alternative 2 and Differences between Them

Alternative[1,2,3] Water Year Type[4]	Monthly Flow (cfs)											
	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
No Action Alternative

6 Bold green font indicates greater than 5% increase in flow; bold red font indicates greater than 5% reduction in flow.

HEC-5Q modeling was used to compare water temperature effects of the No Action Alternative and Alternative 2. Based on recent investigations of Winter-Run Chinook Salmon mortality in the upper Sacramento River (Martin et al. 2017; Anderson 2018), this effects analyses uses an upper water temperature threshold of 53.5°F for suitable salmonid spawning and egg and alevin incubation in the Sacramento River. An important caution regarding the HEC-5Q water temperature modeling results, particularly with regard to meeting water temperature criteria (e.g., 56°F water temperature at Bend

Bridge criterion), relates to the time step used in the modeling. HEC-5Q, like the CalSim II model on which it relies for flow data, has a monthly time step and provides estimates of monthly mean water temperatures. However, most of the regulatory requirements to meet water temperature criteria apply to daily mean (or shorter duration) water temperatures. Daily means are almost always much more variable than monthly means and, therefore, the monthly mean water temperature estimates provided by HEC-5Q are not directly comparable to the regulatory criteria. For example, even with constant flows releases, downstream daily water temperatures would fluctuate around the mean in response to variation in solar radiation and other meteorological conditions within a given month. In view of this limitation, it is helpful to consider the comparisons of temperature effects among the alternatives as indicating the relative likelihoods of exceeding temperature criteria, rather than whether or not the criteria are actually met. These considerations apply to the CalSim II flow data as well, but are less important for flow because there are fewer regulatory criteria for flow and, except during storm events, flow tends to be less variable than water temperature.

During the summer and much of the fall, water released from Keswick Dam warms downstream resulting in warmer water temperatures in more downstream habitats. Therefore, the effects of the alternatives on fish populations depend on the habitat distributions of the populations as well as the results of temperature management operations. Winter-Run Chinook Salmon mostly spawn from Keswick Dam to about 6 miles downstream of the Clear Creek temperature gage, Spring-Run from Keswick Dam to about Balls Ferry, fall-run from Keswick Dam to about RBDD, late fall-run spawning distribution is similar to that of Winter-Run, and Green Sturgeon spawn downstream of the Cow Creek confluence to the GCID oxbow near Hamilton City (NMFS 2018b). Steelhead spawning areas in the upper Sacramento River are poorly known.

Based on the HEC-5Q modeling, the mean monthly water temperatures at Keswick Dam are roughly equal under the No Action Alternative and Alternative 2, except for September of Above Normal water years, which has a 1.3°F higher mean water temperatures under Alternative 2 than under the No Action Alternative (Table O.3-26). Summer mean monthly water temperatures are consistently below the 53.5°F temperature threshold, except in critically dry water years during July through September. The October and November mean water temperatures under Alternative 2 are similar to those under the No Action Alternative and are just above the 53.5°F temperature threshold, except for critically dry water years, when those for both alternatives are well above the threshold (Table O.3-26). For October, the mean water temperature for critically dry water years is 0.7°F higher under Alternative 2 than that under the No Action Alternative. Although this difference is not large, it occurs under highly stressful temperature conditions for salmonids eggs and alevins. The largest predicted increase in mean water temperature under Alternative 2 is 1.3°F for September of Above Normal water years (Table O.3-26). This increase occurs over a range well below the critical temperature threshold and is therefore unlikely to have a large effect on the salmonids. The differences between the No Action Alternative and Alternative 2 in September water temperatures at Keswick Dam are small (Figure O.3-20) relative to those at more downstream locations, as described below.

The HEC-5Q results indicate that late spring through early fall water temperatures in the Sacramento River at Clear Creek are slightly warmer than those at Keswick Dam, with larger increases in September water temperature differences between the No Action Alternative and Alternative 2 (Table O.3-27). Summer mean monthly water temperatures are below the 53.5°F temperature threshold, except in drier water years, especially in August and September. All mean temperatures for October and November are above the threshold for both alternatives. At Balls Ferry, the temperatures are warmer still and the September increases are larger (Table O.3-28). The mean September water temperatures for wet and above normal water years at Balls Ferry exceed the critical water temperature threshold under Alternative 2, but not under the No Action Alternative (Table O.3-28). As discussed previously, the monthly mean water temperatures provide a rough estimate of the probability of mean daily water temperatures exceeding a temperature threshold. Because the mean monthly water temperatures are higher under Alternative 2, the probability or frequency of the threshold being exceeded in September of wet and above normal water years is expected to be higher under Alternative 2 than under the No Action Alternative.

The downstream trends in water temperature conditions noted for Keswick Dam, Clear Creek and Balls Ferry continue to RBDD, with little difference in water temperatures between the alternatives, except for substantially warmer temperatures in September of wet and above normal water years under Alternative 2 (Table O.3-29). The growing downstream differences in wet and above normal water year temperatures for September can be seen in Figures O.3-20, O.3-31 and O.3-22. These temperature differences are largely limited to the cooler 50% of years. Under both the No Action Alternative and Alternative 2, the mean water temperatures at RBDD for April through October are above the critical water temperature threshold in all water year types. The pattern of increasing water temperatures differences in September of wet and above normal water years between the No Action Alternative and Alternative 2 continues downstream to Hamilton City and Knights Landing, (Table O.3-30 and O.3-31; Figures O.3-23 and O.3-24). However, at these locations there are also water temperature reductions of 1°F to 2°F between the No

Action Alternative and Alternative 2 during May, June, August, and September of above normal, below normal or dry water years, depending on the month (Table O.3-30 and O.3-31; Figures O.3-90 and O.3-91). These reductions result from increases in flow under Alternative 2 relative to the No Action Alternative (Tables O.3-32 through O.3-34).

The reduced downstream warming of the river in September of wet and above normal water years under the No Action Alternative relative to the Alternative 2 is due, at least in part, to the much higher flow releases for Fall X2, as noted above (Table O.3-25). Note that November Fall X2 flow releases under the No Action Alternative do not result in higher water temperatures under Alternative 2 (e.g., Table O.3-31), presumably because November air temperatures would, on average, be similar to or lower than the water temperatures.

It is expected that, in general, water temperatures between the No Action Alternative and Alternative 2 would be largely similar, with the exception of September of wet and above normal water years, when water temperatures are warmer under the Alternative 2 because this alternative would not include the Fall X2 flows that reduce downstream warming under the No Action Alternative, and with the exception of May, June, August and September of various water year types at the most downstream locations, when water temperatures are cooler under Alternative 2 because of higher flows.

O.3.5.2.1 Sacramento River Winter-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Winter-Run Chinook Salmon adults spawn from May through August with peak spawning during June and July (Section O.2.4.2.1, *Winter-Run Chinook Salmon*). Fry emergence occurs up to 3 months after eggs are spawned, so effects of flow and water temperature on Winter-Run eggs and alevins may occur from May through November, but primarily occur during June through October.

As previously noted, CalSim II modeling indicates that mean monthly flow released at Keswick Dam under Alternative 2 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 2 flows would be substantially lower than the No Action Alternative flows (Table O.3-25). By September in most years, a large proportion of Winter-Run Chinook Salmon redds still contain incubating alevins. Assuming flows are stable enough to avoid dewatering the redds, which is generally true in September, the most important effect of flows on alevins is to transport dissolved oxygen to the developing alevins and to flush potentially toxic metabolites out of the redds. Although the mean September wet and above normal water year flows are substantially lower under Alternative 2 than under the No Action Alternative, the flows under Alternative 2 flows remain moderately high (>6,000 cfs) (Figure O.3-25). Flows at this level are expected to provide sufficient flow velocity to keep the redds clean and well oxygenated. With regard to redd dewatering, there are some reductions in mean monthly flows below Keswick Dam during the fall under Alternative 2, but these are similar to the fall reductions expected under the No Action Alternative (Table O.3-25). Therefore, differences in flow between the No Action Alternative and Alternative 2 are expected to have little effect on Winter-Run Chinook Salmon spawning and incubation habitat.

As noted in the previous section, there are few differences between the No Action Alternative and Alternative 2 in the HEC-5Q water temperature results for the Winter-Run Chinook Salmon spawning period (Table O.3-26). The largest difference for the Keswick Dam location, a 1.3°F increase in September of Above Normal water years under Alternative 2, would occur within a range of temperature well below the 53.5°F water temperature threshold, and therefore would not affect Winter-Run Chinook Salmon eggs or alevins. The mean October water temperatures at Keswick are predicted to be above the water temperature threshold in about 85% of years under both the No Action Alternative and Alternative 2 (Figure O.3-18). September mean monthly water temperatures exceed the threshold in critically dry water years under both alternatives (Table O.3-26). At the more downstream Winter-Run Chinook Salmon spawning locations, the September water temperatures exceed the threshold for more of the water year types (Tables O.3-27 and O.3-28). At these location, water temperature increases between the No Action Alternative and Alternative 2 for September of wet and above normal water years result in water temperatures approaching or exceeding the 53.5°F temperature threshold under Alternative 2, but not under the No Action Alternative, which would result in adverse effects on Winter-Run Chinook Salmon eggs and alevins under Alternative 2.

Recent investigations of Winter-Run Chinook Salmon mortality in the upper Sacramento River (Martin et al. 2017; Anderson 2018) yielded models for estimating mortality of Winter-Run Chinook Salmon eggs and alevins under different water temperature conditions. These models, referred to hereinafter as the

Martin and Anderson models, were used to compare water-temperature-related mortality of Winter-Run Chinook Salmon eggs and alevins under Alternative 2 and the No Action Alternative. The modeling was based on the HEC-5Q water temperature estimates for the years used in the HEC-5Q modeling (1922 to 2002). The results for all water year types combined indicate that egg/alevin mortality under Alternative 2 would be similar to that under the No Action Alternative (Figure O.3-92). Figure O.3-92 combines results for all water year types, including wet years, when there is little temperature-related mortality. This obscures the modeling results for drier years, when egg/alevin mortalities are especially high. For critically dry water years, the mortality modeling also shows little difference in mortality between Alternative 2 and the No Action Alternative (Figure O.3-93).

The flow effects resulting from Alternative 2 would have a less-than-significant effect relative to the No Action Alternative on Winter-Run Chinook Salmon spawning and the egg and alevin life stages, but the water temperature effects would have a significant adverse impact relative to the No Action Alternative because of the temperature increases in September of wet and above normal water years.

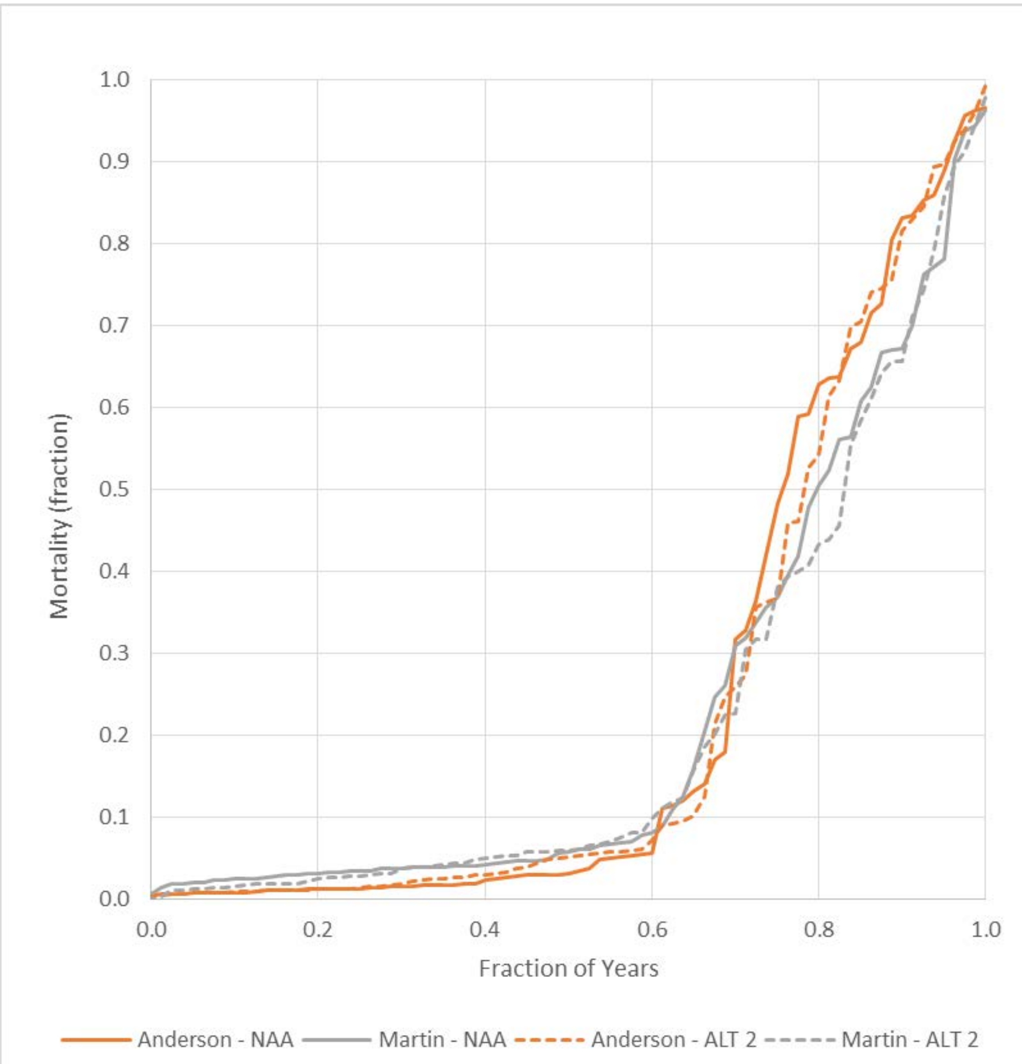

Figure O.3-92. Exceedances of Winter-Run Chinook Salmon Temperature-Dependent Egg Mortality, Alternative 2 vs. No Action Alternative; All Water Year Types.

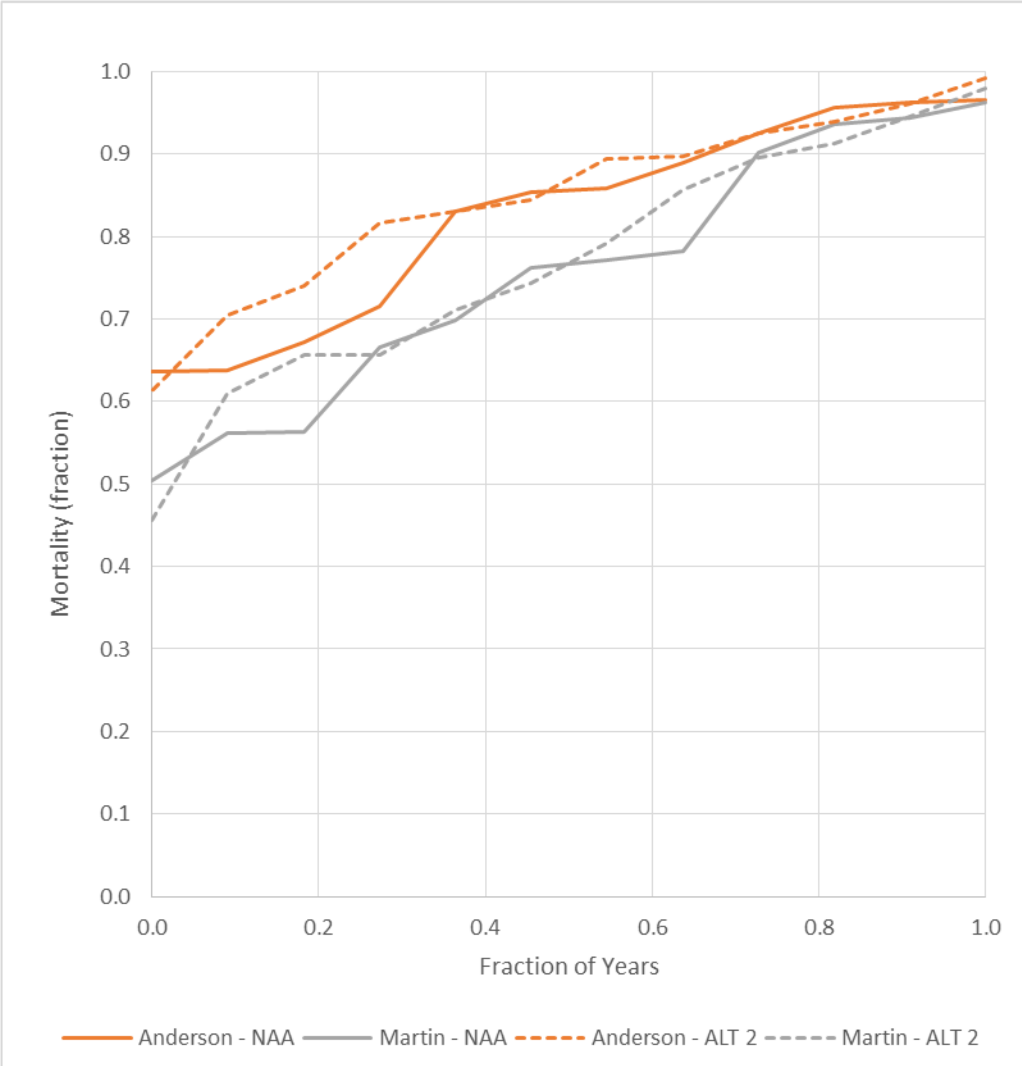

Figure O.3-93. Exceedances of Winter-Run Chinook Salmon Temperature-Dependent Egg Mortality, Alternative 2 vs. No Action Alternative; Critically Dry Water Years

Juvenile Rearing and Emigration

Winter-Run Chinook Salmon juveniles rear in the Sacramento River primarily from late summer to late winter, and emigrate from the river to the Delta beginning in November (see Section O.2.4.2.1, *Winter-Run Chinook Salmon*). The proportion of juveniles surviving to emigrate to the Delta depends largely on habitat conditions, including flow and water temperature. Inundated floodplain habitat has been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Sacramento River flow during the Winter-Run Chinook Salmon juvenile rearing and emigration period differs substantially between the No Action Alternative and Alternative 1, especially during September and November of wet and above normal water years (Tables O.3-25, O.3-32 through O.3-34). The juveniles rear primarily in the upper and middle Sacramento River until about October, when they begin to appear in the lower river (e.g., Knights Landing) (del Rosario et al. 2013). As noted previously, because the No Action Alternative includes Fall X2 releases but Alternative 2 does not, the mean monthly flows during September and November are much lower under Alternative 2 than under the No Action Alternative, which would potentially reduce suitable rearing habitat for juveniles (Tables O.3-25 and O.3-32 through O.3-34; Figures O.3-25, O.3-28 and O.3-29).

Emigration of juvenile Winter-Run Chinook Salmon from the Sacramento River is triggered by pulse flows of about 14,000 cfs and above (at Wilkins Slough) (del Rosario et al. 2013). CalSim II September flows at Wilkins Slough exceed this threshold in about 18% of years under the No Action Alternative and never exceed it under Alternative 2, but September is too early for juvenile Winter-Run Chinook Salmon to emigrate to the Delta (del Rosario et al. 2013). For November, when Winter-Run juveniles are ready to emigrate, monthly mean flow at Wilkins Slough is much higher under the No Action Alternative than under Alternative 2, but remains below the 14,000 cfs threshold for both alternatives, except for the highest 9% of flows (Figure O.3-29). There are no differences between the alternatives for these highest flows. An important limitation with this analysis is that the CalSim II flow estimates are monthly averages and Winter-Run Chinook Salmon emigration can be triggered by flow pulses that exceed 14,000 cfs for only a few days (del Rosario et al. 2013), so the flow differences in Figure O.3-29 incompletely represent the likelihood of triggering pulse flows occurring under the two alternatives.

Results from a more recent analysis suggest that the reduction in November flows from the No Action Alternative to Alternative 2 during wet and above normal water years could adversely affect Winter-Run Chinook Salmon juveniles emigrating at that time. The NMFS Southwest Fisheries Science Center ran statistical models using 2012-2017 tagging data from Spring-Run Chinook Salmon and Fall-Run Chinook Salmon and found a significant increase in smolt survival when Sacramento River flow at Wilkins Slough was above 9,100 cfs during the smolts out-migration period (Cordoleani et al. 2019). The CalSim II results for November at Wilkins Slough indicate that, under the No Action Alternative, 50% of years would have mean monthly flows that exceed the 9,100 cfs threshold, but that under Alternative 2 only 20% of years would exceed the threshold (Figure O.3-29). If these results apply to Winter-Run Chinook Salmon juveniles emigrating in November, they indicate a potential adverse effect of Alternative 2 on emigrating Winter-Run juveniles. The applicability of the results to Winter-Run Chinook Salmon are currently unknown, so the effect on Winter-Run Chinook Salmon is uncertain.

The USEPA (2003) gives 61°F as the critical 7 day average daily maximum (7DADM) water temperature for Winter-Run Chinook Salmon juveniles rearing in the upper Sacramento River and 64°F (7DADM) for those rearing in the middle Sacramento River (Knights Landing). Under the No Action Alternative, NMFS's RPA 1.2.4 requires Reclamation to maintain water temperature from May 15 through October 31 in the Sacramento River at no more than 56°F at compliance locations between Ball's Ferry and Red Bluff Diversion Dam. Under Alternative 2, SWRCB's WRO 90-5 has similar but more flexible water temperature requirements for Reclamation (NMFS 2011, RPA 1.2.4; SWRCB 1990, WRO-90-5). Therefore, under both alternatives, juveniles rearing in the upper Sacramento River are likely to be well protected from water temperature extremes through the end of October in all but the driest years.

Under the No Action Alternative and Alternative 2, mean monthly water temperatures at Keswick exceed the 61°F threshold in only about 5% of years in September and October, with no appreciable water temperatures differences between the alternatives for water temperatures greater than the 61 degree Fahrenheit threshold (Figures O.3-18 and O.3-19; Table O.3-26). The monthly average temperatures for these months should reasonably estimate daily mean temperatures because operations at Shasta and Keswick dams create relatively stable summer and fall flow and water temperature conditions in the upper Sacramento River. From November through March, by which months most juvenile Winter-Run Chinook Salmon have emigrated to the Delta, there are only minor differencs in mean water temperatures at all locations from Keswick Dam to Knights Landing (Tables O.3-26 through O.3-31).

The water temperature effects on juvenile Winter-Run Chinook Salmon rearing in or emigrating from the Sacramento River resulting from Alternative 2 would be less-than-significant relative to the No Action Alternative, but the flow effects are potentially significant because the reductions in September flows in wet and above normal water years could reduce rearing habitat and the reductions November flows in wet and above normal water years could reduce smolt survival.

Adult Upstream Migration and Holding

Winter-Run Chinook Salmon adults enter the Sacramento River from the Delta and make their way to the upper Sacramento River, beginning as early as December. They hold in the upper River within 10 to 15 miles of Keswick Dam until they are ready to spawn, which may extend through August (Windell et al. 2017).

There are no flow or temperature requirements for the middle Sacramento River designed to protect fish. However, releases from Shasta Reservoir during November through early May may be reduced to conserve water for the May through October Winter-Run and Spring-Run Chinook Salmon spawning and incubation periods, resulting in reduced flow in the middle river (NMFS 2011: RPA I.2.2; SWRCB 1990: WRO 90-5). Lower flow in the Sacramento River relative to flow from the lower Yolo and Sutter bypasses and agricultural drains may affect navigation cues and straying of Winter-Run Chinook Salmon adults into canals and behind weirs, increasing their stranding risk. Once the adults reach holding habitat in the upper Sacramento River, they are more directly affected by Shasta and Keswick reservoir operations designed to preserve cold water for the Winter-Run and Spring-Run Chinook Salmon spawning and incubation periods. During the December through August period of adult Winter-Run Chinook Salmon immigration and holding, the mean monthly flows under Alternative 2 at Keswick Dam, RBDD, Hamilton City and Wilkins Slough would generally be similar to or greater than flows under the No Action Alternative, except during December of below normal water years at Keswick, RBDD and Hamilton City (Tables O.3-25, O.3-32 through O.3-34). However, the mean monthly CalSim II flows in December of below normal water years are greater than 6,500 cfs at all four sites for both alternatives, which is much higher than needed enough to allow upstream passage.

The USEPA (2003) gives 68°F as the critical 7DADM water temperature for Winter-Run Chinook Salmon adults migrating upstream in the Sacramento River and 61°F for adult Winter-Run holding in the upper river. There are no major differences in HEC-5Q water temperature estimates between the No Action Alternative and Alternative 2 during any of the months that adult Winter-Run Chinook Salmon migrate upstream in the Sacramento River or hold in the upper river (Tables O.3-26 through O.3-31). However, the monthly mean water temperatures are moderately cooler under Alternative 2 at Hamilton City and Knights Landing sites during May, June and August in some of the water year types (Tables O.3-30 and O.3-31). Under both alternatives, the mean monthly water temperatures in the middle Sacramento River (Knights Landing) would be below the 68°F threshold for immigrating adults from December through April, but would exceed the threshold in May of critically dry water years and June through August of all water year types (Table O.3-31). Most Winter-Run Chinook Salmon adults have migrated upstream of RBDD by late May (see Section O.2.4.2.1, *Winter-Run Chinook Salmon*) and would therefore not be adversely affected by the elevated summer downstream water temperatures. In the upper Sacramento River from Keswick to Balls Ferry, the mean water temperatures would be well below the 61°F threshold for holding adults from December through August under both alternatives (Table O.3-26, O.3-27, and O.3-28).

Alternative 2 is expected to have a less-than-signficant effect on Winter-Run Chinook Salmon adult upstream migration and holding relative to the No Action Alternative.

O.3.5.2.2 Central Valley Spring-Run Chinook Salmon

O.3.5.2.3 Spawning and Egg/Alevin Incubation

Spring-Run Chinook Salmon adults spawn from August through October with peak spawning in September (see Section O.2.4.2.2, *Spring-Run Chinook Salmon*). Monitoring Spring-Run Chinook Salmon spawning in the mainstem Sacramento River is complicated due to lack of spatial/geographic segregation and temporal isolation from Fall-Run Chinook Salmon. Most spring-sun spawning occurs between the Keswick Dam and Ball Ferry Bridge (NMFS 2017b). Fry emergence occurs up to 3 months after eggs are spawned (Moyle 2002), so effects of flow in the upper Sacramento River on incubating Spring-Run Chinook Salmon eggs and alevins potentially occur from August through January, peaking in December.

As previously noted, CalSim II modeling indicates that mean monthly flow released at Keswick Dam under Alternative 2 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 2 flows would be substantially lower (up to 43% lower) than the No Action Alternative flows (Table O.3-25). Spawning and incubating eggs and alevins could be negatively or positively affected by the flow reductions. Assuming flows are stable enough to avoid dewatering the redds, which as noted previously is an important criterion for operators of Shasta and Keswick dams, the most important effect of flows on eggs and alevins is to transport dissolved oxygen to the developing eggs and alevins and to flush potentially toxic metabolites out of the redds. Although the mean September and November wet and above normal water year flows are substantially lower under Alternative 2 than under the No Action Alternative, the flows under Alternative 2 flows remain sufficiently high (>5,900 and >7,700 cfs for September and November, respectively) to provide the flow velocity needed to keep most redds clean and well oxygenated (Figure O.3-25). Therefore, differences in flow between the No Action Alternative and Alternative 2 are expected to have little effect on Spring-Run Chinook Salmon spawning and incubation habitat.

Differences in water temperature during the Spring-Run Chinook Salmon spawning period may be important. As described previously, HEC-5Q mean October water temperatures at Keswick Dam under Alternative 2 are predicted to be similar to the No Action Alternative and above the 53.5°F water temperature threshold in in most years (Figure O.3-18; Tables O.3-26). Summer mean monthly water temperatures are consistently below the 53.5°F temperature threshold, except in critically dry water years during August through October. For October, the mean water temperature for critically dry water years is 0.7°F higher than those under the No Action Alternative. Although this difference in mean October critically dry water year water temperatures between the No Action Alternative and Alternative 2 is not large, it occurs under highly stressful temperature conditions for salmonid eggs and alevins. The largest predicted increase in mean water temperature under Alternative 2 is 1.3°F for September of Above Normal water years (Table O.3-26). This increase occurs over a range well below the critical temperature threshold and is therefore unlikely to have a large effect on the salmonids. The differences between the No Action Alternative and Alternative 2 in September water temperatures at Keswick Dam are generally small (Figure O.3-20).

Between the Clear Creek confluence and Balls Ferry, where more of the Spring-Run Chinook Salmon spawning occurs, more of the October mean monthly water temperatures under Alternative 2 exceed the threshold in all years, but most of them continue to be above or equal to the No Action Alternative means (Tables O.3-27 and O.3-28). September water temperatures in wet and above normal water years are expected to be higher under Alternative 2 than under the No Action Alternative, especially downstream of Keswick Dam (Tables O.3-27 through O.3-31), and the increases would result in more years with mean water temperatures exceeding the 53.5°F water temperature threshold (Figures O.3-30 and O.3-31). At Balls Ferry, the temperatures are even higher than at Clear Creek and the September increases are larger (Table O.3-28). September water temperatures for wet and above normal water years at Balls Ferry exceed the critical water temperature threshold under Alternative 2, but not under the No Action Alternative (Table O.3-28). Because the mean monthly water temperatures are higher than the threshold under Alternative 2, the probability or frequency of the threshold being exceeded by daily mean temperatures in September of wet and above normal water years is expected to be higher under Alternative 2 than under the No Action Alternative. The critical temperature threshold for spawning adult Chinook Salmon in the Sacramento River is the same as that for eggs and alevins, 53.5°F (Martin et al. 2017) or 55.4°F (USEPA 2003).

The HEC-5Q modeling results, which show an increased exceedance of the 53.5°F water temperature threshold during September under Alternative 2 relative to the No Action Alternative, suggest that Alternative 2 would have a significant adverse impact on Spring-Run Chinook Salmon spawning and egg and alevin incubation. It is concluded that Alternative 2 would have a significant impact on Spring-Run Chinook Salmon spawning and egg and alevin incubation with respect to water temperature.

O.3.5.2.4 Juvenile Rearing and Emigration

Spring-Run Chinook Salmon juveniles rear in the Sacramento River primarily from November through early May and most emigrate to the Delta during December and again in March and April (see Section O.2.4.2.2, *Spring-Run Chinook Salmon*). Migratory cues, such as increased flow and/or turbidity from runoff, may spur emigration of juveniles from the upper Sacramento River basin when they have reached the appropriate stage of maturation (NMFS 2009). Inundated floodplain habitats have been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Based on the CalSim II modeling results, during most of the Spring-Run Chinook Salmon juvenile rearing and emigration period, Sacramento River flow would be higher under Alternative 2 than under the No Action Alternative and many of the increases would be greater than 5% (Table O.3-25). However, the mean monthly flows for November of wet and above normal water years would be much lower under Alternative 2, because of the Fall X2 flows that are included in the No Action Alternative but not Alternative 2. Despite the reductions, the November flows under Alternative 2 remain relatively high (Tables O.3-25 and O.3-32 through O.3-34; Figures O.3-28 and O.3-29), so they are not expected to substantially affect rearing juveniles. Furthermore, as noted above, emigration occurs primarily in December and in the spring. Mean monthly flows would also be lower under Alternative 2 in January of critically dry water years, December, February and March of dry water years and December of below normal water years, (Tables O.3-25 and O.3-32 through O.3-33). Of these, only reductions in December of below normal years and February of dry years are greater than 5%. Results from a recent study suggest that for Spring-Run Chinook Salmon that do emigrate as early as November, the Alternative 2 flow reductions in November of wet and above normal water years would have a potentially adverse effect. The NMFS Southwest Fisheries Science Center ran statistical models using 2012-2017 tagging data from Spring-Run Chinook Salmon and Fall-Run Chinook Salmon and found a significant increase in smolt survival when Sacramento River flow at Wilkins Slough was above 9,100 cfs during the smolts emigration period (Cordoleani et al. 2019). The CalSim II results for November at Wilkins Slough indicate that 50% of years would have mean monthly flows that exceed the 9,100 cfs threshold under the No Action Alternative, and 20% of years would have flows that exceed the threshold under Alternative 2 (Figure (O.3-29). As shown by recent sampling at RBDD (Figure O.3-31-A), almost all Spring-Run Chinook Salmon juveniles emigrate from the upper Sacramento River after November, so the percentage of Spring-Run juveniles that would be affected by the expected reductions in November flows at Wilkins Slough would be small. Therefore changes in flow resulting from Alternative 2 are not expected to substantially affect rearing and emigrating juvenile Spring-Run Chinook Salmon.

The USEPA (2003) gives 61°F as the critical 7 day average daily maximum (7DADM) water temperature for Spring-Run Chinook Salmon juveniles rearing in the upper Sacramento River and 64°F (7DADM) for those rearing in the middle Sacramento River (Knights Landing). Under the No Action Alternative and Alternative 2, HEC-5Q estimates of mean monthly water temperatures from Keswick to RBDD do not exceed the 61°F threshold during any month and water year type during the November through May rearing period (Tables O.3-26 through O.3-29). The mean monthly water temperatures for Hamilton City do not exceed the 64°F threshold for the middle Sacramento River during any of the months, but the mean monthly water temperatures for May exceed the middle river threshold at Knights Landing in all water year types under both alternatives. However, the May temperatures are consistently lower under Alternative 2 than the No Action Alternative, especially in below normal and dry water years (Table O.3-31). These results indicate that water temperature conditions would be too warm for juvenile Spring-Run Chinook Salmon rearing and emigrating in the middle Sacramento River during May, but would be improved under Alternative 2 relative to the No Action Alternative. It should be noted that May is the last month during spring or summer that Spring-Run Chinook Salmon juveniles are found in the middle river, and it is likely that when water temperatures are too high they emigrate to the ocean before May. However, early emigration could have other adverse effects.

The flow and water temperature effects resulting from Alternative 2 would have a less-than-significant effect relative to the No Action Alternative on juvenile Spring-Run Chinook Salmon in the Sacramento River.

O.3.5.2.5 Adult Upstream Migration and Holding

Spring-Run Chinook Salmon adults enter the Sacramento River from the Delta as early as January and make their way to the upper Sacramento River beginning in February, where they hold until ready to spawn in late summer and early fall (Windell et al. 2017). Adults may continue migrating upstream until August, and holding continues until October when spawning is complete. There are no flow or temperature requirements for the middle Sacramento River designed to protect fish. Once the adults reach holding habitat in the upper Sacramento River, they are more directly affected by Shasta and Keswick reservoir operations designed to preserve cold water for the Winter-Run and Spring-Run Chinook Salmon spawning and incubation periods.

During the January through August period of adult Spring-Run Chinook Salmon immigration, the mean monthly CalSim II flows under Alternative 2 at Keswick, RBDD, Hamilton City, and Wilkins Slough would generally be similar to or greater than those under the No Action Alternative (Tables O.3-25 and O.3-32 through O.3-34). During the holding period, September flow in wet and above normal years would be much lower under Alternative 2 than under the No Action Alternative (Tables O.3-25 and O.3-32 through O.3-34; Figure O.3-25), but the mean September Alternative 2 flows at Keswick Dam would not fall below 6,000 cfs over the range of flows for which the alternatives have major flow differences (i.e., upper 50% in Figure O.3-25). A flow of 6,000 cfs would presumably be sufficient to maintain good water quality conditions in the Spring-Run Chinook Salmon holding habitats. Note that monthly mean flows for these months should reasonably estimate daily mean flows because operations at Shasta and Keswick dams create relatively stable summer and fall flow and water temperature conditions in the upper Sacramento River.

The USEPA (2003) gives 68°F as the critical 7DADM water temperature for Spring-Run Chinook Salmon adults migrating upstream in the Sacramento River and 61°F for adult Spring-Run holding in the upper river. Throughout the January through August period of Spring-Run Chinook Salmon upstream migration, HEC-5Q water temperatures for Alternative 2 are similar to or slightly lower than those for the No Action Alternative, including greater than 1°F reductions in mean monthly water temperature for May, June, and August in various water year types at Hamilton City and Knights Landing (Tables O.3-26 through O.3-31). Under both alternatives, the mean monthly water temperatures in the middle Sacramento River (Knights Landing) would be below the 68°F threshold for immigrating adults from December through April, but would exceed the threshold in May of critically dry water years and in June through August of all water year types (Table O.3-31). The high May through August water temperatures would be likely to adversely affect any Spring-Run Chinook Salmon adults that were migrating upstream in those months. High water temperatures were found to cause adult Spring-Run Chinook Salmon in Butte Creek to terminate their upstream migrations, which made them more susceptible to mortality from rising water temperatures (Mosser et al. 2012). The June temperature reductions under Alternative 2 occur in a range slightly above the 68°F threshold and, therefore, would likely have a beneficial effect on upstream migrating adults. In the upper Sacramento River at Keswick Dam to Balls Ferry, the mean water temperatures under both alternatives would be well below the 61°F threshold for holding adults from February through October (Tables O.3-26 through O.3-28). As previously noted, flow below Keswick Dam is relatively stable during the summer and fall months, so monthly mean flows and temperatures are likely to be fairly representative of daily means in those months.

May through August water temperature reductions under Alternative 2, especially in the middle Sacramento River are expected to have a beneficial effect on adult Spring-Run Chinook Salmon migrating upstream to spawn. Temperatures in the upper River under Alternative 2 and changes in flow in the upper and middle River are expected to have a less-than-significant impact on migrating and holding adults. Therefore, Alternative 2 is expected to have a less-than-significant effect relative to the No Action Alternative on Spring-Run Chinook Salmon with respect to flow, and a minor beneficial effect with respect to water temperature.

O.3.5.2.6 Central Valley Steelhead

Spawning and Egg Incubation

CV steelhead adults spawn from November through April with peak spawning from January through March. Based on the general timing of hatching and fry emergence, eggs and alevins may occur from November through May. Little is known about steelhead spawning locations in the Sacramento River, but it is generally assumed that spawning occurs primarily between Keswick Dam and RBDD.

During the steelhead spawning and incubation period, CalSim II modeling indicates that Alternative 2 flows would be substantially lower than No Action Alternative flows in November of wet and above normal water years (Table O.3-25). Reductions in mean monthly flow of approximately 3,500 cfs under Alternative 2 would increase the amount of available spawning habitat (as measured by WUA) by approximately 18% relative to the No Action Alternative (Figure WUA-SH-S). However, in subsequent months, Alternative 2 flows would generally be higher than those under the No Action Alternative, reducing the amount of available spawning habitat. For example, higher flows under Alternative 2 in December of wet years (averaging approximately 1,800 cfs higher) would reduce WUA by approximately 6%, and higher flows in January of above normal and below normal water years (averaging approximately 1,000 and 1,300 cfs higher, respectively) would reduce WUA by approximately 3%. Therefore, changes in flows under Alternative 2 would have both positive and negative effects on the availability of steelhead spawning habitat relative to the No Action Alternative.

HEC-5Q modeling for Alternative 2 indicates that the water temperatures in the upper Sacramento River during the steelhead spawning and incubation period (November through May) would be similar to those under the No Action Alternative (Tables O.3-26 through O.3-29). Based on the steelhead spawning and incubation threshold of 53°F (see O.3.3 Alternative 1, Central Valley Steelhead Spawning and Egg Incubation), both alternatives would maintain suitable water temperatures for spawning and incubation through April or May in the reach between Keswick Dam and Clear Creek (Tables O.3-6 through O.3-8). Therefore, changes in water temperatures under Alternative 2 would not likely have significant effects on spawning adults, eggs, and alevins relative to the No Action Alternative.

Juvenile Rearing and Emigration

CV steelhead rear year-round in the Sacramento River, and use the river downstream from spawning areas as both a rearing and migration corridor. The timing of downstream migration is variable but generally peaks in the upper river at RBDD in spring and summer (March through June) and in the lower river at Knights Landing in winter and spring (January through May) (NMFS 2009). The peak migration of yearling and older juveniles through the Delta occurs in March and April (NMFS 2009).

CalSim II modeling indicates that the largest differences in Sacramento River flows between Alternative 2 and the No Action Alternative would occur in the late summer and fall (September and November) of above normal and wet years, and in late spring (most notably May and June) of most water year types, potentially affecting fry and juvenile rearing habitat (Table O.3-25). Based on the flow-habitat relationships for Late Fall-Run Chinook Salmon fry and juvenile life stages (see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration), lower flows under Alternative 2 in the fall of wet and above normal water years would increase the amount of juvenile rearing habitat (as measured by WUA), while higher flows in spring would have variable effects on fry and juvenile rearing habitat (Figures O.3-39 and O.3-40). For example, in wet years, reductions in average flows of approximately 6,000 cfs in September and 3,500 cfs in November under Alternative 2 would increase juvenile WUA by 30% and 40% relative to the No Action Alternative. In below normal years, increases in average flows of 1,600 cfs in May and 2,300 cfs in June would reduce juvenile WUA by approximately 10% relative to the No Action Alternative. These same flow increases would reduce fry WUA by 4% in May and increase fry WUA by 6% in June. Therefore, changes in flows under Alternative 2 would have both positive and negative effects on the availability of steelhead rearing habitat relative to the No Action Alternative.

In the upper Sacramento River, HEC-5Q modeling for Alternative 2 and the No Action Alternative indicates that average water temperatures between Keswick Dam and RBDD would be maintained at or below the “core rearing area threshold” of 61°F (see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration) throughout the year except in the summer (July through September) of critically dry water years (Tables O.3-26 through O.3-29). During the summer, water temperatures under Alternative 2 would be similar or cooler than those under the No Action Alternative, except in September of wet and above normal years when average water temperatures would be 0.7 to 3.4°F higher (Tables O.3-26 to O.3-29); however, there would be no major differences in the frequency and magnitude of temperatures above 61°F (Figure O.3-22). Similarly, water temperatures during the steelhead emigration season (January through June) are expected to similar or cooler than those under the No Action Alternative (Table O.3-29 to O.3-31). For example, although water temperatures at Knights Landing would frequently exceed the 64°F “non-core rearing area” threshold in May under both alternatives (e.g., Figure O.3-41), water temperatures would average over 1°F cooler in below normal and dry water years (Table O.3-31). Therefore, changes in water temperature under Alternative 2 would not likely have significant effects on rearing and emigrating steelhead relative to the No Action Alternative.

Adult Upstream Migration and Holding

Adult steelhead immigration into Central Valley streams potentially occurs during all months of the year but typically begins in August and continues through March or April (McEwan 2001; NMFS 2014a). In the Sacramento River, adults migrate upstream past RBDD during all months of the year, but primarily during September and October (NMFS 2009). Adults may hold until the spawning season which generally extends from November through April.

During the steelhead immigration and holding period, lower flows in September and November of wet and above normal water years under Alternative 2 could affect immigrating and holding adults. However, mean monthly flows would be maintained at a minimum of 3,250 under both alternatives, and would not differ substantially in frequency and magnitude between the alternatives until flows exceed approximately 5,000 cfs (Figures O.3-25, O.3-27 and O.3-29). Within this flow range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Under both Alternative 2 and the No Action Alternative, HEC-5Q modeling indicates that suitable water temperatures for steelhead immigration in the Sacramento River (based on the immigration threshold of 68°F; see O.3.3 Alternative 1, Central Valley Steelhead Adult Upstream Migration and Holding) would generally not occur until September or October (Table O.3-31). However, under Alternative 2, substantially lower flows in September would increase the frequency of water temperatures exceeding this threshold, resulting in potential delays in migration or adverse physiological effects on migrating adults relative to the No Action Alternative. For example, at Knights Landing, mean monthly water temperatures in September exceeded 68°F approximately 80% of the time compared to 52% of the time under the No Action Alternative (Figure O.3-24). Therefore, changes in water temperatures under Alternative 2 in September would have a potentially adverse effect on immigrating adult steelhead in the Sacramento River relative to the No Action Alternative. Lower flows in September would also result in higher water temperatures in the upper Sacramento River, potentially affecting holding adults. However, no major differences would be expected to occur in the frequency and magnitude of water temperatures exceeding the threshold for holding adults (61°F; see O.3.3 Alternative 1, Central Valley Steelhead Adult Upstream Migration and Holding) (Figure O.3-22).

O.3.5.2.7 Southern DPS Green Sturgeon

Spawning and Egg Incubation

Green Sturgeon spawn in deep pools (averaging about 28 feet deep) (NMFS 2018b). Eggs from spawning Southern DPS Green Sturgeon have been found in the middle and upper Sacramento River from the GCID oxbow (RM 207) to Inks Creek (RM 265) and spawning is believed to extend upstream to the confluence with Cow Creek (RM 277) (Heublein et al. 2017b). Spawning occurs primarily from April through July, although it periodically occurs in late summer and fall (as late as October) (Heublein et al. 2009, 2017b, NMFS 2018b). Eggs hatch about a week after fertilization (at 60ºF) (Heublein et al. 2017b). Because the incubation time for Green Sturgeon is so short, the effects analysis period for incubating eggs is considered to be the same as the spawning period. Based on laboratory studies for Northern DPS Green Sturgeon, Heublein et al. 2017b) concluded that the optimal range for normal embryo development of Southern DPS Green Sturgeon is 53 to 64°F, and impaired fitness occurs below 52°F and above 71°F.

During the April through July Green Sturgeon spawning period, CalSim II estimates of mean monthly flows at RBDD (RM 244) under the No Action Alternative and Alternative 2 range from about 5,000 cfs for April of critically dry water years to about 14,300 cfs in July of Above Normal water years (Table

O.3-32). Mean flows during most of this period are moderate (~8,000 cfs to ~12,000 cfs). These flow levels are likely to be suitable for Green Sturgeon spawning and egg incubation, and no adverse effects are expected to result. Differences in flows between Alternative 2 and the No Action Alternative are small in most months, but flows are moderately higher for Alternative 2 in May and June of all water years (Table O.3-32). During the August through October period, when Green Sturgeon spawning occurs in occasional years, the flows under both alternatives tend to be lower than those in April through July, but the mean flows would be close to or above 5,000 cfs for all water year types in all three months. Large reductions in mean flows from the No Action Alternative to Alternative 2 are predicted for September of wet and above normal water years and, although the resulting Alternative 2 mean flows are greater than 5,000 cfs, the flow reductions are so large (about 44%) that conditions for Green Sturgeon spawning and egg incubation are likely to be adversely affected (Table O.3-32). However, September spawning occurs only sporadically, so any effect on the Green Sturgeon population would be minor (NMFS 2018b). Therefore, the September flow reductions are expected to have a minor adverse impact on Green Sturgeon.

Based on the HEC-5Q modeling, mean water temperatures during the April through July primary spawning period of Green Sturgeon are below the 53 and 52°F lower temperature thresholds for Green Sturgeon egg development (see Section O.3.3, *Alternative 1*) at Clear Creek and Balls Ferry during many of the months and water year types (Tables O.3-27 and O.3-28). As discussed previously, daily water temperatures are likely to be more variable than monthly mean temperatures, so the reductions of the mean temperatures below the 52 and 53°F thresholds probably underestimate the largest daily reductions below the thresholds.

The HEC-5Q modeling results show little difference in Clear Creek confluence mean water temperatures between Alternative 2 and the No Action Alternative during the April through July primary Green Sturgeon spawning and incubation period (Table O.3-27). Therefore, Alternative 2 is unlikely to cause a reduction in water temperatures relative to the No Action Alternative and thereby would not adversely affect Green Sturgeon spawning and egg incubation.

Larval and Juvenile Rearing and Emigration

As discussed under Alternative 1 (Section O.3.3, *Alternative 1*), the larval period for Green Sturgeon is considered to be April through September. The downstream distribution of Green Sturgeon larvae in the Sacramento River is uncertain, but is estimated to extend to the Colusa area, at RM 157 (Heublein et al. 2017b). The upstream limit is the Cow Creek confluence. Green Sturgeon juveniles rear in the Sacramento River from about May through December (NMFS 2017b). During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near the Cow Creek confluence to the Delta.

CalSim modeling for the Sacramento River at RBDD indicates that mean monthly flows during the April through September period of larval rearing are generally similar between the No Action Alternative and Alternative 2 in April, July and August but would be greater in May (all water years except wet), June (all water years) and September (below normal to critically dry years) (Table O.3-32). The September reductions in flow from the No Action Alternative to Alternative 2 during wet and above normal years would potentially affect Green Sturgeon larvae adversely because, as discussed for Alternative 1 (Section O.3.3, *Alternative 1*), there appears to be a positive relationship between annual outflow and abundance of White Sturgeon larvae and juveniles. However, but the applicability of the relationship to Green Sturgeon is uncertain.

CalSim modeling for the Sacramento River at Hamilton City indicates that mean monthly flows during the period of juvenile rearing and emigration, May through December, are generally similar between the No Action Alternative and Alternative 2 except for higher flows under Alternative 2 during May (all years except wet), June (all years), and September (below normal to critically dry) (Table O.3-32). Reductions in flows occur in September and November (wet and above normal years) and below normal years in December. These reductions in flow could adversely affect Green Sturgeon juveniles under Alternative 2 because, as noted above, there may be a positive relationship between annual outflow and abundance of Green Sturgeon.

There are few notable differences in the HEC-5Q mean monthly water temperature estimates at RBDD or Hamilton City between the No Action Alternative and Alternative 2 during the Green Sturgeon larval and juvenile rearing and emigration period in any month, except for September (Tables O.3-29 and O.3-30). During over half of the years in September, the Alternative 2 water temperature at RBDD is greater than the No Action Alternative temperature, with a maximum difference of about 3°F (Figure O.3-22). Over the range of years for which there are temperature differences, the water temperatures of both the No Action Alternative and Alternative 2 are under the 63°F lower limit of the optimal range for larvae. However, the Alternative 2 water temperatures are closer to the optimal range and therefore would potentially provide more favorable conditions for larval growth and survival. For the juveniles at RBDD, the September water temperatures under the No Action Alternative are below the 59°F lower limit of the optimal temperature range in about half of the years, and under Alternative 2 they are below the optimal range in about a third of the years (Figure O.3-22). The September HEC-5Q temperature estimates for Hamilton City also fall within or are closer to the optimal ranges of Green Sturgeon larvae and juveniles in more years under the Alternative 2 than the No Action Alternative, however overall temperatures are slightly lower in the other months (Table O.3-30; Figure O.3-23).

The CalSim II flow results indicate that Alternative 2 would have a less-than-significant adverse impact on rearing larval and juvenile southern DPS Green Sturgeon relative to the No Action Alternative, and the HEC-5Q water temperature modeling results indicate that Alternative 2 would provide a minor adverse impact to rearing larval and juvenile Green Sturgeon relative to the No Action Alternative.

Adult Upstream Migration and Holding

Green Sturgeon adults enter the Sacramento River from the Delta as early as February and ultimately make their way upstream to spawn in deep pools from the GCID oxbow (near Hamilton City) to the Cow Creek confluence (Heublein et al. 2017b). After spawning, the adults hold in the river for varying amounts of time, but typically emigrate back to the San Francisco Estuary and the ocean from about October through December (Heublein et al. 2017b).

Flows during the February through December period of Green Sturgeon immigration, spawning and holding would generally be similar between Alternative 2 and the No Action Alternative at RBDD, Hamilton City, and Wilkins Slough (Tables O.3-32 through O.3-34). Exceptions include moderately higher mean monthly flows under Alternative 2 at all locations during May and June, and in September during below normal to critically dry years. Substantially lower flows under Alternative 2 occur during September and November during wet and above normal years. All of the more notable flow differences occur within a range of river flows (~5,000 cfs to 14,000 cfs) that are not expected to substantially affect upstream passage of migrating Green Sturgeon, but the September and November flow reductions under Alternative 2 at Hamilton City and RBDD could result in reduced habitat quality in holding pool habitats, adversely affecting holding adults.

There are few major differences in mean monthly water temperatures between the No Action Alternative and Alternative 2 in the Sacramento River at Knights Landing during the February through April period when most adult Green Sturgeon migrate upstream or during the later months (through December) when the sturgeon migrate downstream after spawning (Table O.3-31). Temperatures are lower during May and June, which would benefit migrating adults by bringing temperatures closer to the 66 degree threshold. However, increases of more than 4°F are expected in September of wet and above normal water years. The means exceed the 66°F threshold for migrating Green Sturgeon adults in both water year types under Alternative 2 and in neither water year type under the No Action Alternative. The mean monthly water temperatures at Knights Landing also exceed the 66°F threshold under both alternatives during June through August of all water year types and May of all but wet years (Table O.3-31). Adults migrating downstream from May through September would potentially be adversely affected by the high water temperatures. However, adults migrating upstream would be less affected because most upstream immigration occurs before late spring (Heublein et al. 2009), when water temperatures are below the 66°F threshold.

During the May through December spawning and post-spawn holding period for Green Sturgeon, the HEC-5Q mean monthly water temperatures at Hamilton City, which is located in the most downstream, warmest section of the Green Sturgeon spawning reach, are generally similar between the No Action Alternative and Alternative 2, except for higher temperatures under Alternative 2 in September (Table O.3-30). The mean monthly water temperatures during the hottest months of this period, July through September, range from 58 to 68°F (both in September). The temperatures frequently exceed the 63°F threshold for spawning adults and the 61°F threshold for holding adults during these months. During September, the mean water temperatures exceed the 63 and 61°F thresholds in wet and above normal years under Alternative 2 but not under the No Action Alternative and the mean water temperatures in the remaining water years are slightly lower under Alternative 2 than under the No Action Alternative. September water temperatures are cooler at RBDD and there is no difference at this location between Alternative 2 and the No Action Alternative in the frequency of the threshold exceedances (Figure O.3-22). During October through December, the mean monthly water temperatures stay below both thresholds in every water year type.

The CalSim II modeling results indicate that for adult southern DPS Green Sturgeon holding in September or November, reduced flows under Alternative 2 would have a potentially significant adverse impact on holding habitat relative to the No Action Alternative. The HEC-5Q modeling results indicate that the water temperatures for September of wet and above normal water years would be substantially higher under Alternative 2 than under the No Action Alternative and would exceed the 61°F thresholds for migrating, spawning and holding adult Green Sturgeon only under Alternative 2. In conclusion, the HEC-5Q results for Alternative 2 are expected to result in substantially less favorable water temperatures for Green Sturgeon in September of wet and above normal water years and moderately more favorable water temperatures in a number of other water year types and months. In combination, the reduced flows in September and November of wet and above normal water years and increased water temperatures in September of wet and above normal water years are expected to have a significant adverse impact on southern DPS Green Sturgeon adults.

O.3.5.2.8 Fall-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Fall-Run Chinook Salmon migrate upstream past RBDD on the Sacramento River between July and December, typically spawning in upstream reaches from October through January, with a peak in October and November. Eggs and alevins are present from October through April. The primary spawning area used by Fall-Run Chinook Salmon in the Sacramento River is the area from Keswick Dam downstream to RBDD. Spawning densities for all Chinook Salmon runs are highest in this reach, but the distribution of spawning fall-run generally extends downstream to spawning areas below RBDD (Gard 2013).

During the Fall-Run Chinook Salmon spawning and incubation period, relatively large reductions in flows in November of wet and above normal water years under Alternative 2 (averaging 3,500 cfs lower than No Action Alternative flows) would increase the amount of available spawning habitat, while moderate increases in flow in subsequent months (averaging 1,000 to 2,000 cfs higher than No Action Alternative flows) would decrease available spawning habitat (Figure O.3-35). For example, in wet years, a reduction in average flow of 3,500 cfs in November would increase the amount of available spawning habitat (as measured by WUA) by 72%, while an increase in average flow of 1,800 cfs in December would decrease available spawning habitat by 24%. In above normal years, a reduction in average flow of 3,500 cfs in November would increase the amount of available spawning habitat by 74%, while an increase in average flow of 1,000 cfs in January would decrease available spawning habitat by 15%. Therefore, changes in flows under Alternative 2 would have both positive and negative effects on the availability of spawning habitat relative to the No Action Alternative.

HEC-5Q modeling indicates that Alternative 2 would not substantially affect the frequency of water temperatures exceeding the 53.5°F threshold (see O.3.3.1.2, Sacramento River, *Potential changes to aquatic resources in the Sacramento River from seasonal operations*) during the Fall-Run Chinook Salmon spawning and incubation period (Table O.3-26). For example, during October, a peak spawning month, mean monthly water temperatures at Keswick Dam under the Alternative 2 and the No Action Alternative exceeded 53.5°F approximately 80% of the time (Figure O.3-18). Therefore, changes in flows and water temperatures under Alternative 2 are not likely to have significant effects on steelhead spawning and incubation relative to the No Action Alternative.

Juvenile Rearing and Emigration

Fall-Run Chinook Salmon juveniles rear in the Sacramento River primarily from December through May. Following emergence, juveniles rear for variable lengths of time in the Sacramento River before entering the Delta and estuary, and may emigrate as fry, parr, or smolts. The timing of emigration is variable but generally peaks in the upper river from January through April and in the lower river from January through May (NMFS 2009).

Relative to the No Action Alternative, higher winter and spring flows in the Sacramento River under Alternative 2 could affect rearing and emigrating Fall-Run Chinook Salmon. The largest differences in flows between Alternative 2 and the No Action Alternative would occur in December of wet years (averaging 1,800 cfs) and in January and May of below normal years (averaging 1,300 and 1,600 cfs, respectively), potentially affecting the availability of fry and juvenile rearing habitat (Table O.3-26). Based on the flow-habitat relationships for Fall-Run Chinook Salmon fry and juvenile life stages (see O.3.3 Alternative 1, Central Valley Fall-Run Chinook Salmon, Juvenile Rearing and Emigration), higher flows under Alternative 2 in December of wet years and January of below normal years would reduce the amount of fry rearing habitat (as measured by WUA) by 7% and 9%, respectively (Figures O.3-36 and O.3-37). In May of below normal years, fry WUA would be reduced by 3% while juvenile WUA would be reduced by 9%. While these results indicate that Alternative 2 would potentially reduce the availability of suitable rearing habitat for Fall-Run Chinook Salmon relative to the No Action Alternative, uncertainty exists in the importance of this reduction relative to other factors that affect the quantity and quality of rearing habitat for juvenile Chinook Salmon in the Sacramento River.

In the upper Sacramento River, HEC-5Q modeling for Alternative 2 and the No Action Alternative indicates that both alternatives would maintain suitable water temperatures (≤ 61°F; see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration) between Keswick Dam and RBDD during the Fall-Run Chinook Salmon fry and juvenile rearing period (December through May) (Tables O.3-26 through O.3-29). Farther downstream, mean monthly water temperatures in the lower river at Knights Landing would be similar or slightly cooler under Alternative 2 (Table O.3-7-7), but there would be no differences in the frequency of temperatures exceeding the 64°F "non-core rearing area threshold" (Figure O.3-41). Therefore, changes in Sacramento River water temperatures under Alternative 2 would not likely have significant effects on rearing and emigrating juvenile Fall-Run Chinook Salmon relative to the No Action Alternative.

Adult Upstream Migration and Holding

Fall-Run Chinook Salmon migrate upstream past RBDD on the Sacramento River between July and December. Adults may hold until the spawning season, which occurs primarily from October through January.

CALSIM II modeling indicates that mean monthly flows in the Sacramento River under Alternative 2 would be substantially lower in September and November of wet and above normal water years relative to the No Action Alternative (Tables O.3-25, O.3-32, and O.3-33). However, flows under both alternatives would be maintained at or above 3,250 cfs throughout the immigration and holding period. Although flows would differ substantially in September and November, the differences would be limited to flows exceeding approximately 5,000 cfs (Figures O.3-25, O.3-27, and O.3-29). Within this range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Under both Alternative 2 and the No Action Alternative, HEC-5Q modeling indicates that suitable water temperatures for Fall-Run Chinook Salmon immigration in the Sacramento River (based on the immigration threshold of 68°F; see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding) would generally not occur until September or October (Table O.3-31). However, under Alternative 2, substantially lower flows in September would increase the frequency of water temperatures exceeding this threshold, resulting in potential delays in migration or adverse physiological effects on migrating adults relative to the No Action Alternative. For example, at Knights Landing, mean monthly water temperatures in September exceeded 68°F approximately 80% of the time compared to 52% of the time under the No Action Alternative (Figure O.3-24). Therefore, changes in water temperatures under Alternative 2 in September would have a potentially adverse effect on immigrating adult Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative. Lower flows in September would also result in higher water temperatures in the upper Sacramento River, potentially affecting holding adults. However, no major differences would be expected to occur in the frequency and magnitude of water temperatures exceeding the threshold for holding adults (61°F; see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding) (Figure O.3-22).

O.3.5.2.9 Late Fall-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Late Fall-Run Chinook Salmon spawn primarily from December through April, and eggs and alevins are present in the gravel from December through June. In the Sacramento River, most adults spawn upstream of Red Bluff Diversion Dam, with the majority spawning between Keswick Dam and the ACID Dam.

During the late Fall-Run Chinook Salmon spawning and incubation period, CalSim II modeling indicates that mean monthly flows at Keswick Dam under Alternative 2 would generally be higher than or similar to the flows under the No Action Alternative (Table O.3-5). The largest increases in flow are expected to occur in the winters of wet, above normal, and below normal years, averaging approximately 1,000 cfs to 2,000 cfs higher than flows under the No Action Alternative. Based on PHABSIM results (flow-habitat relationships) developed by the USFWS for the Sacramento River between Keswick Dam and Battle Creek (USFWS 2003a), higher flows under Alternative 2 would reduce the amount of available spawning habitat for Late Fall-Run Chinook Salmon (as measured by WUA) (Figure O.3-38). For example, spawning habitat WUA would be reduced by approximately 16% in December of wet years and 10% in January and February of above normal years. While these results indicate that Alternative 2 would potentially reduce the availability of suitable spawning habitat for late Fall-Run Chinook Salmon relative to the No Action Alternative, uncertainty exists regarding the importance of these reductions on spawning success or fry production in the Sacramento River.

HEC-5Q modeling for Alternative 2 indicates that the water temperatures in the upper Sacramento River during the Late Fall-Run Chinook Salmon spawning and incubation period (November through June) would be similar to those under the No Action Alternative (Tables O.3-26 through O.3-29). Based on the spawning and incubation threshold of 53.5°F (see O.3.3.1.2, Sacramento River, *Potential changes to aquatic resources in the Sacramento River from seasonal operations*), both alternatives would maintain suitable water temperatures from spawning and incubation through May or June in the reach between Keswick Dam and Balls Ferry (Table O.3-26 to O.3-28). Therefore, changes in water temperatures under Alternative 2 are unlikely to have significant effects on spawning adults, eggs, and alevins relative to the No Action Alternative.

Juvenile Rearing and Emigration

Late fall–run Chinook Salmon fry generally emerge from March through June, and juveniles rear in the Sacramento River through the summer before emigrating at a relatively large size (150- to 170-mm fork length) primarily from November through May.

Similar to Alternative 1, CalSim II modeling indicates that Sacramento River flows under Alternative 2 would generally be higher than or similar to the flows under the No Action Alternative during early rearing period (March through August) and substantially lower in September and November of wet and above normal water years (Table O.3-25). Based on PHABSIM results (flow-habitat relationships) for Late Fall-Run Chinook Salmon fry (<60 mm) and juveniles (≥60 mm) developed by the USFWS for the Sacramento River between Keswick Dam and Battle Creek (USFWS 2005), generally higher flows during spring and summer would reduce the amount of available fry and juvenile rearing habitat (Figures O.3-39 and O.3-40). For example, in below normal water years, higher flows from March to May under Alternative 2 (averaging 600 cfs to 1,600 cfs higher than No Action Alternative flows) would result in 3% to 10% reductions in fry WUA relative to the No Action Alternative. In May and June, higher flows under Alternative 2 (averaging 1,600 cfs higher in May and 2,300 cfs higher in June) would correspond to 12% and 9% reductions in juvenile WUA relative to the No Action Alternative. However, substantially lower flows under Alternative 2 in late summer and fall of wet and above normal water years (averaging 4,000 to 6,000 cfs lower in September and 3,500 cfs lower in November) correspond to 39% and 33% increases in juvenile WUA relative to the No Action Alternative. Therefore, changes in flows under Alternative 2 would have both positive and negative effects on the availability of juvenile rearing habitat relative to the No Action Alternative.

In the upper Sacramento River, HEC-5Q modeling for Alternative 2 and the No Action Alternative indicates that average water temperatures between Keswick Dam and RBDD would be maintained at or below the “core rearing area threshold” of 61°F (see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration) throughout the year except in the summer (July through September) of critically dry water years (Tables O.3-26 through O.3-29). During the summer, water temperatures under Alternative 2 would be similar or cooler than those under the No Action Alternative except in September of wet and above normal years when average water temperatures would be 0.7 to 3.4°F higher (Tables O.3-26 to O.3-29); however, there would be no major differences in the frequency and magnitude of temperatures above 61°F (Figure O.3-22). Similarly, water temperatures during the Late Fall-Run Chinook Salmon emigration season (November through May) are expected to similar or cooler than those under the No Action Alternative (Table O.3-29 to O.3-31). Although the frequency of water temperatures exceeding the 64°F “non-core rearing area” threshold would be similar under the two alternatives (e.g., Figure O.3-41), water temperatures in May at Hamilton City and Knights Landing would average up to 1.1°F to 1.2°F cooler in May (Tables O.3-30 and O.3-31). Therefore, changes in water temperature under Alternative 2 would not likely have significant effects on rearing and emigrating Late Fall-Run Chinook Salmon relative to the No Action Alternative.

Adult Upstream Migration and Holding

In the Sacramento River, adult Late Fall-Run Chinook Salmon migrate from October through April, with a peak during January through March (NMFS 2009). Adults hold for 1 to 3 months prior to spawning, which occurs primarily from December through April.

Under Alternative 2, CALSIM II modeling indicates that mean monthly flows in the Sacramento River during the Late Fall-Run Chinook Salmon immigration period would be similar or higher than those under the No Action Alternative except in November of wet and above normal water years when flows would be substantially reduced relative to the No Action Alternative (Tables O.3-25, O.3-32, and O.3-33). However, flows under both alternatives would be maintained at or above 3,250 cfs throughout the immigration period. Although flows would differ substantially in November, the differences would be limited to flows exceeding approximately 5,000 cfs (Figures O.3-25, O.3-27, and O.3-29). Within this range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Based on the water temperature thresholds for immigration (68°F) and holding (61°F) (see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding), Alternative 2 and the No Action Alternative would maintain suitable water temperatures for Late Fall-Run Chinook Salmon throughout the immigration and holding period (October through April) (Tables O.3-29 and-O.3-31). Therefore, changes in water temperatures under Alternative 2 would not likely have significant effects on immigrating and holding Late Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative.

O.3.5.2.10 White Sturgeon

Spawning and Egg Incubation

White sturgeon spawn in deep water in the middle and lower Sacramento River from Verona (RM 80) to just upstream of Colusa (~RM 156) from late February to early June, but primarily during March and April, (Moyle et al. 2015; Heublein et al. 2017). The adults typically return promptly to the Delta/Estuary after spawning.

During the March and April spawning and egg incubation period of White Sturgeon, CalSim II estimates of mean monthly flows at Wilkins Slough (RM 117) under the No Action Alternative and Alternative 2 range from about 5,300 cfs for April of critically dry water years to about 17,800 cfs for March of wet water years (Table O.3-34). These flow levels are likely to be adequate for White Sturgeon spawning and egg incubation, so no adverse effects are expected to result. Differences in flows between Alternative 2 and the No Action Alternative are small in both months, but flows are moderately higher for Alternative 2 in March of below normal and critically dry water years and April of below normal years (Table O.3-34). Therefore, it is concluded that Alternative 2 would have no flow effects on White Sturgeon eggs and embryos relative to the No Action Alternative.

The HEC-5Q water temperature modeling results for March and April indicate that mean monthly water temperatures at Knights Landing were well below the 63°F threshold for optimal temperatures (see Section O.3.3.1.2, *Sacramento River*), except in April of critically dry water years (Table O.3-31). As noted earlier, the mean monthly water temperatures for water year types combine water temperatures for many years and therefore mask individual year variations. The monthly means for individual years show that April water temperatures exceed the 63°F threshold in 15% of years, but lie below the 68°F lethal temperature in all years (Figure O.3-43). There are no appreciable differences in water temperatures between Alternative 2 and No Action Alternative in March or April (Table O.3-31; Figure O.3-43). During June, the warmest month of the full spawning and egg incubation period, the mean monthly water temperatures are predicted to exceed the 68°F lethal temperature in all water year types, but the water temperatures are lower for Alternative 2 than for the No Action Alternative (Table O.3-31). Therefore, it is concluded that Alternative 2 would have no water temperature effects on White Sturgeon eggs and embryos relative to the No Action Alternative.

O.3.5.2.11 Larval and Juvenile Rearing and Emigration

During the March through June larval period, water temperature modeling indicates that water temperatures frequently exceed water temperature thresholds (61 and 68°F, see Section O.3.3.1.2, *Sacramento River*) at Knights Landing under the No Action Alternative and Alternative 2 (Table O.3-31), especially in June. Such high levels of temperature threshold exceedances suggest that typical water temperature conditions in the lower Sacramento River may be highly stressful for White Sturgeon larvae. In any case, the water temperatures, especially in June, are lower under Alternative 2 than under the No Action Alternative (Table O.3-31). It is concluded that Alternative 2 compared to the No Action Alternative will not have an adverse effect on larval and juvenile rearing.

During the of White Sturgeon juvenile emigration period, approximately April to July, CalSim II results indicate that flows at Wilkins Slough during May and June would increase with Alternative 2 compared to No Action Alternative (Table O.3-14). Alternative 2 may have a beneficial effect on juvenile White Sturgeon.

Adult Upstream Migration and Holding

As previously noted, White Sturgeon adults to initiate their upstream spawning migrations during late winter and early spring, presumably in response to elevated flows (Heublein et al. 2017). CalSim II flows at Wilkins Slough for December through February are not much different between Alternative 2 and No Action Alternative for all water year types. There are a few months and water year types when flows are higher under Alternative 2, such as December during wet years and January during below normal years. These increased flows would be beneficial for White Sturgeon migration, but all flows are between 7,700 and 18,800 cfs which are adequate for migration. There are no temperature differences from December through February for Knights Landing. Alternative 2 would have no flow or water temperature effects on White Sturgeon adults.

The CalSim II flow results for Wilkins Slough and the HEC-5Q water temperature results for Knight Landing indicate that Alternative 2 would not have an adverse effect on White Sturgeon relative to the No Action Alternative.

O.3.5.2.12 Sacramento Splittail

Sacramento splittail occur in the Sacramento River upstream of the Delta from about December through May. The adults spawn in river-margin and inundated floodplain habitats in February through April (Feyrer et al. 2005, 2006; Sommer et al. 2007; Moyle et al. 2015). The larvae hatch several days after spawning then rear for about a month in habitat similar to the spawning habitat (Moyle et al. 2004). The juveniles rear upstream and then begin their downstream migration during April and May, as the river level recedes back to the channel (Moyle et al. 2004; Feyrer et al. 2005). Floodplain spawning in wet years overwhelmingly dominates production, but spawning in side channels and channel margins is important during low-flow years when floodplains are not inundated. In the Sacramento River drainage, splittail spawn from Colusa to Knights Landing, but the the most important spawning areas are the inundated floodplains of the Yolo and Sutter bypasses (Feyrer et al. 2005).

High flows benefit adults migrating upstream (Feyrer et al. 2006), and greatly enhance spawning and rearing habitat for larvae and early juveniles (Crain et al. 2004). Mean monthly flows at Wilkins Slough during January through March of wet and above normal water years consistently equal or exceed 17,000 cfs under both alternatives (Table O.3-33). Figure O.3-44 shows the expected mean February flows for each year of the CalSim II record. About 15% of the years have mean February flows greater than 22,500 cfs, which is the approximate flow at which the Tisdale Weir begins to spill into the Sutter Bypass (DWR 2010b). In any case, differences between Alternative 2 and the No Action Alternative in flows at Wilkins Slough during December through May are relatively minor, and generally result from higher flow under the Alternative 2 (Table O.3-34; Figure O.3-44). It is concluded that Alternative 2 would have no flow effects on Sacramento Splittail relative to the No Action Alternative.

Preferred water temperature for Sacramento splittail ranges from about 66°F for adults to about 75°F for juveniles, and the “upper limit of safe temperatures” ranges from about 75°F for adults and 81°F for juveniles (Young and Cech 1996). Mean monthly water temperatures during December through May at Knights Landing, which is at the approximate downstream limit of splittail spawning in the Sacramento River, range up to 68°F under both alternatives in May of critically dry water years (Table O.3-31). There are no meaningful water temperature differences between the alternatives at Knights Landing during the December through May period when Sacramento Splittail occupy the river upstream of the Delta, except in May of below normal and dry water years when water temperatures are just over 1°F lower under Alternative 2 than the No Action Alternative (Table O.3-31). There is evidence that some juvenile splittail remain in the Sacramento River well upstream of the Delta through the entire year (Feyrer et al. 2005), but summer water temperatures in the more upstream locations where they have been found are considerably cooler than those at Knights Landing (compare Tables O.3-30 and O.3-31). Therefore, Alternative 2 is considered to have no adverse water temperature effects on splittail relative to the No Action Alternative.

The CalSim II flow results for Wilkins Slough and the HEC-5Q water temperature results for Knight Landing indicate that Alternative 2 would not have an adverse impact on Sacramento Splittail relative to the No Action Alternative.

O.3.5.2.13 Pacific Lamprey

Sacramento River Pacific Lamprey adults enter the Sacramento River from the Delta primarily during about March through June and hold in the river for about a year prior to spawning (Moyle et al. 2015). Spawning occurs in gravel redds in the upper river from March through July. The eggs and pro-larvae incubate for about 1 to 1.5 months. After the larvae (ammocoetes) emerge, they drift downstream and burrow into fine sediments primarily in off-channels habitats, where they rear (Schultz et al. 2014; Moyle et al. 2015). After 5 or more years, the ammocoetes metamorphose to the macropthalmia (juvenile) stage and migrate downstream to the Delta and ocean, typically migrating from March through June during pulse flow events (Moyle et al. 2015).

River flow potentially affects survival of Pacific Lamprey eggs and larvae, and migratory habitat of the juveniles and adults. Pacific lamprey build their spawning redds in shallow water (about 0.5 to 3.5 feet) (Gunckel et al. 2009; Schultz et al. 2014; Moyle et al. 2015), so reductions in water level can dewater the redds. The larvae select habitats, often off-channel, with fine sediments, low flow velocity, and shallow depths (~1 ft), so they are vulnerable to stranding by reductions in water level. Migrations of the juveniles and adults may be triggered by surges in flow (Moyle et al. 2015).

The types of variations in flow that potentially affect Pacific Lamprey, as described above, often occur on a time scale of hours or days, and therefore may not be detectable using the CalSim II monthly time-step modeling results. However, the CalSim II results mostly show no large differences in Sacramento River flow between the No Action Alternative and Alternative 2, so there is no reason to expect much difference in short period flow fluctuations between the alternatives. The biggest differences in monthly mean flows occur in September and November of wet and above normal water years, when flows are much lower under Alternative 2 than the No Action Alternative because Alternative 2 operations do not include releases for Fall X2 flows (Table O.3-32; Figures O.3-25 and O.3-28). Pacific lamprey are generally done spawning by late July and the prelarvae have finished emerging from their redds by early September. In contrast, the larvae are present in the river yearround and so could be vulnerable to flow reductions during September and November. However, water levels during these months are generally relatively stable because they are largely determined by Shasta and Keswick dam releases rather than runoff. The adults and juveniles carry out their migrations primarily during March through June. CalSim II modeling flow results for these months are generally higher under Alternative 2 than under the No Action Alternative (Table O.3-33 and O.3-34). Therefore, Alternative 2 and the No Action Alternative are expected to similarly affect Pacific Lamprey with respect to flow in the Sacramento River.

As described for Alternative 1, laboratory studies conducted on Columbia River Pacific Lamprey indicated that survival of incubating eggs and pre-larvae and of young larvae was greatest at a water temperature of 64°F and lowest at the highest water temperature included in the study, 72°F (Meeuwig et al. 2005). HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River between Keswick and RDBB during the March through August spawning and egg/prelarvae incubation period would be consistently below 64°F, with minor differences between the alternatives (Tables O.3-26 through O.3-29). During September, when Pacific Lamprey larvae would be present in the river, mean water temperatures would exceed the 64°F optimal temperature at RBDD in critically dry water years. September has the highest water temperatures of the year upstream of RBDD. Mean September water temperatures at RBDD for individual years exceed 64°F in about 7% of years for both alternatives, but are below 72°F for all years (Figure O.3-22). The downstream distribution of Pacific Lamprey larvae is uncertain, but if the larvae drift well downstream of RBDD or enter the Sacramento River from downstream tributaries, they would be subject to higher water temperatures, especially during July and August. However, there are few differences between July and August water temperatures at the lower temperature modeling sites, except in below normal water years when water temperatures are about

1°F cooler under Alternative 2, which would likely benefit the larvae (Table O.3-30 and O.3-31; Figure O.3-45). There are no biologically meaningful differences in water temperature conditions for Pacific Lamprey between the No Action Alternative and Alternative 2.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 2 would have a less-than-significant impact on Pacific Lamprey relative to the No Action Alternative.

O.3.5.2.14 River Lamprey

River Lamprey adults migrate from the ocean to spawning areas during the fall and late winter (Beamish 1980). Spawning is believed to occur from February through May in small tributary streams (Moyle 2002). The redds are built at the upstream end of small riffles (Moyle 2002). After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juvenile (macrothalmia) migrate downstream in the following year from May to July (Moyle 2002).

River flow potentially affects survival of River Lamprey eggs and larvae, and migratory habitat of the juveniles and adults. River lamprey build their spawning redds in shallow water (Moyle et al. 2015), so reductions in water level can dewater the redds. Assuming River Lamprey larvae habitat requirements are similar to those of Pacific Lamprey, the larvae select habitats, often off-channel, with low flow velocity and shallow depths, so they are vulnerable to stranding by reductions in water level.

The types of variations in flow likely to cause redd dewatering and stranding of larvae often occur on a time scale of hours or days and, therefore, may not be detectable using the CalSim II monthly time-step modeling results. However, the CalSim II results mostly show little difference in Sacramento River flow between the No Action Alternative and Alternative 2, so there is no reason to expect much difference in short period flow fluctuations between the alternatives. The biggest differences in monthly mean flows occur in September and November of wet and above normal water years, when flows are lower under Alternative 2 than the No Action Alternative because Alternative 2 operations do not include releases for Fall X2 flows (Table O.3-32; Figures O.3-25 and O.3-28). River lamprey are generally done spawning by May and, assuming their incubation times are similar to those of Pacific Lamprey, the prelarvae complete their emergence from redds by June or July. In contrast, the larvae are present in the river yearround and so could be vulnerable to flow reductions during September and November. However, water levels during these months are generally relatively stable because they are largely determined by Shasta and Keswick dam releases rather than runoff.

The juveniles carry out their migrations during May through July. CalSim II modeling flow results for May and June at Hamilton City and Wilkins Slough are consistently higher under Alternative 2 than under the No Action Alternative, but flows for July are generally slightly lower (Table O.3-33 and O.3-34). The adults migrate upstream primarily in the fall and winter and could be adversely affected by the September and November reductions in flow under Alternative 2 relative to the No Action Alternative (Table O.3-52), but little is know about flow needs of migrating adult River Lamprey. Overall, Alternative 2 and the No Action Alternative are expected to similarly affect River Lamprey with respect to flow in the Sacramento River.

The water temperature requirements of River Lamprey have not been studied, but they are assumed to be similar to those of Columbia River Pacific Lamprey with 64°F for maximum survival of eggs and prelavae and 72°F and above for minimum survival (Meeuwig et al. 2005). HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River between Keswick and RDBB during the February through May spawning and egg/prelarvae incubation period would be consistently below 64°F, with minor differences between the alternatives (Tables O.3-26 through O.3-29). It should be noted that River Lamprey are believed to spawn in tributary streams rather than the mainstem, but this is uncertain (Moyle et al. 2015). During September, when River Lamprey larvae would be present in the river, mean water temperatures would exceed the 64°F optimal temperature at RBDD in critically dry water years. September has the highest water temperatures of the year upstream of RBDD. Mean September water temperatures at RBDD for individual years exceed 64°F in about 7% of years for both alternatives, but are below 72°F for all years (Figure O.3-22). The downstream distribution of River Lamprey larvae is uncertain, but if the larvae drift well downstream of RBDD or enter the Sacramento River from downstream tributaries, they would subject to higher water temperatures, especially during July and August. However, there are few differences between July and August water temperatures at the downstream temperature modeling sites, except in below normal water years when water temperatures are about 1 dgree Fahrenheit cooler under Alternative 2, which would likely benefit the larvae (Table O.3-30 and O.3-31; Figure O.3-45). There are no biologically meaningful differences in water temperature conditions for River Lamprey between the No Action Alternative and Alternative 2.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 2 would have a less-than-signficant impact on River Lamprey relative to the No Action Alternative.

O.3.5.2.15 Hardhead

Hardhead are believed to spawn in riffles, runs, and heads of pools, primarily during April and May (Moyle et al. 2015). Most spawning probably occurs in tributaries rather than in the Sacramento River mainstem (Moyle et al. 2015). Larvae and juveniles likely inhabit stream margins with abundant cover, and move into deeper habitats as they grow larger. Adults occupy the deepest part of pools. Juvenile and adult Hardhead are present in the Sacramento River year-round. They tend to prefer water temperatures near 67°F (Thompson et al. 2012), but have been captured at RBDD, where water temperatures are generally much cooler (USFWS 2002) (Table O.3-9).

Spawning success of Hardhead in the lower Tuolumne River is highest when there are higher flows during in April and May (Brown and Ford 2002), which is likely true for the Sacramento River Hardhead as well. The CalSim II results for Keswick, Red Bluff, Hamilton, and Wilkins Slough indicate that monthly mean flow would be moderately higher under Alternative 2 than under the No Action Alternative during the April and May peak spawning months (Tables O.3-25, O.3-32 through O.3-34). During most of the other months, when Hardhead may forage in the river, flows would generally be similar between Alternative 2 and the No Action Alternative, but, from Keswick Dam to Wilkins Slough, they would be 10 to 27% higher under Alternative 2 in June of all water year types and would be 29 to 44% lower in September and November of wet and above normal water years. The large flow reductions in September and November would likely have little effect on Hardhead because they are predicted for wet and above normal years, when flows are generally high, and because by September and November, Hardhead hatched in the spring would be well developed and have gravitated to deeper water. Similarly, the large flow increases in June would likely have little effect because June flows are adequate under both alternatives. The flow effects of Alternative 2 are not expected to substantially affect hardhead.

Hardhead juveniles and adults performed well in laboratory tests at water temperatures from about 61 to 70°F (Thompson et al. 2012). They consistently preferred a mean water temperature of 67°F and avoided temperatures above about 79°F. HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River would be below 79°F at all locations under both alternatives (Tables O.3-26 through O.3-31). There would be only minor differences in mean water temperatures between the alternatives, except for moderate increases under Alternative 2 during September of wet and above normal water years. However, these mean water temperatures would be only slightly warmer than the

Hardhead preferred temperature, and only at Knights Landing (Table O.3-31). There are no biologically meaningful differences in water temperature conditions for Hardhead between the No Action Alternative and Alternative 2.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 2 would not have no impact on Hardhead relative to the No Action Alternative.

O.3.5.2.16 Central California Roach

As discussed under Alternative 1, California Roach primarily inhabit small tributary streams (Baumsteiger and Moyle 2019) and have a broad range of habitat types and temperature tolerances (Moyle 2002). Given that most Central California Roach inhabit tributary streams rather than the mainstem Sacramento River and have a broad range of habitat types and temperature tolerances, it is unlikely that flow or water temperature conditions under Alternative 2 would adversely affect California Roach. Therefore, Alternative 2 is expected to have no impact on Central California Roach relative to the No Action Alternative.

O.3.5.2.17 Striped Bass

Striped Bass spawn in the Sacramento River primarily between about Verona (RM 78) and Wilkins Slough (RM 121) during April through June (Moyle 2002). No spawning occurs until water temperature reaches 57°F (Moyle 2002). The eggs are free-floating and negatively buoyant and hatch in about two days after spawning (at 66°F) as they drift downstream. Low flows can result in eggs settling on the bottom, which they cannot survive for long. The larvae may inhabit shallow, open water of the lower river from April to mid-June and then are carried by flows to the Delta and Suisun Bay (Stevens 1966; Moyle 2002). Adult striped bass are found in the upper Sacramento River at RBDD and upstream, primarily from late spring through early fall, where they forage heavily on juvenile salmon and other fish (Tucker et al. 1998).

High flows in April through June benefit striped bass eggs because they help prevent them from settling to the river bottom. High flows likely also accelerate transport of Striped Bass larvae to their nursery habitats in the Delta and Suisun Bay (Moyle 2002). CalSim II flow results for Wilkins Slough indicate that mean monthly flow during April through June under Alternative 2 would be similar to or higher than flow under the No Action Alternative, with higher flow especially in May and June, which would potentially benefit conditions for eggs and larvae drifting downstream (Table O.3-34). The greatest reductions in flow resulting from Alternative 2 would occur in September and November of wet and above normal water years. Adult Striped Bass may reside throughout the Sacramento River in September (Tucker et al. 1998). However, although the Alternative 2 mean monthly flows are reduced from the No Action Alternative flows in wet and above normal years, they remain close to or well above 5,000 cfs (Tables O.3-32 through O.3-34), which is likely adequate for foraging Striped Bass.

Optimal spawning temperature range for Striped Bass is 59 to 68°F and spawning ceases at about 70°F (Moyle 2002). The eggs can withstand temperatures of about 54 to 75°F, with the optimum being about 64°F (Emmett et al. 1991). Larvae tolerate temperatures of 50 to 77°F, but optimal temperatures for survival are 59 to 72°F (Emmett et al. 1991). Striped Bass adults and juveniles are tolerant of a wide range and rapid swings of water temperatures. The adults appear to prefer water temperatures ranging from about 68 to 75°F (Emmett et al., 1991) and juveniles prefer rearing temperatures of 61 to 66°F (Hasler 1988). Adults are under stress at temperatures over 77°F, and temperatures over 86°F are lethal (Moyle 2002).

HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River at Knights Landing during the April through June spawning period would be within the optimal range for spawning in April of all but wet years and in May of all but critically dry years, but would be above the optimal range in June during all water year types (Table O.3-31). The mean monthly temperatures would be below the optimal range for adults during April and May of all water year types, except critically dry years in May, but would be within this range in all water year types in June. The temperatures would be acceptable for eggs and optimal for larvae throughout the spawning period (Table O.3-31). Juvenile striped bass generally do not occur in the Sacramento River upstream of the Delta. The adults, as noted earlier, may forage in the river upstream to and above RBDD from about May through early October. Mean monthly water temperatures at RBDD throughout this period would be well below the optimal range for adults (Table O.3-29).

The largest difference in water temperatures between the No Action Alternative and Alternative 2 at Knights Landing during the Striped Bass spawning season are moderate reductions in May of below normal and dry years and June of above normal, below normal and dry water years (Table O.3-31). With these reductions, water temperatures under Alternative 2 would be closer to the optimal range for spawning than those under the No Action Alternative, providing a minor benefit. The largest temperature differences at any time of year are substantial increases under Alternative 2 for September of wet and above normal water years. These increases would be potentially beneficial for foraging Striped Bass adults because the No Action Alternative water temperatures for these months and water year types would be well below the optimal range for adults throughout the river (Tables O.3-29 through O.3-31).

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 2, with regard to flow and water temperature, would have a less-than-significant impact on Striped Bass relative to the No Action Alternative.

O.3.5.2.18 American Shad

American shad migrate upstream in the Sacramento River starting in March, and typically spawn from April to June. Water temperature influences the timing of runs, with peak runs and spawning usually occurring at water temperatures of 62°F to 75°F (Moyle 2002). Shad eggs drift downstream from spawning areas and hatch in 3 to 12 days, depending on water temperature (MacKenzie et al. 1985). However, more rapid development at higher temperatures appears to be associated with lower survival rates of embryos (Moyle 2002). Larval shad are planktonic for about 4 weeks, after which they metamorphose to actively swimming juveniles. Juveniles spend the next several months in freshwater, and seem to prefer temperatures of 63°F to 77°F. In the Sacramento River, summer rearing habitat occurs in the main river from Colusa to the north Delta (Stevens et al. 1987). As the season progresses, juvenile shad move downstream and enter salt water primarily during September through November (Moyle 2002). In general, variations in river discharge and temperature during early larval development are considered important regulators of year-class strength and recruitment of American shad (Hinrichsen et al. 2013). Although the importance of various potential mechanisms is unknown, the abundance of juvenile American shad in the Sacramento-San Joaquin Delta has been shown to be positively correlated with freshwater inflow during the April through June spawning and nursery periods (Stevens et al. 1987, Kimmerer 2002, Kimmerer et al. 2009).

During the spawning and larval rearing period (April through June), CalSim II modeling results at Wilkins Slough indicates that average monthly flows in May and June under Alternative 2 would be higher than those under the No Action Alternative, which may have positive effects on spawning and early rearing success of American shad (Table O.3-25). In addition, with higher flows under Alternative 2, HEC-5Q modeling results indicate that mean monthly temperatures in the lower Sacramento River

(Knights Landing) during May and June would be lower on average, which may improve water temperatures for developing embryos and larvae (Table O.3-31; Figures O.3-41 and O.3-91). The largest differences in flows and water temperatures in the Sacramento River under Alternative 2 and the No Action Alternative would occur in September and November of wet and above normal water years (Table O.3-31 and O.3-34). However, the importance of river inflows and river temperatures for juvenile shad in September and November is unknown. Correlations between Delta inflows and abundance of juvenile shad have been demonstrated for the months of April through August, with the highest correlations in April through June, suggesting that the principal factors influencing abundance occur during periods of larval dispersal and transport. Sacramento River flows and temperatures under Alternative 2 may have minor benefits to American Shad relative to the No Action Alternative, but because the potential effects are highly uncertain, Alternative 2 is considered to have a less-than-significant effect on American Shad.

O.3.5.2.19 Largemouth Bass

The Sacramento River above the Delta generally provides poor habitat conditions for Largemouth Bass because of large seasonal flow fluctuations, relatively cold water, and lack of suitable nesting and rearing habitat. Consequently, Largemouth Bass populations in the Sacramento River above the Delta are largely dependent on upstream sources, including reservoirs, floodplain ponds and sloughs, and irrigation canals that provide suitable conditions for spawning and rearing during the late spring and summer months.

Largemouth bass spawning activity typically starts in April when water temperatures reach 59 to 61°F, and continues through June (Moyle 2002). Nests are typically constructed at a depth of about 3 feet (Brown et al. 2009a). Optimal temperatures for successful spawning and incubation are 68 to 70°F, although spawning is generally observed over a range of 55 to 79°F (Stuber et al. 1982). Eggs hatch in 2 to 7 days after spawning and the sac fry usually spend 5 to 8 days in the nest until they begin actively feeding (Moyle 2002). Optimal temperatures for growth of juvenile and adult bass range from 77 to 86°F, although growth will occur over a much wider range (50 to 95°F) (Moyle 2002).

The CALSIM II and HEC-5Q modeling results for Alternative 2 indicate that Sacramento River flows would be higher and water temperatures would be lower in May and June relative to the No Action Alternative, potentially affecting largemouth bass spawning and incubation (Tables O.3-31 and O.3-34). However, based on modeled mean monthly water temperatures in the lower Sacramento River at Knights Landing, no substantial changes would be expected to occur in the frequency of suitable water temperatures for spawning and incubation (Figures O.3-41 and O.3-91). The relatively large changes in flows and water temperatures in September and November of wet and above normal years under Alternative 2 (Tables O.3-31 and O.3-34) could also affect habitat conditions for juvenile and adult bass, but water temperatures would remain below optimum levels for growth under both alternatives. Consequently, the generally poor habitat conditions for largemouth bass in the Sacramento River under the No Action Alternative would persist under Alternative 1. Therefore, changes in Sacramento River flows and water temperatures associated with Alternative 1 would have a less-than-significant effect on largemouth bass in the Sacramento River relative to the No Action Alternative.

O.3.5.2.20 Smallmouth Bass

The temperature optimal range for Smallmouth Bass spawning is 55 to 70°F (Brown et al. 2009b) and the optimal for adult growth is approximately 77 to 80°F, but rapid growth of has been seen in the wild at temperatures as high as 84°F, providing prey is abundant (Moyle 2002). Young-of-year Smallmouth Bass will select temperatures as high as 84 to 87°F. Populations are rarely established in water temperatures that do not exceed 66°F in summer for extended periods, and most smallmouth populations in California are present where summer temperatures are typically 69 to 71°F. In northern California reservoirs most spawning takes place in May and June, but spawning in streams may occur into July, depending on flows and temperatures. Males start making nest depressions when water temperatures reach 55°F to 61°F. The nests are typically built at depths of about 3 to 8 feet (Brown et al. 2009). In streams, nesting and reproduction can be disrupted by flow reductions that lead to nest dewatering, or elevated flows that wash embryos and fry out of nests or lower water temperatures excessively (Graham and Orth 1986; Lukas and Orth 1995).

CalSim II results for Wilkins Slough flow for Alternative 1 compared to No Action Alternative during the May through July spawning season indicate increased flow during May and June of all of the water year types and slightly reduced flow in July, except in critically dry water years (Table O.3-52). Higher flows could adversely affect embryos and fry by dewatering nests or washing them out of the nests, but it is unknown what magnitude of flows would have these effects.

HEC-5Q monthly mean water temperatures at Hamilton City consistently fall within the 55 to 70°F optimal spawning range during the spawning season of May through July under both Alternative 2 and the No Action Alternative (Table O.3-30). At Knights Landing, however, the temperatures fall within the optimal range during May of all water year types, but lie above the range during June and July of most water year types (Table O.3-31). The water temperatures under Alternative 2 are generally similar or moderately lower than those under the No Action Alternative. The monthly mean summer water temperatures at Hamilton City consistently fall below the 66°F threshold that has been found to be a minimum for Smallmouth Bass to establish populations in California (Moyle 2002), except for critically dry water years in August and September (Table O.3-30). At Knights Landing, however, the 66°F threshold is exceeded in all summer months and water year types except September of wet and above normal years under the No Action Alternative (Table O.3-31). Note that the large wet-and-above-normal-year September water temperature increases under Alternative 2 result in water temperatures exceeding the threshold, which may benefit Smallmouth Bass. The mean water temperatures are consistently well below the optimal range for adult growth, 77 to 80°F, at both locations.

The CalSim II flow and HEC-5Q water temperature results indicate that Alternative 2 would have a less-than-significant impact on Smallmouth Bass relative to the No Action Alternative with regard to flow and water temperature.

O.3.5.2.21 <u>Spotted Bass</u>

Spotted Bass inhabit streams and reservoirs and prefer moderate-size, clear, low-gradient sections of rivers and reservoirs (McKechnie 1966). They prefer pool habitat and slower, more turbid water than Smallmouth Bass but faster water than Largemouth Bass (Moyle 2002). Their summer water temperature preference is 75 to 87°F (Moyle 2002). In streams, nests are constructed in low-current areas on bottoms ranging from debris to gravel (Moyle 2002). Spawning depths are deeper than those of largemouth bass (Aasen and Henry 1981). They spawn in the spring when water temperatures rise to 59 to 64°F (Aasen and Henry 1981; Howland 1931). Spawning continues through late May and early June, until temperatures reach 71 to 73°F.

During the spring (April through June) spawning season, CalSim II results for Wilkins Slough monthly mean flows under Alternative 2 are mostly higher than the No Action Alternative flows (Table O.3-34). Higher flows could adversely affect embryos and fry by dewatering nests or washing them out of the nests, but it is unknown what magnitude of flows would have these effects.

HEC-5Q monthly mean water temperatures at Knights Landing during the spawning season of April through June would largely be within the 59 - 64°F spawning range in April under Alternative 2 and the

No Action Alternative, but would exceed the range in May and June under both alternatives. The preferred summer water temperatures range of 75 to 87°F would be available only in critically dry years, especially in August, under both Alternative 2 and the No Action Alternative (Table O.3-31).

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 2, with regard to flow and water temperature, would have a less-than-significant impact on Spotted Bass relative to the No Action Alternative.

Potential changes to aquatic resources in the Sacramento River from Shasta cold water pool management

Shasta Cold Water Pool Management will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to some potential effects of this action. However, the No Action Alternative includes NMFS's 2009 BO RPAs to operate Shasta Reservoir for management of cold water in the reservoir and river for protection of anadromous salmonids, and includes requirements for Fall X2 flow releases, but Alternative 2 includes neither requirement. The effects of these differences in operations on water temperatures and flows in the Sacramento River and potential effects on water temperature and flow differences on the focal fish species in the river are discussed above in the assessments for the individual fish species in the section *Potential changes to aquatic resources in the Sacramento River from seasonal operations* under Alternative 2.

Potential changes to aquatic resources in the Sacramento River from spring pulse flows

Spring Pulse Flows for fish will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

Potential changes to aquatic resources in the Sacramento River from fall and winter refill and redd maintenance

Fall and winter refill and redd maintenance will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

Potential changes to aquatic resources in the Sacramento River from rice decomposition smoothing

Rice decomposition smoothing will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

O.3.5.3 *Clear Creek*

O.3.5.3.1 <u>Whiskeytown Reservoir Operations</u>

Under Alternative 2 Reclamation would operate the CVP to meet the legal requirements for flow associated with their water rights but would not release additional flows for downstream fish and wildlife purposes. Similar to the No Action Alternative, flows from Whiskeytown Dam to Clear Creek would be managed for base flow of 50 cfs to 100 cfs based on downstream water rights and the 1963 Reclamation proposal to USFWS and NPS. Unlike the No Action Alternative, there would be no planned channel maintenance flows or pulse flows released from Whiskeytown Dam.

Under current operations and the No Action Alternative, Whiskeytown Lake is annually drawn down 13 feet (approximately 35 TAF) between November and April for flood control purposes, although it can be lowered as much as 30 feet as needed for maintenance. Model output for Whiskeytown Lake predicts that compared to the No Action Alternative, minimum reservoir volumes would be lower under Alternative 2 during the months of May (1.3 TAF lower) and July (37.4 TAF lower) (Figure O.3-94, Table O.3-35). During those two months, water surface elevations would also be lower than under the No Action Alternative. In March, April, and June, water surface elevations would be higher than under the No Action Alternative, an increase of 6.6 TAF, 1.6 TAF, and 2.2 TAF, respectively. In all other months, Whiskeytown Lake storage volume under Alternative 2 would be 0.1 TAF to 0.2 TAF higher than under the No Action Alternative.

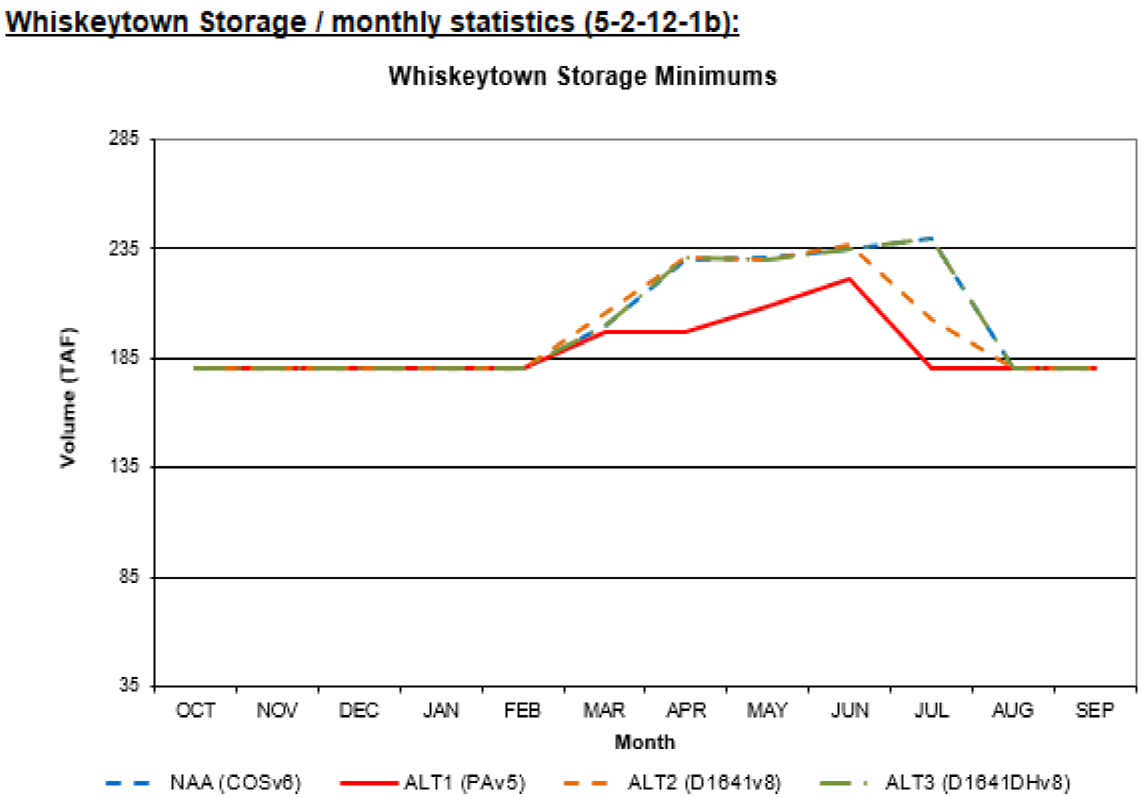

Figure O.3-94. Modeled Whiskeytown Lake Minimum Storage Volume under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 during All Water Year Types

Table O.3-35. Modeled Differences in Whiskeytown Lake Minimum Storage Volumes from March to July under Alternative 2 Relative to the No Action Alternative

Month	Change in Volume from No Action Alternative (TAF)
March	6.6
April	1.6
May	-1.3
June	2.2
July	-37.4

The additional seasonal draw-downs in May and July under Alternative 2 could cause an increase in bank and bed erosion in newly exposed areas of tributary stream mouths where they are devoid of stabilizing riparian vegetation. This scour could cause channel incision (i.e., down-cutting) and result in increased lake water turbidity. Channel incision can create erosional nick points that propagate upstream until they encounter scour-resistant grade-controlling materials such as bedrock, at which point a cascade can form. However, annual minimum storage volume is not expected to change under this alternative. The additional draw-downs therefore represent a change in timing and duration of lower water surface elevation, not a new type or mechanism of disturbance, and channel incision may have already occurred and stabilized as a result of past operations.

Potential changes to aquatic resources from seasonal variation in water surface elevation

Hardhead

Hardhead migrate from the reservoir into tributaries in April and May to spawn upstream of Whiskeytown Lake. The timing of proposed increased draw-downs from March through July under Alternative 2 could affect Hardhead if the lower water surface elevations in May expose any previously submerged cascades at tributary mouths or create new ones. No such cascades have been documented, but if they are present or created by tributary incision at low water, they could present barriers to migration that would prevent reservoir-dwelling adult Hardhead from spawning in tributary streams. Alternately, higher water surface elevation in April may benefit migrating Hardhead at the start of their upstream migration season.

Hardhead are not a cold-water species, so drawing additional cold water from the bottom layers of the reservoir would not be expected to affect them directly. Hardhead have shown sensitivity to high sediment loads (Gard 2002), so increased reservoir turbidity due to varial zone erosion during draw-down periods could reduce suitability of reservoir and downstream waters for Hardhead persistence.

The increased annual variations in reservoir water surface elevations under Alternative 2 could cause Hardhead to be affected by reducing habitat connectivity and increasing water turbidity. However, under Alternative 2 the largest change to storage volume and water surface elevation in Whiskeytown Lake would occur in July, after Hardhead upstream migration and spawning are likely to be complete. Higher water surface elevation in April could affect migrating Hardhead at the start of their upstream migration season.

Other Fish Species

Central California Roach are not likely to be affected by changes in reservoir operations because, although they are found in upstream tributaries, they do not reside in Whiskeytown Lake, having likely been extirpated from the reach after the reservoir was originally filled in 1963. Future operations of Whiskeytown Dam under Alternative 2 are therefore unlikely to affect either individuals or populations.

Increased annual variations in reservoir water surface elevation under Alternative 2 compared to the No Action Alternative could cause varying effects to stocked and introduced nonnative game species in Whiskeytown Lake. Stocked species would not be expected to be affected by changes in reservoir operations. Rainbow Trout, Brown Trout, Kokanee Salmon, and Brook Trout typically spawn in tributary streams, but they are capable of spawning in lakes if they are unable to access moving water. Whiskeytown Lake Kokanee spawn in the fall, a period when no differences in water levels are expected under Alternative 2 compared to the No Action Alternative. Pond species such as Largemouth Bass, Smallmouth Bass, Spotted Bass, Bluegill, Black Crappie, Channel Catfish, and Brown Bullhead are able to tolerate a wide range of conditions, but the basses and panfish spawn in relatively shallow lake areas when water warms to at least 50°F in late spring or summer. Reducing reservoir volume in July could put some of their nests at risk of being dewatered. However, these species have rapid reproductive rates which can enable them to recover from episodic recruitment failures.

O.3.5.3.2 Clear Creek Flows

Under Alternative 2 Reclamation proposes minimum base flows in Clear Creek of 50 cfs to 100 cfs in normal water years and 30 cfs to 70 cfs in critically dry water years, based on downstream water rights and the 1963 Reclamation proposal to USFWS and NPS, as described in the No Action Alternative (Table O.3-36). Under Alternative 2 there are no channel maintenance flows or pulse flows, whereas under the No Action Alternative channel maintenance flows would occur in congruence with flood operations and two pulse flows would be released in May and June of at least 600 cfs for at least 3 days per pulse per year.

Table O.3-36. Minimum Flows at Whiskeytown Dam

Period	Alternative 2 Normal Year (cfs)	Alternative 2 Critically Dry Year (cfs)	No Action Alternative Normal Year (cfs)	No Action Alternative Critically Dry Year (cfs)
Jan 1 to Oct 31	50	30	50	30
Nov 1 to Dec 31	100	70	100	70

Modeling results indicate that average Clear Creek flow below Whiskeytown Dam under Alternative 2 would generally exceed Alternative 2 minimum instream flows in all water year types but remain lower than average flow under the No Action Alternative in all months and water year types (Figure O.3-95). Relative to the No Action Alternative, the minimum decrease in flow would be 69 cfs in dry years, and the maximum decrease would be 100 cfs in wet years (Figure O.3-96).

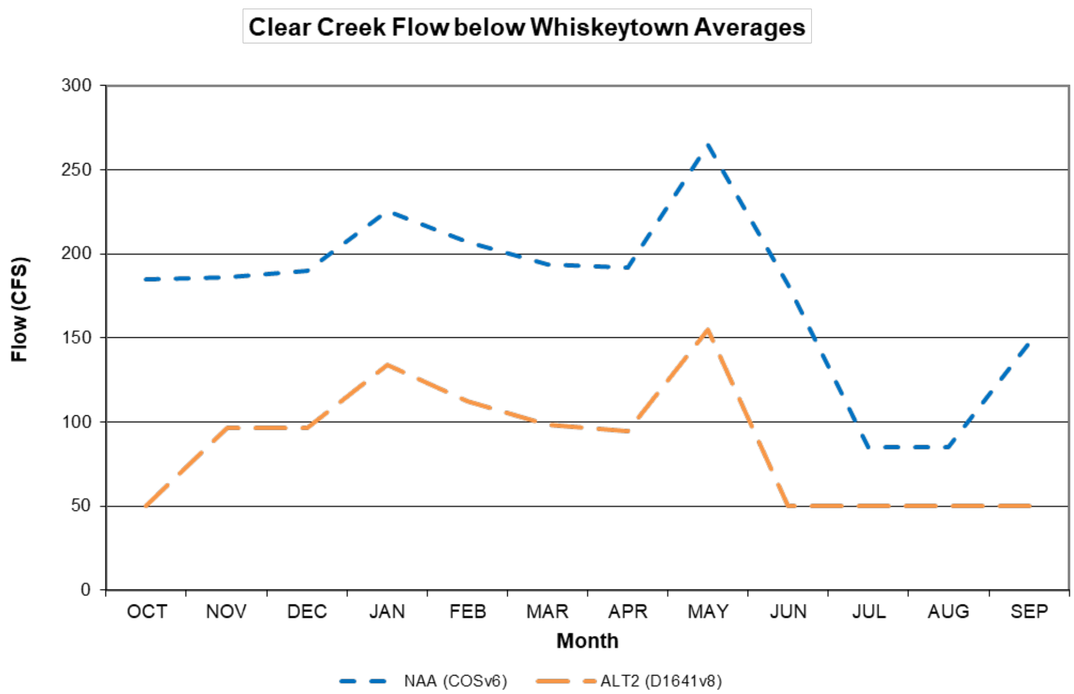

Figure O.3-95. Average Monthly Flow in Clear Creek below Whiskeytown Dam for the No Action Alternative and Alternative 2 during All Water Years (40-30-30 Index)

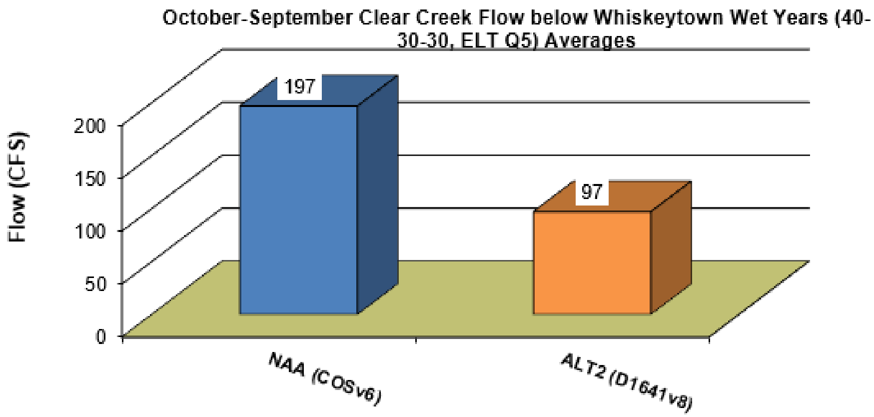

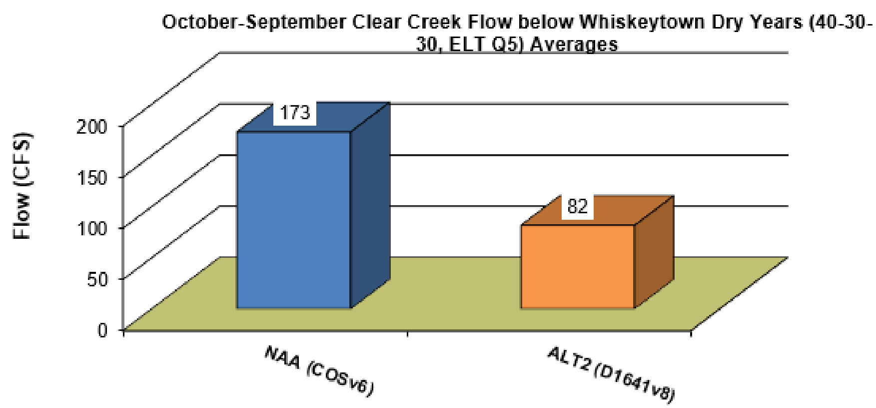

Figure O.3-96. Average Annual Flow in Clear Creek below Whiskeytown Dam for the No Action Alternative and Alternative 2 during Wet and Dry Water Years (40-30-30 Index).

Potential changes to aquatic resources in Clear Creek from variation in flow

Spring-Run Chinook Salmon

Under Alternative 2 Clear Creek flow downstream of Whiskeytown Dam would average approximately 58% of Clear Creek flow under the No Action Alternative in all water years. These differences in flow would coincide with the seasonal occurrence of all life stages of Spring-Run Chinook Salmon in Clear Creek, including migrating and holding adults, spawning adults, rearing and outmigrating juveniles, and eggs and fry. Because flow under Alternative 2 would be substantially less than flow under the No Action Alternative, this difference in base flow under Alternative 2 may adversely affect Spring-Run Chinook eggs and fry by increasing temperature and reducing DO, juveniles by decreasing available habitat and reducing migration cues for juveniles, and adults by decreasing pool connectivity and available holding and spawning habitat.

The lack of channel maintenance flows and pulse flows under Alternative 2 would result in a reduction of gravel mobilization and attraction flows in Clear Creek, which would adversely affect all life stages of Spring-Run Chinook Salmon. Reduced gravel mobilization would lead to a decrease in suitable spawning habitat, while the lack of pulse flows would lead to a reduction in cues triggering upstream and downstream migration. Implementation of Mitigation Measure AQUA-3 would mitigate any adverse effects of flow in Clear Creek downstream of Whiskeytown Dam under Alternative 2; therefore, Alternative 2 is not expected to adversely affect Spring-Run Chinook Salmon compared to the No Action Alternative.

Fall-Run Chinook Salmon

Under Alternative 2 Clear Creek flow downstream of Whiskeytown Dam would average approximately 58% of Clear Creek flow under the No Action Alternative in all water years. These differences in flow would coincide with the seasonal occurrence of all life stages of Fall-Run Chinook Salmon in Clear Creek, including migrating and spawning adults, rearing and outmigrating juveniles, and eggs and fry. Because flow under Alternative 2 would be substantially less than flow under the No Action Alternative, this difference in base flow under Alternative 2 may adversely affect Fall-Run Chinook eggs and fry by increasing temperature and reducing DO, juveniles by decreasing available habitat and reducing migration cues for juveniles, and adults by decreasing pool connectivity and available holding and spawning habitat.

The lack of channel maintenance flows and pulse flows under Alternative 2 would result in the reduction of gravel mobilization and attraction flows in Clear Creek, which would negatively affect all life stages of Fall-Run Chinook Salmon. Reduced gravel mobilization would lead to a decrease in suitable spawning habitat, while the lack of pulse flows would lead to a reduction in cues triggering upstream and downstream migration. Implementation of Mitigation Measure AQUA-3 would mitigate any adverse effects of flow in Clear Creek downstream of Whiskeytown Dam under Alternative 2; therefore, Alternative 2 is not expected to adversely affect Fall-Run Chinook Salmon compared to the No Action Alternative.

Central Valley Steelhead

Under Alternative 2 Clear Creek flow downstream of Whiskeytown Dam would average approximately 58% of Clear Creek flow under the No Action Alternative in all water years. These differences in flow would coincide with the seasonal occurrence of all California Central Valley DPS Steelhead life stages in Clear Creek, including migrating and spawning adults, rearing and outmigrating juveniles, and eggs and fry. Because flow under Alternative 2 would be substantially less than flow under the No Action Alternative, this difference in base flow under Alternative 2 may adversely affect Central Valley Steelhead eggs and fry by increasing temperature and reducing DO, juveniles by decreasing available habitat and reducing migration cues for juveniles, and adults by decreasing pool connectivity and available holding and spawning habitat.

The lack of channel maintenance flows and pulse flows under Alternative 2 would result in the reduction of gravel mobilization and attraction flows in Clear Creek, which would negatively affect all life stages of California Central Valley DPS Steelhead. Reduced gravel mobilization would lead to a decrease in suitable spawning habitat, while the lack of pulse flows would lead to a reduction in cues triggering upstream and downstream migration. Implementation of Mitigation Measure AQUA-1 would mitigate any adverse effects of flow in Clear Creek downstream of Whiskeytown Dam under Alternative 2; therefore, Alternative 2 is not expected to adversely affect Steelhead compared to the No Action Alternative.

Pacific Lamprey

Under Alternative 2 Clear Creek flow downstream of Whiskeytown Dam would average approximately 58% of Clear Creek flow under the No Action Alternative in all water years. These differences in flow would coincide with the seasonal occurrence of various life stages of Pacific Lamprey in Clear Creek, including spawning and outmigrating adults and ammocoetes. Because the modeled flow under Alternative 2 is significantly lower than flow under the No Action Alternative, changes to base flows under Alternative 2 could potentially adversely affect Pacific Lamprey by increasing temperature, reducing DO, and reducing available habitat.

The lack of channel maintenance flows and pulse flows under Alternative 2 would result in the reduction of gravel mobilization and attraction flows in Clear Creek, which would negatively affect all life stages of Pacific Lamprey. Implementation of Mitigation Measure AQUA-3 would mitigate any adverse effects of flow in Clear Creek downstream of Whiskeytown Dam under Alternative 2; therefore, Alternative 2 is not expected to adversely affect Pacific Lamprey compared to the No Action Alternative.

Potential changes to aquatic resources in Clear Creek from variation in water temperature

Under Alternative 2, Reclamation would manage Whiskeytown releases without any water temperature thresholds, whereas under the No Action Alternative, daily water temperature objectives would be 60°F at the Igo gage from June 1 through September 15 and 56°F at the Igo gage from September 15 through October 31.

Modeling results show that changes in water temperatures in Clear Creek downstream of Whiskeytown Dam would be similar under Alternative 2 and No Action Alternative between November and January of all water year types (Figure O.3-97). Water temperatures under Alternative 2 would exceed those under the No Action Alternative in all other months with temperature differences reaching a maximum of approximately 5°F throughout the summer. Clear Creek water temperatures would exceed 65°F in July under Alternative 2 as opposed to 60°F under the No Action Alternative.

Figure O.3-97. Average Monthly Water Temperatures in Clear Creek above Sacramento River for the No Action Alternative and Alternative 2 during All Water Year Types (40-30-30 Index).

Table O.3-37. Water Temperatures Suitable for Spring-Run and Fall-Run Chinook Salmon, and Central Valley Steelhead by Life Stage

Life Stage	**Peak Occurrence**	**Optimal**	**Suboptimal**	**Stre**  **ss-inducing**
Spring-Run Chinook Salmon				
Eggs to fry	September to October	< 54°F	54°F to 58°F	> 58°F
Rearing to out-migrating	November to May	< 60°F	60°F to 65°F	> 65°F
Migrating adults	March to June	< 56°F	56°F to 65°F	> 65°F
Adult holding	May to August	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Fall-Run Chinook Salmon				
Eggs to fry	October to April	48.2°F to 55.4°F	55.4°F to 62.6°F	> 62.6°F
Rearing to out-migrating	April to June	55.4°F to 68°F	68°F to 75.2°F	> 75.2°F
Migrating adults	June to April	50°F to 68°F	68°F to 69.8°F	> 69.8°F
Central Valley Steelhead				
Eggs to fry	January	46°F to 52°F	52°F to 55°F	> 55°F
Rearing to out-migrating	January to May	< 65°F	65°F to 68°F	> 68°F
Migrating adults	September to October	< 52°F	52°F to 70°F	> 70°F
Adult holding	December to March	< 60.8°F	60.8°F to 66.2°F	> 66.2°F

Sources: NMFS 2016a; Stillwater Sciences 2006; CDFG 2012a, 2012b.

Spring-Run Chinook Salmon

Under Alternative 2, Spring-Run Chinook Salmon eggs and emerging fry would experience stress-inducing temperatures during September of all water year types (Table O.3-37, Figure O.3-97). In October, temperatures would fall within the stress-inducing range for eggs and emerging fry during critically dry year types and within the suboptimal range for during all other year types. November temperatures would be optimal during all water year types (Figure O.3-97). Rearing to outmigrating juveniles would experience optimal temperature ranges under Alternative 2 during their period of peak occurrence in all water year types (Figure O.3-97). Migrating adults would experience sub-optimal temperatures in June of critically dry years and optimal temperatures during all other months of peak occurrence during all other water year types (Figure O.3-97). Relative to the No Action Alternative, Spring-Run Chinook Salmon would experience more frequent stress-inducing temperatures during the incubation and emerging fry life stages. Implementation of Mitigation Measure AQUA-3 would mitigate any adverse effects of flow and water temperature in Clear Creek downstream of Whiskeytown Dam under Alternative 2; therefore, Alternative 2 is not expected to adversely affect Spring-Run Chinook Salmon compared to the No Action Alternative.

Fall-Run Chinook Salmon

Under Alternative 2, Fall-Run Chinook eggs and emerging fry would experience suboptimal temperatures in Clear Creek during October of all water year types (56.1°F to 58.9°F), whereas under the No Action Alternative suboptimal October temperatures would only be encountered in critically dry year types. For the remainder of their period of peak occurrence during all year types, eggs and emerging fry would experience optimal temperature conditions (Table O.3-37, Figure O.3-97). Rearing and outmigrating juveniles would experience optimal temperature conditions during their period of peak occurrence for all water year types, as would migrating adults (Figure O.3-97). Alternative 2 could result in increased occurrences of suboptimal temperatures for incubation and emerging fry. However, HEC-5Q/RecTemp provides water temperature results as average monthly values, which do not have sufficient temporal resolution to facilitate direct comparison with average daily temperature objectives. Implementation of Mitigation Measure AQUA-1 would mitigate any adverse effects of flow in Clear Creek downstream of Whiskeytown Dam under Alternative 2; therefore, Alternative 2 is not expected to adversely affect Fall-Run Chinook Salmon compared to the No Action Alternative.

Central Valley Steelhead

Under Alternative 2, California Central Valley Steelhead migrating adults would experience suboptimal temperatures in Clear Creek in all water years (Table O.3-37, Figure O.3-97). All other life stages of California Central Valley Steelhead would encounter optimal temperatures during their periods of peak occurrence during all water year types. Under the No Action Alternative, California Central Valley Steelhead would experience temperatures within the same optimal and suboptimal temperature ranges as under Alternative 2. Therefore, relative to the No Action Alternative, Alternative 2 is expected to have a negligible effect.

Pacific Lamprey

Under Alternative 2, spawning Pacific Lamprey would experience temperatures ranges suitable for spawning in April and May of all water year types. During the remainder of the peak spawning period, Pacific Lamprey will experience temperatures below the general spawning range; however, under Alternative 2, temperatures are slightly higher than under the No Action Alternative (Table O.3-38, Figure O.3-97). Modeled Alternative 2 and No Action Alternative temperatures do not exceed suitable ranges during the period of peak occurrence of ammocoetes and outmigrating adults in any water year types (Figure O.3-97). Overall, Alternative 2 and the No Action Alternative should not negatively affect Pacific Lamprey in Clear Creek, as suitable temperatures overlap or coincide with the period of peak occurrence for all life stages.

Table O.3-38. Summary Table of Water Temperatures Suitable for Pacific Lamprey by Life Stage

Life Stage	**Peak Occurrence**	**Temperature Range**
Ammocoetes	Year-round	< 82°F [1]
Adult spawning	January to May	50°F to 64°F, peak 57°F to 59°F
Adult out-migration	Early winter to spring	<68°F

Source: Stillwater Sciences 2014.
[1] Temperature of 82°F is lethal to ammocoetes of four North American species of lamprey, however it is uncertain if Pacific Lampreys have similar tolerances.

O.3.5.3.3 Spring Creek Debris Dam

Existing operations of the SCDD will continue under both Alternative 2 and the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources.

O.3.5.3.4 Clear Creek Restoration Program

The goals of the Clear Creek Restoration Program are to (1) provide flows to allow sufficient spawning, incubation, rearing, and out-migration for Central Valley Chinook Salmon and Steelhead; (2) restore the stream channel and associated instream habitat; (3) operate the segregation weir to create reproductive isolation between Fall-Run (Fall-Run and Late Fall-Run) Chinook and Spring-Run Chinook Salmon; and (4) determine impacts of restoration actions on anadromous fish and geomorphology.

The program manages flows and temperatures through releases from Whiskeytown Dam on a year-round basis to improve survival and condition of Salmon and Steelhead in Clear Creek. The magnitude and timing of flows and water temperature are controlled to meet this goal. The 2009 NMFS BO RPA Action I.1.3 (Clear Creek Spawning Gravel Augmentation), implemented under the No Action Alternative, requires restoration on a two-mile section of Clear Creek floodplain and stream channel by annual gravel augmentation to recharge and maintain gravel supply (approximately 8,000 to 10,000 tons of gravel per year). The aim of the 2009 NMFS BO RPA Action I.1.3 is to create and maintain 347,288 square feet of usable spawning habitat in Clear Creek. However, under Alternative 2 the gravel augmentation in Clear Creek set forth by the 2009 NMFS BO RPA Action I.1.3 would not be implemented. Additionally, the picket weir (segregation weir) would not be operated under Alternative 2. Therefore, this section analyzes effects on focal species resulting from differences between Alternative 2 and the No Action Alternative.

Potential changes in aquatic resources due to gravel augmentation and segregation weir operation

Fall-Run and Spring-Run Chinook Salmon

Gravel augmentation would not occur under Alternative 2. As a result, spawning gravel availability in Clear Creek would likely decrease over time through downstream transport of existing coarse sediment during periods of high flow, leading to decreased quantity and quality of Central Valley Fall-Run and Spring-Run Chinook spawning and incubation habitat. A decrease in available spawning and incubation habitat could increase the probability of redd superimposition and limit the number of successful spawners and juvenile recruits, leading to potential adverse effects on Fall-Run and Spring-Run Chinook

Salmon. Operation of the segregation weir would not occur under Alternative 2. Therefore, hybridization of Fall-Run and Spring-Run Chinook Salmon would likely increase over time, leading to additional, potential adverse effects on Spring-Run Chinook Salmon population genetic integrity. However, these potential adverse effects would be reduced to a negligible level by implementation of Mitigation Measure AQUA-3.

Central Valley Steelhead

Gravel augmentation would not occur under Alternative 2. As a result, spawning gravel availability in Clear Creek would likely decrease over time through downstream transport of existing coarse sediment during periods of high flow, leading to decreased quantity and quality of Central Valley Steelhead spawning and incubation habitat. A decrease in available spawning and incubation habitat could increase the probability of redd superimposition and limit the number of successful spawners and juvenile recruits, leading to adverse effects on Central Valley Steelhead. These potential adverse effects would be reduced to a negligible level by implementation of Mitigation Measure AQUA-3.

Pacific Lamprey

Gravel augmentation would not occur under Alternative 2. As a result, spawning gravel availability in Clear Creek would likely decrease over time through downstream transport of existing coarse sediment during periods of high flow, leading to decreased quantity and quality of Pacific Lamprey spawning and incubation habitat. A decrease in available spawning and incubation habitat could limit the number of successful spawners, leading to adverse effects on Pacific Lamprey.

O.3.5.4 *Feather River*

O.3.5.4.1 FERC Project #2100-134

DWR, under Alternative 2, would operate Oroville Dam consistent with the NMFS, USFWS, and CDFW environmental requirements applicable for the current FERC License for the Oroville Complex (FERC Project #2100-134). Reclamation would operate Oroville Dam with minimum flows of 700 cfs to 800 cfs below the Thermalito Diversion Dam in the low flow channel (2006 Settlement Agreement), 750 cfs to 1,700 cfs below the Thermalito Afterbay outlet in the high flow channel (HFC; 1983 DWR-CDFG Agreement), and the DFG/DWR operation objective of 2,800 cfs at the mouth of the Feather River from April through September, with options to vary flow depending on year types. Under the No Action Alternative, DWR would operate Oroville Dam in accordance with ongoing management policies, criteria, and regulations, including water right permits and licenses issued by the SWRCB and operational requirements of the 2008 USFWS BO and the 2009 NMFS BO. Under the No Action Alternative, DWR typically releases water from Lake Oroville to meet the requirements of instream flows and D-1641.

Potential changes to aquatic resources in the Feather River due to seasonal variation in flow

CalSim II model output shows that Feather River flows under Alternative 2 and the No Action Alternative would comply with Feather River HFC minimum instream flow requirements during all months in wet, above normal, and below normal water years. In dry years where the preceding April to July unimpaired runoff is less than 55% of normal, Alternative 2 and the No Action Alternative would comply with minimum instream flow requirements in the HFC; however, where the preceding April to July unimpaired runoff is greater than 55% of normal, Alternative 2 would not comply with minimum instream flow requirements from October through March (Table O.3-39 and Figure O.3-98). In critically dry years where the preceding April to July runoff is 55% or greater of normal, Alternative 2 and the No Action Alternative would not comply with minimum instream flows from October to March; however, where the preceding April to July runoff is less than 55% of normal, Alternative 2 and the No Action Alternative would not comply with minimum instream flow requirements in the HFC only in November (Table O.3-39 and Figure O.3-98).

Table O.3-39. Feather River HFC Minimum Instream Flow Requirements

Preceding April to July Unimpaired Runoff (Percent of Normal)	Oct to Feb Minimum Instream Flow (cfs)	March Minimum Instream Flow (cfs)	April to Sept Minimum Instream Flow (cfs)
55% or greater	1,700	1,700	1,000
Less than 55%	1,200	1,000	1,000

Overall, flows under Alternative 2 and the No Action Alternative are similar, but flows under the No Action Alternative are greater than flows under Alternative 2 from July through September of wet, above normal, and below normal years, and flows under Alternative 2 are greater than under the No Action Alternative from April through June of above normal, below normal, and dry water years (Figure O.3-98). Flows under Alternative 2 are also much greater than under the No Action Alternative in February of below normal years.

Figure O.3-98. CalSim II estimates of Feather River Long-Term Average Flow below Thermalito, All Scenarios in Wet, Above Normal, Below Normal, Dry, and Critically Dry Water Years

Winter-Run Chinook Salmon

Winter-Run Chinook Salmon are not likely to be affected by changes in flow under Alternative 2 compared to the No Action Alternative due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Spring-Run Chinook Salmon would be exposed to the effects of Alternative 2 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Eggs and emerging fry of Spring-Run Chinook Salmon occur in the Feather River from September through February (NMFS 2016a); juvenile Spring-Run Chinook Salmon occur in the Feather River year-round, with peak abundance from November through May; and adult Spring-Run Chinook Salmon peak in abundance in the Feather River from March through June. All life stages would thus be exposed to the effects of Alternative 2.

Spring-Run Chinook Salmon eggs and emerging fry would benefit from increased Alternative 2 flows, leading to increased dissolved oxygenin February of below normal years when Alternative 2 flows are higher than No Action Alternative flows (Figure O.3-98). Juvenile Spring-Run Chinook Salmon would benefit from increased Alternative 2 flows relative to No Action Alternative flows from November through March of wet years, January through April of above normal years, and February of below normal years when the increased flows result in increased rearing and foraging habitat and higher dissolved oxygencontent (Figure O.3-98). Adult Spring-Run Chinook Salmon would benefit from increased Alternative 2 flows relative to No Action Alternative flows from April through June of below normal, dry, and critically dry years due to the resulting increased attraction flows and holding habitat (Figure O.3-98). Because Spring-Run Chinook Salmon benefit from increased Alternative 2 flows relative to No Action Alternative flows during key months of all life stages, and because Alternative 2 flows do not comply with minimum instream flow requirements only in dry and critically dry years, flow-related actions under Alternative 2 may have beneficial effects on Spring-Run Chinook Salmon.

Fall-Run Chinook Salmon

Fall-Run Chinook Salmon would be exposed to the effects of Alternative 2 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Fall-Run Chinook Salmon occur in the Feather River year-round, with eggs and emerging fry occurring between January and April, juveniles out-migrating year-round with peaks from January to April and August to November, and holding and migrating adults occurring between April and July (NMFS 2016a). All life stages would thus be exposed to the effects of Alternative 2.

Fall-Run Chinook Salmon eggs and emerging fry may benefit from the increased dissolved oxygendue to higher Alternative 2 flows from January to April of wet and above normal years and in February of below normal years (Figure O.3-98). Juvenile Fall-Run Chinook Salmon would benefit from increased Alternative 2 flows relative to No Action Alternative flows from January to April of wet and above normal years and in February of below normal years when increased flows result in increased rearing and foraging habitat and higher dissolved oxygencontent (Figure O.3-98). Migrating adult Fall-Run Chinook Salmon would benefit from increased Alternative 2 flows relative to No Action Alternative flows from April to July of below normal, dry, and critically dry years due to increased attraction flows and holding habitat (Figure O.3-98). Because Fall-Run Chinook Salmon benefit from increased Alternative 2 flows relative to No Action Alternative flows during key months of all life stages and because Alternative 2 flows do not comply with minimum instream flow requirements only in dry and critically dry years, flow-related actions under Alternative 2 may have beneficial effects on Fall-Run Chinook Salmon.

Central Valley Steelhead

Central Valley Steelhead would be exposed to the effects of Alternative 2 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Central Valley Steelhead eggs and fry occur in the Feather River from December to May; juveniles typically migrate to the ocean from January to May after spending 1 to 3 years in freshwater (CDFG 1996); peak adult migration occurs in September and October; and adult holding occurs December to March (NMFS 2016a).

Alternative 2 flows can affect Central Valley Steelhead by influencing water temperature, DO, sedimentation, substrate composition, habitat, food availability, predation, entrainment and stranding risk, habitat availability, and migration cues. Differences in flow under Alternative 2 and the No Action Alternative are minimal during the January to May period in which Central Valley Steelhead juveniles are out-migrating in all but below normal water years when Alternative 2 flows are considerably higher than No Action Alternative flows from mid-January through mid-March and can benefit juveniles via increased rearing and foraging habitat and higher dissolved oxygencontent (Figure O.3-98). The same is true for the December to May period in which Central Valley Steelhead eggs and fry may be present in the Feather River. During the September and October adult peak migration period, No Action Alternative flows are considerably higher than Alternative 2 flows in September in wet and above normal water years, causing higher levels of flow attraction (Figure O.3-98); there are minimal differences in all other water years. During adult holding from December to March, differences between Alternative 2 and No Action Alternative flows are minimal except for in February of below normal water years when increased flows could increase available habitat. Because Central Valley Steelhead benefit from increased Alternative 2 flows relative to No Action Alternative flows during key months of all life stages and because Alternative 2 flows do not comply with minimum instream flow requirements only in dry and critically dry years, flow-related actions under Alternative 2 may have beneficial effects on Central Valley Steelhead.

North American Green Sturgeon

North American Green Sturgeon would be exposed to the effects of Alternative 2 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Green Sturgeon eggs and larvae occur in the Feather River from March to July; larvae and juveniles occur from April to August; subadults occur year-round; and adults occur from March to August (NMFS 2016a).

Differences in flow under Alternative 2 and the No Action Alternative are minimal during all water years in the March to August period in which Green Sturgeon eggs, larvae, juveniles, and adults occur in the Feather River; subadults occur year-round. Thus, only Green Sturgeon subadults would be exposed to the larger differences between Alternative 2 and the No Action Alternative in February of below normal water years when Alternative 2 flows are greater than they are under the No Action Alternative and in September of above normal and wet water years when No Action Alternative flows are greater than flows under Alternative 2. Because flow differences between Alternative 2 and the No Action Alternative during key periods of Green Sturgeon presence in the Feather River are minimal and flows below the minimum instream flow requirements occur only in dry and critically dry water years, flow-related actions under Alternative 2 are not anticipated to substantially affect North American Green Sturgeon.

Potential changes to aquatic resources in the Feather River due to changes in water temperature from differences in flow

Water flow, combined with other environmental drivers, has the potential to affect aspects of water quality such as temperature. Water temperature has the potential to influence the condition and survival of fish species during all stages of their life cycle. Optimal water temperatures can facilitate physiological responses that range from faster growth rates to a heightened immune system, leading to a higher likelihood of survival. In contrast, effects of elevated water temperatures include an inability to satisfy metabolic demand and acute to chronic physiological stress, possibly leading to mortality (Stillwater Sciences 2006; Martin et al. 2017).

Water temperatures in the Feather River HFC at Gridley Bridge follow a seasonal pattern where they increase to a high point around 72°F in July or August and decrease to a low point around 47°F in January (Figure O.3-99). Flow releases from Oroville facilities influence Feather River water temperature primarily in summer and fall when these releases can help to lessen water temperatures when air temperatures and solar radiation levels are at their highest. Minimum water temperatures in the Feather River do not change substantially between water year type, but water temperatures can reach a maximum up to 4°F warmer (approximately 75°F) in critically dry years than in wet years (approximately 71°F; Figure O.3-89).

Effects of water temperature on fish in the Feather River vary among species and life stages. Temperatures surpass suboptimal levels for all species and life stages at 68°F and stress-inducing levels at 75.2°F (Table O.3-40). There is, therefore, potential for adverse temperature-related effects on Feather River fish species.

Alternative 2 was designed to follow flow regulation procedures similar to procedures under the No Action Alternative as a way to minimize potential adverse temperature-related effects on various fish species in the Feather River. Certain water temperature objectives were developed to aid the development of Alternative 2 operations (Table O.3-41).

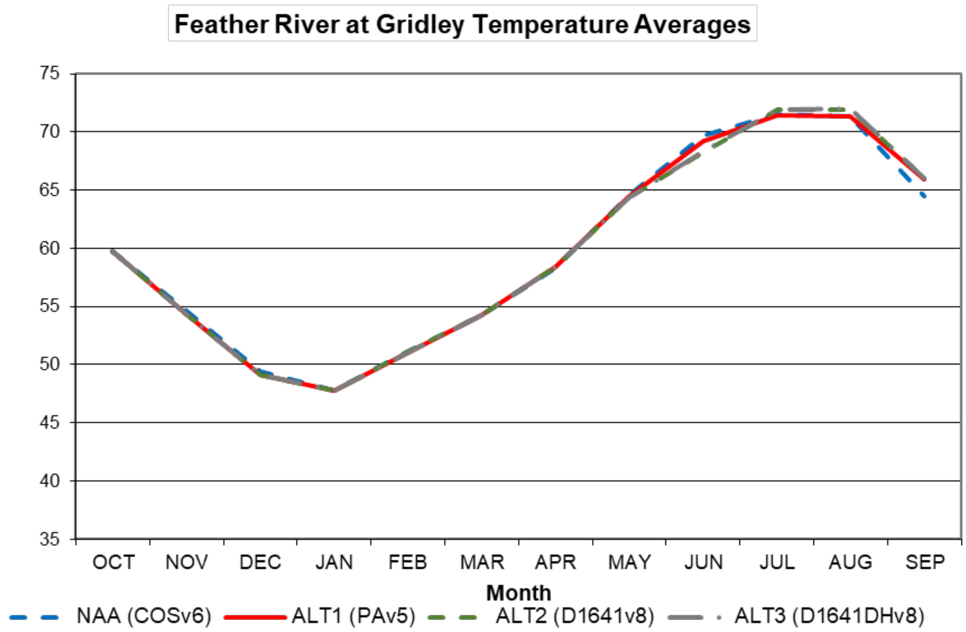

Figure O.3-99. RecTemp average Feather River water temperatures at Gridley Bridge under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 scenarios.

Figure O.3-100. RecTemp Average Estimated Feather River Water Temperatures at Gridley Bridge in Wet, Above Normal, Below Normal, Dry, and Critically Dry Water Year Types under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 Scenarios

Table O.3-40. Water Temperatures Suitable for Spring- and Fall-Run Chinook, Central Valley Steelhead, and Green Sturgeon by Life Stage

Life Stage	**Peak Occurrence**	**Optimal**	**Suboptimal**	**Stress-inducing**
Spring-Run Chinook				
Eggs to fry	September to October	< 54°F	54°F to 58°F	> 58°F
Rearing to out-migrating	November to May	< 60°F	60°F to 65°F	> 65°F
Migrating adults	March to June	< 56°F	56°F to 65°F	> 65°F

Modeling results indicate that water temperatures under Alternative 2 operations would be similar to temperatures under the No Action Alternative for much of the year (Figures O.3-99 and O.3-100). However, in August and September, water temperatures at Gridley Bridge would reach averages up to 1°F warmer than under the No Action Alternative (Figure O.3-99). The most pronounced difference in August and September water temperatures between Alternative 2 and No Action Alternative scenarios would occur in wet years when this temperature difference could reach as much as 3°F and 1°F warmer in below normal years, whereas no difference is projected in dry or critically dry water years (Figure O.3-100). In below normal to dry water years, a notable difference in water temperature between Alternative 2 and No Action Alternative scenarios would occur instead in June, when Alternative 2 water temperatures would be lower than No Action Alternative temperatures by approximately 4°F (Figure O.3-100). In below normal to dry water years, a small difference in water temperature between Alternative 2 and No Action Alternative scenarios would also occur in July, when Alternative 2 water temperatures would surpass No Action Alternative temperatures by approximately 1°F (Figure O.3-100). These differences in water temperature between Alternative 2 and the No Action Alternative would therefore predominantly occur in summer months when water temperatures are higher (> 60°F) and more likely to lead to physiological stress and mortality.

Winter-Run Chinook Salmon

Winter-Run Chinook Salmon are not likely to be affected by changes in flow under Alternative 2 compared to the No Action Alternative due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Effects of water temperature on Spring-Run Chinook Salmon have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-40).

In the Feather River, Spring-Run Chinook eggs and emerging fry occur from September to February, peaking in abundance from September to October (NMFS 2016a). The only difference in water temperature between Alternative 2 and No Action Alternative scenarios during this period would occur in September of wet to dry water years when temperatures under Alternative 2 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-100). This would result in potentially adverse effects from the slightly higher water temperatures under Alternative 2 than under the No Action Alternative, yet water temperatures under both scenarios would fall in the stress-inducing range for this life stage (Table O.3-40). The slightly higher water temperatures in September under Alternative 2 in wet and above normal water years, therefore, would result in a slightly adverse effect on Spring-Run Chinook Salmon eggs and emerging fry relative to the effect of the No Action Alternative.

The occurrence of rearing juvenile Spring-Run Chinook Salmon in the Feather River is possible year-round, but peak abundance is usually between November and May. During this period of peak abundance, there is little to no projected difference between water temperatures under Alternative 2 and the No Action Alternative (Figure O.3-99); therefore, the effect of water temperatures on juvenile Spring-Run Chinook Salmon would be negligible under Alternative 2 operations relative to operations under No Action Alternative.

Migrating adult (ocean to river) Spring-Run Chinook Salmon reach the Feather River between March and June at generally consistent levels across all four months. During the first three months of this time span, water temperatures would be nearly identical under Alternative 1 and the No Action Alternative (Figure O.3-99). In June of above normal and dry water years, however, water temperatures under Alternative 2 could be up to 4°F lower than under the No Action Alternative (Figure O.3-100), yet modeled water temperatures are above the threshold for stress-inducing temperatures for migrating adults under both Alternative 2 and the No Action Alternative (Table O.3-40). Effects of water temperature on this life stage, therefore, are anticipated to be slightly less severe under Alternative 2 than under the No Action Alternative.

Holding adult Spring-Run Chinook Salmon have the potential to occur in the Feather River from March to September with peak abundance between May and August. As indicated by the RecTemp model, Feather River water temperatures would be similar under Alternative 2 and the No Action Alternative during peak abundance and the majority of the possible time range (Figures O.3-99 and O.3-100) but would differ in June and September of wet to normal water years when temperatures under Alternative 2 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-100). Additionally, water temperatures in normal to dry water years would also differ when temperatures under Alternative 2 flows would be up to 4°F lower than temperatures under No Action Alternative flows (Figure O.3-100). Water temperatures in most water type years would remain at stress-inducing levels for holding adults for an additional month under Alternative 2 than under the No Action Alternative, before decreasing into the suboptimal range in September and June (Table O.3-40). Alternative 2 operations would therefore result in slightly adverse temperature-related effects on holding adult Spring-Run Chinook Salmon relative to the effects under the No Action Alternative in September and slightly lower adverse effects in June.

Alternative 2 has the potential for slightly adverse water temperature-related effects on eggs and fry, but very slightly beneficial effects on migrating adults and holding adults, so its overall effect on Spring-Run Chinook Salmon relative to the No Action Alternative is slightly adverse.

Fall-Run Chinook Salmon

Effects of water temperature on Fall-Run Chinook Salmon have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-40).

In the Feather River, Fall-Run Chinook Salmon eggs and emerging fry occur from October to April (CDFG 2012c). During this period there is no projected difference between water temperatures under Alternative 2 and the No Action Alternative (Figures O.3-99 and O.3-100); therefore, the effect of water temperatures on Fall-Run Chinook eggs and fry would be negligible under Alternative 2 operations relative to under No Action Alternative operations.

Juvenile Fall-Run Chinook Salmon typically occur in the Feather River from April to June. During the first two months of this time span, water temperatures would be essentially identical under Alternative 2 and the No Action Alternative (Figures O.3-99 and O.3-100). In June of below normal and dry water years, however, water temperatures under Alternative 2 could be up to 4°F lower than under the No Action Alternative (Figure O.3-100). The effect of this temperature difference would be slightly beneficial as temperature in these years would likely rise to suboptimal levels for juvenile Fall-Run Chinook Salmon under both Alternative 2 and No Action Alternative scenarios.

Migrating adult (ocean to river) Fall-Run Chinook Salmon reach the Feather River between June and April. This time span includes the slightly higher August and September water temperatures under Alternative 2 in wet and above normal years as well as the slightly lower June water temperatures in normal to dry years (Figure O.3-100). For migrating adult Fall-Run Chinook Salmon, water temperatures under Alternative 2 would then reach suboptimal and stress-inducing levels a couple of weeks more in summer of wet and above normal water than under the No Action Alternative but would drop to suboptimal and optimal levels approximately a couple of weeks more than under the No Action Alternative scenario in early summer of years below normal and dry water years (Figure O.3-100 and Table O.3-40). The net effect of Alternative 2 water temperatures on migrating adult Fall-Run Chinook Salmon relative to the No Action Alternative would be expected to be slightly adverse overall but would ultimately depend on rainfall levels experienced in the watershed.

Alternative 2 has the potential for slightly beneficial water temperature-related effects on juveniles and slightly adverse on migrating adults. Overall effect on Fall-Run Chinook Salmon relative to the No Action Alternative is slightly beneficial.

Central Valley Steelhead

Effects of water temperature on Central Valley Steelhead have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-40).

Central Valley Steelhead eggs and emerging fry occur in the Feather River from December to May, peaking in abundance in January (NMFS 2016a). Under Alternative 2 and the No Action Alternative, water temperature estimates for all water year types are essentially identical throughout this time period (Figure O.3-100), so no effect of Alternative 2 relative to the No Action Alternative is expected for Central Valley Steelhead eggs and fry.

Rearing juveniles typically migrate to the ocean from January to May after spending 1 to 3 years in freshwater (CDFG 1996). Under Alternative 2 and the No Action Alternative, water temperature estimates for all water year types are nearly identical throughout this time period (Figure O.3-100). Therefore, no effect of Alternative 2 relative to the No Action Alternative is expected for juvenile Central Valley Steelhead.

Migrating adult (ocean to river) Central Valley Steelhead reach the Feather River between September and October. Modeled water temperatures for Alternative 2 and the No Action Alternative differ in September of wet and above normal water years when temperatures under Alternative 2 could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-100), yet water temperatures would remain in the suboptimal range for migrating adults under Alternative 2 and the No Action Alternative (Table O.3-40). Adverse effects of water temperature on this life stage are therefore anticipated to be slightly more severe under Alternative 2 than under the No Action Alternative.

Holding adult Central Valley Steelhead have the potential to occur in the Feather River from December to March. Under Alternative 2 and the No Action Alternative, water temperature estimates for all water year types are essentially identical throughout this time period (Figure O.3-100), and no effect of Alternative 2 relative to the No Action Alternative is expected for Central Valley Steelhead eggs and fry.

Alternative 2 has the potential for slightly adverse water temperature-related effects on migrating adults. Overall effects on Central Valley Steelhead under Alternative 2 relative to the No Action Alternative is slightly adverse.

North American Green Sturgeon

Effects of water temperature on North American Green Sturgeon have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-40).

Green Sturgeon eggs and emerging fry occur in the Feather River from May to July (NMFS 2016a). During May, water temperatures would be essentially identical under Alternative 2 and the No Action Alternative (Figures O.3-99 and O.3-100). In June of below normal and dry water years, however, water temperatures under Alternative 2 could be up to 4°F lower than under the No Action Alternative (Figure O.3-100), yet modeled water temperatures are above the threshold for stress-inducing temperatures for eggs and fry under both Alternative 2 and the No Action Alternative (Table O.3-40). However, in July of below normal and dry water years, water temperatures would be up to 1°F higher under Alternative 2 than under the No Action Alternative (Figure O.3-100), and similarly to June would have stress-inducing temperatures for eggs and fry under both Alternative 2 and the No Action Alternative (Table O.3-40). Effects of water temperature on this life stage of Green Sturgeon are therefore anticipated to be slightly less severe under Alternative 2 than under the No Action Alternative.

Rearing juvenile Green Sturgeon are present in the Feather River from May to October, with abundance peaking in September. During May and October, water temperatures would be essentially identical under Alternative 2 and the No Action Alternative (Figures O.3-99 and O.3-100). In June of below normal and dry water years, however, water temperatures under Alternative 2 could be up to 4°F lower than under the No Action Alternative (Figure O.3-100). This would result in water temperatures reaching suboptimal stress-inducing levels for juveniles later in June under Alternative 2 than under the No Action Alternative (Table O.3-40). However, in July of below normal and dry water years, water temperatures would be up to 1°F higher under Alternative 2 than under the No Action Alternative (Figure O.3-100), which would likely have stress-inducing temperatures for juveniles under both Alternative 2 and the No Action Alternative (Table O.3-40). Water temperatures would differ in August and September of wet and above normal water years when temperatures under Alternative 2 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-100). Water temperatures in wet and above normal years would drop from stress-inducing levels for juveniles to suboptimal levels and again to optimal levels later in the month under Alternative 2 than under the No Action Alternative (Figure O.3-100, Table O.3-40). The effects of water temperature on juvenile Green Sturgeon under Alternative 2 would then be dependent on water year types with slightly beneficial effects in below normal and dry water years and slightly adverse effects in wet and above normal water years; therefore, the net effect would be slightly adverse under Alternative 2 than under the No Action Alternative.

Migrating adult (ocean to river) Green Sturgeon reach the Feather River between March and May and, upon spawning, can remain in the vicinity until August. From March to May, water temperatures would be essentially identical under Alternative 2 and the No Action Alternative (Figures O.3-99 and O.3-100). In June of below normal and dry water years, however, water temperatures under Alternative 2 could be up to 4°F lower than under the No Action Alternative (Figure O.3-100). Modeled June water temperatures are above the threshold for stress-inducing temperatures for migrating adults under both Alternative 2 and the No Action Alternative (Table O.3-40). However, water temperatures would reach the suboptimal threshold for post-spawn adults later in below normal and dry years under the No Action Alternative and optimal levels under Alternative 2. Water temperatures would differ in August of wet and above normal water years when temperatures under Alternative 2 flows could be up to 1°F higher than temperatures under No Action Alternative flows (Figure O.3-100), which would likely result in stress-inducing levels in migrating adults under both Alternative 2 and the No Action Alternative; yet these temperatures could reach stress inducing temperatures for post-spawn adults a couple of weeks more under Alternative 2 than under the No Action Alternative. Effects of water temperature on this life stage, therefore, are anticipated to be slightly less severe under Alternative 2 than under the No Action Alternative.

Alternative 2 has the potential for slightly adverse water temperature-related effects on juveniles in wet and above normal years but slightly beneficial effects on eggs, fry, and post-spawn adults in below normal and dry years. Overall, effect on North American Green Sturgeon under Alternative 2 relative to the No Action Alternative is minor and dependent on annual rainfall totals.

O.3.5.5 *American River*

Potential changes to aquatic resources in the American River from flood control

Flood Control for the American River at Folsom Dam would be the same under the Alternative 2, compared to the No Action Alternative, since flood control follows the USACE Water Control Manual and flow management for Alternative 2 is according to the American River 2006 Flow Management Standard (Water Forum 2006), the same as the No Action Alternative. The Water Control Manual has been updated over time, and a new Water Control Manual was developed that utilizes forecasted inflow as the criteria for determining flood control releases. The new manual looks ahead five days and considers the forecasted inflow volume for the total of those five days. If that volume exceeds a threshold, a flood control release is specified. The concept is to pre-emptively draw the reservoir down in anticipation of high inflows, thus providing space to store the rain event when it arrives. This will allow Reclamation to pass higher precipitation events with lower peak releases which relieves stress on the downstream levees and provides a higher level of flood protection to downstream areas.

Potential changes to aquatic resources from Folsom Reservoir operations in the American River to meet Delta salinity requirements

Folsom Reservoir operations to address Delta water quality requirements under D-1641 would not change under Alternative 2, compared to the No Action Alternative. Folsom Reservoir flow requirements includes releases to meet Delta standards under D-1641, as needed. Since Folsom Reservoir is the closest reservoir to the Delta, releases from Folsom can more quickly address Delta water quality requirements. Releases to address Delta water quality objectives would be conducted, as needed, in coordination with the American River stakeholders. Releases to address Delta water quality objectives would improve water quality conditions, and thus habitat conditions for fish and other aquatic species in the Delta when hydrologic conditions are negatively affecting salinity levels.

Potential changes to aquatic resources from flows in the American River

Flows in the American River would be the same under Alternative 2, compared to the No Action Alternative, since flow management for Alternative 2 is according to the American River 2006 Flow Management Standard (Water Forum 2006), the same as the No Action Alternative. Under the Alternative 2, flow releases are managed according to the American River 2006 Water Forum Lower American Flow Management Standard, with the objective of providing suitable conditions for Fall-Run Chinook Salmon and Steelhead. Under the Flow Management Standard, flows are managed according to the Minimum Flow Requirements (MFR), which establishes minimum flows, as measured by the total release at Nimbus Dam, which vary throughout the year in response to the hydrology of the Sacramento and American River basins. The October 1 through December 31 MFR range between 800 and 2,000 cfs. The January 1 through Labor Day MFR range between 800 and 1,750 cfs. The post Labor Day through September MFR range between 800 and 1,500 cfs. As a general rule, the MFR must equal or exceed 800 cfs year round. Narrowly defined exceptions to this rule allow Nimbus releases to drop below 800 cfs to avoid depletion of water storage in Folsom Reservoir when dry or critically dry hydrologic conditions are forecasted to occur. These narrowly defined exceptions to the MFR are an important component of the Flow Management Standard. Since the No Action Alternative follows the existing condition implementation of the Alternative 2 would result in no change to flows in the lower American River.

Potential changes to aquatic resources in the American River due to changes in water temperature

Alternative 2 does not include water temperature objectives. However, water temperature modeling indicates that differences in water temperatures are more a function of hydrologic conditions than operations to meet objectives, water temperatures in the American River would be similar for Alternative 2, compared to the No Action Alternative (Figure 8). Since flow objectives are the same for Alternative 2 as for the No Action Alternative and follow the American River 2006 Flow Management Standard (Water

Forum 2006), the flow conditions in the American River remain the same, and thus water temperatures no change in water temperatures are expected under Alternative 2. Temperature modeling indicates that there would be no change average water temperatures in the American River (Figure 8), or in wet years (Figure 9) and dry years (Figure 10).

Potential changes to aquatic resources in the American River from habitat restoration

No additional habitat restoration is proposed under the No Action Alternative, therefore, there would be no changes to habitat in the lower American River.

O.3.5.6 *Stanislaus River*

Potential changes to aquatic resources in the Stanislaus River due to changes in flow

O.3.5.6.1 Below Goodwin Dam

Below Goodwin Dam, the largest difference in flow under Alternative 2 (compared to the No Action Alternative, Figures 11 and 12) would occur between the months of February through September. As mentioned previously, flows are currently managed to benefit various Central Valley lifestages for salmonids occur in the river during this period. Decreases in flow could affect juvenile salmonid out-migration, reduce suitable habitat for to varying degree by salmonid life stages, or have other undesirable results. Specifically, the flow differences under Alternatives 2 may result in higher water temperature, therefore, if Steelhead are present within the river, survival would be impeded with the decrease. Specifically, Steelhead eggs and emerging fry may be present in the river, as the species egg/fry emergence period is from December through June. Additionally, Steelhead that rear year-round within the river may also be exposed to the decreased flow and associated effects such as increased water temperature, decreased dissolved oxygen, and loss of suitable off-channel rearing and refuge habitat.

O.3.5.6.2 Mouth of Stanislaus River

The largest difference in flow under Alternative 2 at the mouth of the Stanislaus River would occur between the months of March through May (Figures 13 and 14). Similar to the discussions above, decreased flows compared to the No Action Alternative has effects to salmonid habitat, and in turn, the individuals. The larger flow decreases would likely increase water temperatures; therefore, salmonids, if present within the river, would likely not survive the summer and subsequent life stages would be determinately affected.

During the March through May period, Central Valley Steelhead are emerging (through June), and would be exposed to higher water temperatures and associated decreased dissolved oxygen. Rearing Steelhead and Chinook Salmon, if present, would be exposed to the same conditions.

Spring-Run Chinook Salmon emigrate from the Stanislaus River from mid-January through June; therefore, under Alternative 2, the Salmon would be exposed to lower flows and increased water temperatures as well. Similar to decreases in flow below Goodwin Dam, reduction of flow may decrease the quality and quantity of off-channel habitat for rearing and refuge. As the majority of adult Chinook Salmon hold from March to mid-September in the Stanislaus River, the Salmon would be exposed to the lower flow for a few months. Based on the typical seasonal occurrence of this life stage in the Stanislaus River (mid-January to late June), no adult migrating Spring-Run Chinook Salmon would be expected to be exposed to the effects of the alteration of dissolved oxygen requirements at Ripon.

Spring-Run Chinook Salmon that do hold in the river, and survive to spawn in early fall would likely not successfully reproduce due to higher water temperature. The Steelhead egg/fry that may be present through June, would be exposed to higher water temperatures, likely decreasing survival. Additionally, reduced flow would decrease the quality and quantity of habitat conditions. Off-channel habitat for rearing and refuge would potentially decrease.

Alternative 2 does result in higher flows at the mouth of the Stanislaus River when compared to the No Action Alternative during the January through February period. This increase is beneficial of spawning and emerging fry for salmonids, Steelhead. The increase in flow would directly result in increasing migratory cues for both emigrating and immigrating Steelhead.

Potential changes to aquatic resources in the Stanislaus River due to changes in water temperature

Alternatives 2 and 3 result in the highest increase in TAF compared to the No Action Alternative (Figures O.3-101 and O.3-102). The overall average increase in TAF benefits salmonids in the Stanislaus River by potentially increasing coldwater pool available for downstream salmonids. Recognizing that there is no ability for Reclamation to release water from different depths at New Melones, increased water depth above the static intake structure would function like a thermal cap, keeping the water below cooler. More cold water in New Melones Reservoir may lower water temperatures downstream of Goodwin Dam, which would benefit salmonids in all life stages in the lower Stanislaus River.

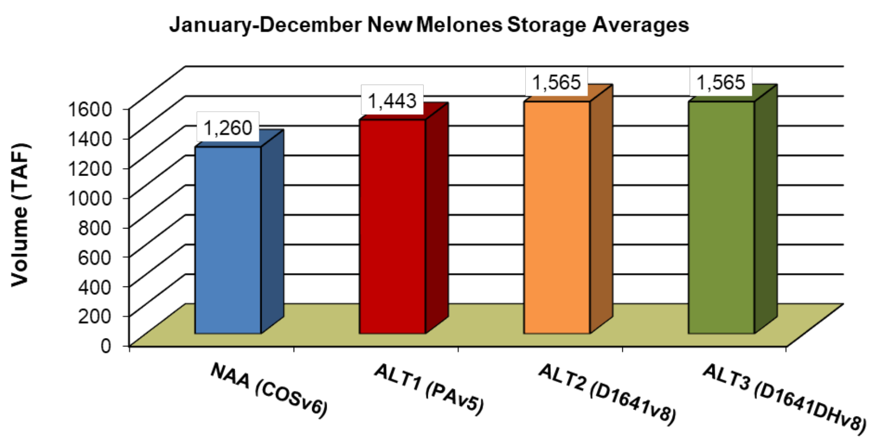

Figure O.3-101. Average Annual Storage at New Melones Reservoir by Project Alternative

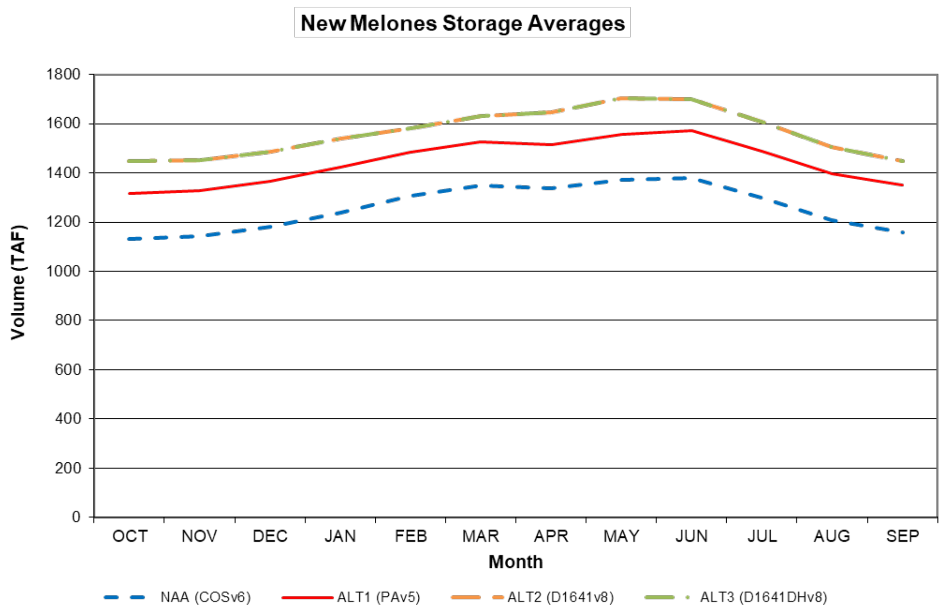

Figure O.3-102. Average Monthly Storage at New Melones Reservoir by Project Alternative

Temperature modeling for the Stanislaus River at Ripon shows that there is a small increase in overall annual temperature for Alternatives 1 through 3 with the No Action Alternative reflecting the coolest conditions (Figures O.3-103 and O.3-104). Monthly average temperature shows that Alternatives 2 and 3 are warmer from March through May, but cooler from July through September. Juvenile salmonids rear and out-migrate during the March through May period, which may be exposed to warmer conditions and represent a more sensitive lifestage. During July through September, Steelhead and possibly Spring-Run Chinook Salmon may hold and warmer conditions may incrementally reduce the amount of suitable holding habitat available.

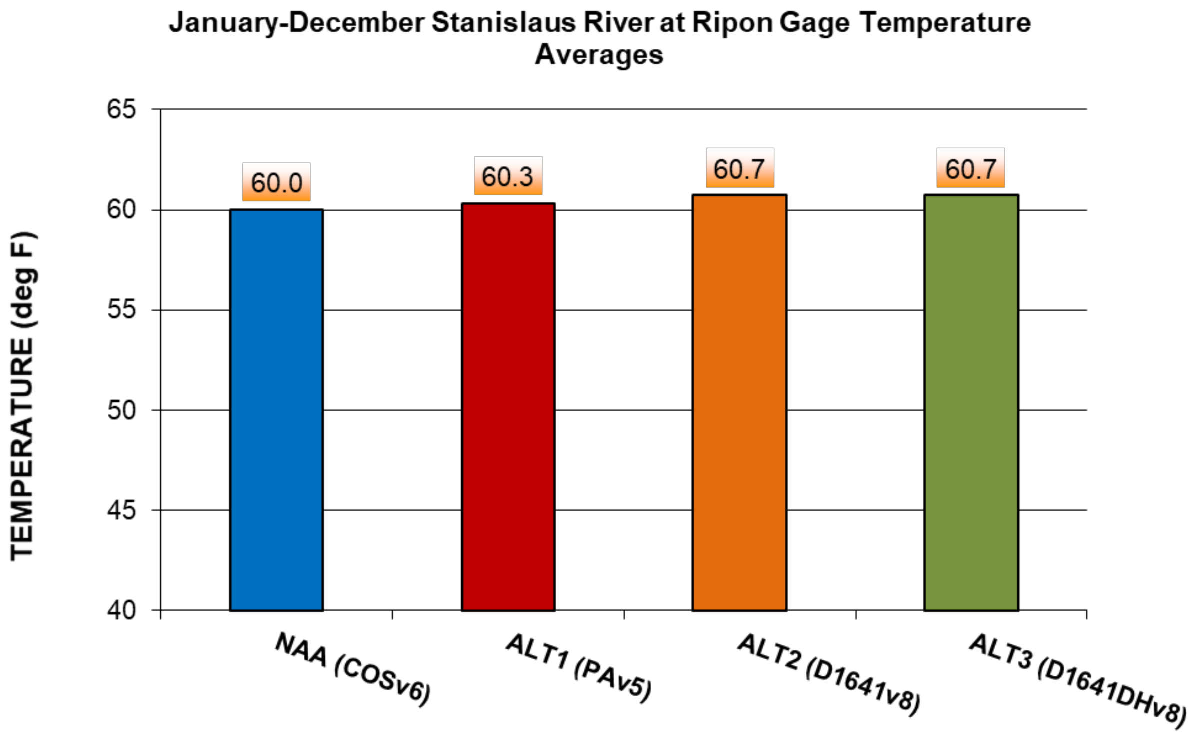

Figure O.3-103. Annual Average Water Temperature at Ripon on the Stanislaus River

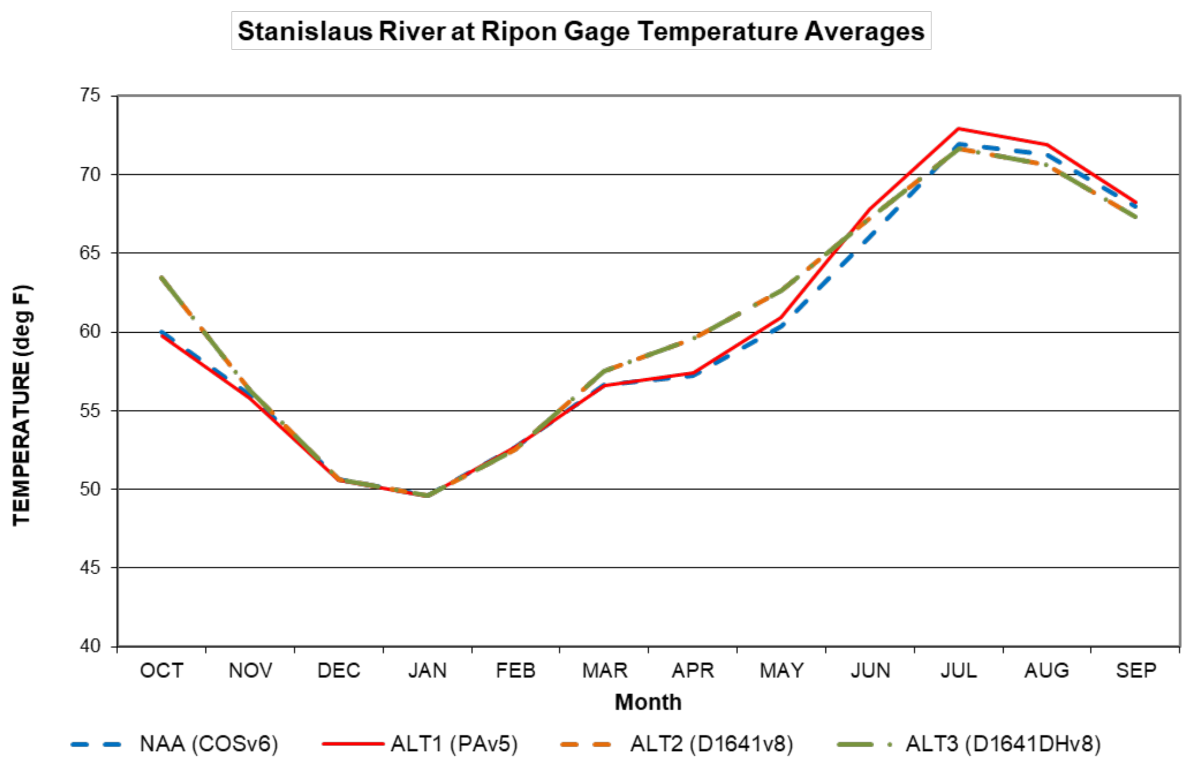

Figure O.3-104. Average Monthly Temperature at Ripon on the Stanislaus River

Restoration activities have the potential to increase growth and survival of juvenile Chinook Salmon, Steelhead, and other naïve fish by providing increased seasonal access to productive foraging and high quality rearing habitat.

O.3.5.7 *San Joaquin River*

The following effects would be expected to be similar under Alternative 2 to the potential effects as previously described for the No Action Alternative:

Potential changes to aquatic resources in the San Joaquin River due to changes in flow

Potential changes to aquatic resources in the San Joaquin River due to changes in water temperature

O.3.5.8 *Bay-Delta*

O.3.5.8.1 Delta Smelt

Potential changes to Delta Smelt due to seasonal operations

Relative to the No Action Alternative, potential negative effects on Delta Smelt from seasonal operations would tend to be greater under Alternative 2. Absence of the entrainment risk management included in the USFWS (2008) BO such as OMR restrictions would lead to appreciably lower OMR flows in December to June (Appendix F, Attachment 3-2, Figures 40-9 through 40-15), which based on historical data could lead to relatively high proportional entrainment loss of Delta Smelt (Kimmerer 2008; Miller 2011; Kimmerer 2011).

With respect to other habitat attributes discussed previously under analysis of *Potential changes to Delta Smelt due to seasonal operations* for Alternative 1, delivery of sediment to the Delta and resulting turbidity-related predation risk would be expected to be similar to the No Action Alternative, as indicated by similarity of CalSim-modeled flows in the Sacramento River at Rio Vista (e.g., Appendix E, Attachment 3-2, Figures 32-9 through 32-14). Related to predation risk from Silversides, March to May south Delta exports would be greater under Alternative 2 than the No Action Alternative (which could give less predation risk under Alternative 2, based on the correlative analysis described in the ROC LTO BA), whereas June to September Delta inflow would be similar or potentially greater under the No Action Alternative as a result of inclusion of the USFWS (2008) BO RPA for fall X2 under the No Action Alternative, resulting in potentially greater Silverside abundance and therefore predation risk under Alternative 2. As discussed for Alternative 1, the extent to which the opposing effects of differences in exports and inflow could affect Silverside abundance under Alternative 1 is uncertain, particularly given that the relationships are correlations and do not necessarily imply causality and require further investigation (Reclamation 2019). Similar to Alternative 1, the inclusion of the USFWS (2008) fall X2 criteria under the No Action Alternative but not in Alternative 2 has the potential to affect Delta Smelt predation risk by resulting in less overlap of the low salinity zone with turbid habitat.

As described for Alternative 1, various aspects of seasonal operations under Alternative 2 have the potential to affect Delta Smelt food availability relative to the No Action Alternative. There would be little difference in Yolo Bypass flooding and therefore little difference between Alternative 2 and the No Action Alternative in potential food effects for adult Delta Smelt in winter/spring (Appendix E, Attachment 3-2, Figures 25-6 through 25-18). In spring, the general similarity in X2 between Alternative 1 and Alternative 2 has the potential to produce similar negative effects on Delta Smelt prey (*E. affinis*) as described for Alternative 1; Alternative 2 also includes completion of the 8,000 acres of tidal restoration to offset such effects, although given less Delta outflow than the No Action Alternative and absence of any of the food subsidy actions proposed for Alternative 1, 8,000 acres of restoration may not be sufficient to offset negative effects of Alternative 2. Summer/fall subsidy of *P. forbesi* to the low salinity zone, as described for Alternative 1, may be negatively affected relative to the No Action Alternative to a similar extent as under Alternative 1, given the general similarity in the frequency of negative San Joaquin River at Jersey Point flows under Alternative 2 and Alternative 1 (Figures O.3-70 through).3-72).

Relative to the No Action Alternative and similar to Alternative 1, under Alternative 2 the size of the low salinity zone in wet and above normal years would be expected to be considerably reduced (Figures O.3-73 through O.3-75), and the percentage of time that the low salinity zone is outside of Suisun Bay would also be expected to considerably less under Alternative 2 than Alternative 1 (Figure O.3-76), thereby potentially negatively affecting Delta Smelt under Alternative 2 relative to the No Action Alternative.

Based on the overall similarity between Alternative 1 and Alternative 2 in operations during the summer/fall period of potential harmful algal bloom occurrence, there would be expected to be little difference in modeled velocity (a potential indicator of harmful algal bloom disruption) between Alternative 2 and the No Action Alternative, given the similarity in velocity between the No Action Alternative and Alternative 1 (Reclamation 2019). This suggests that there would be little difference in harmful algal bloom potential between Alternative 2 and the No Action Alternative.

Potential changes to Delta Smelt due to changes in Delta Cross Channel operations

The potential effects of DCC operations on Delta Smelt under Alternative 2 may be generally similar to those occurring under Alternative 1 but somewhat different given that the DCC would be open more often under Alternative 2. However, the nature of the difference is uncertain given the uncertainty in the effects that the DCC has on Delta Smelt, as described for Alternative 1.

Potential changes in Delta Smelt survival related to the Temporary Barriers Project

Under Alternative 2, potential effects of the three south Delta agricultural barriers on Delta Smelt generally would be expected to be similar to the effects under Alternative 1 (i.e., near-field predation and potential effects on transport of *P. forbesi* to the low salinity zone; see also ROC LTO BA), although the effects may be greater because of less OMR restrictions and therefore greater risk of Delta Smelt being present in the south Delta under Alternative 2. As with Alternative 1, there may be less potential effect because of no HOR barrier, although Delta Smelt would rarely be found near the HOR barrier based on historical observations.

Potential changes to Delta Smelt due to changes from Tracy and Skinner fish facilities improvements

The potential effects to Delta Smelt from the Tracy and Skinner fish facilities under Alternative 2 (i.e., mortality from pre-screen loss, collection, handling, transport, and release, with only a very small fraction potentially surviving the salvage process) would be somewhat greater than the effects described under the No Action Alternative and Alternative 1 because of the probable greater proportion of Delta Smelt entering the south Delta in the absence of OMR management that would continue under the No Action Alternative and is proposed under Alternative 1.

The following project-level effects would be expected to be similar under Alternative 2 to the potential effects as previously described for the No Action Alternative and Alternative 1 because of limited potential for effect or because the operations are similar:

Potential changes to Delta Smelt from Contra Costa Water District operations

Potential changes to Delta Smelt from North Bay Aqueduct operations

Potential changes to Delta Smelt from water transfers

Potential changes to Delta Smelt from Clifton Court aquatic weed and algal bloom management

Potential changes to Delta Smelt due to changes from Suisun Marsh facilities

O.3.5.8.2 Longfin Smelt

Potential changes to Longfin Smelt due to seasonal operations

As described for Alternative 1, the principal potential effect of seasonal operations on Longfin Smelt would be changes in population abundance as a result of changes in Delta outflow. During the December–May period identified as important for Delta outflow by Nobriga and Rosenfield (2016), CalSim modeling suggests that under Alternative 2 Delta outflow generally would be less than No Action Alternative in December (Appendix F, Attachment 3-2, Figures 41-9 through 41-14), thereby potentially negatively affecting Longfin Smelt through reductions in population abundance. However, as described for Alternative 1, the magnitude of the difference may be limited because of density-dependent effects (Nobriga and Rosenfield 2016), there is appreciable (several orders of magnitude) variability in the estimates generated by the Nobriga and Rosenfield (2016) model, and other analyses have found stronger correlations with general hydrological conditions rather than Delta outflow specifically (Maunder et al. 2015). As described for Alternative 1, completion of the 8,000 acres of tidal habitat restoration would have the potential to provide positive effects to Longfin Smelt larvae in the north Delta and therefore provide some offsetting of potential negative effects from seasonal operations, although this offsetting may be limited because Longfin Smelt would tend to be downstream of restored areas.

Relative to the No Action Alternative, there is the potential for Longfin Smelt entrainment risk to be greater under Alternative 2, as reflected by generally lower OMR flow in December to May (Appendix F, Attachment 3-2, Figures 40-9 through 40-15) and generally lower San Joaquin River flow at Jersey Point in January to March (Figures O.3-77 through O.3-79). However, as noted previously for Alternative 1, it should be borne in mind that the modeling for Alternative 2 does not reflect continued adherence to the criteria of the CDFG (2009) SWP ITP, nor to any subsequent ITP that may govern Longfin Smelt south Delta entrainment protection. In addition and as previously discussed for Alternative 1, while entrainment risk may be relatively greater under Alternative 2 compared to the No Action Alternative, estimates of Longfin Smelt population-level entrainment loss during the D-1641-based regulatory period (i.e., prior to 2007, and what is included under Alternatives 2 and 3) suggest that low percentages (0–3.6%) of Longfin Smelt were lost to entrainment (ICF International 2016, Table 4.2-10 [p. 4-286] and Table 4.2-11 [p. 4-288]). This suggests that Longfin Smelt proportional entrainment loss under Alternative 2 would also be limited.

Potential changes to Longfin Smelt due to changes in Delta Cross Channel operations

As discussed for Alternative 1, the potential effects of DCC operations on Longfin Smelt under Alternative 2 would be expected to be limited given that Longfin Smelt occur downstream of the DCC and there has been limited south Delta entrainment under the D-1641 management framework.

Potential changes in Longfin Smelt survival related to the Temporary Barriers Project

Under Alternative 2, potential effects of the three south Delta agricultural barriers on Longfin Smelt (e.g., near-field predation) could be greater than the No Action Alternative, but as with Alternative 1, effects would be expected to be limited given the low frequency of occurrence of Longfin Smelt occurring in the south Delta (Merz et al. 2013).

Potential changes to Longfin Smelt due to changes from Tracy and Skinner fish facilities

The potential effects to Longfin Smelt from the Tracy and Skinner fish facilities under Alternative 2 (e.g., prescreen predation loss) would be somewhat greater than the effects described under the No Action Alternative and Alternative 1 because of the probable greater proportion of Longfin Smelt entering the south Delta in the absence of OMR management that would continue under the No Action Alternative and is proposed under Alternative 1. However, the effects would be limited because of historically low entrainment loss of Longfin Smelt.

The following project-level effects would be expected to be similar under Alternative 2 to the potential effects as previously described for the No Action Alternative and Alternative 1 because of limited potential for effect or because the operations are similar:

Potential changes to Longfin Smelt from Contra Costa Water District operations

Potential changes to Longfin Smelt from North Bay Aqueduct operations

Potential changes to Longfin Smelt from water transfers

Potential changes to Longfin Smelt from Clifton Court aquatic weed and algal bloom management

Potential changes to Longfin Smelt due to changes from Suisun Marsh facilities

O.3.5.8.3 Sacramento Winter-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Rearing Winter-Run Chinook Salmon are present in the Delta between October and May. Key habitat attributes relevant to seasonal operations in the Delta include out-migration cues and entrainment risk.

Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to adversely affect juvenile Chinook Salmon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, and 2) “far-field” mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team’s (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver-linkage-outcome (DLO) framework for specifying how water project operations (the “driver”) can influence juvenile salmonid behavior (the “linkage”) and potentially cause changes in survival or routing (the “outcome”). The SST concluded altered “Channel Velocity” and altered “Flow Direction” were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O.3-105 provides a simplified conceptual model of the DLO defined by the CAMT SST.

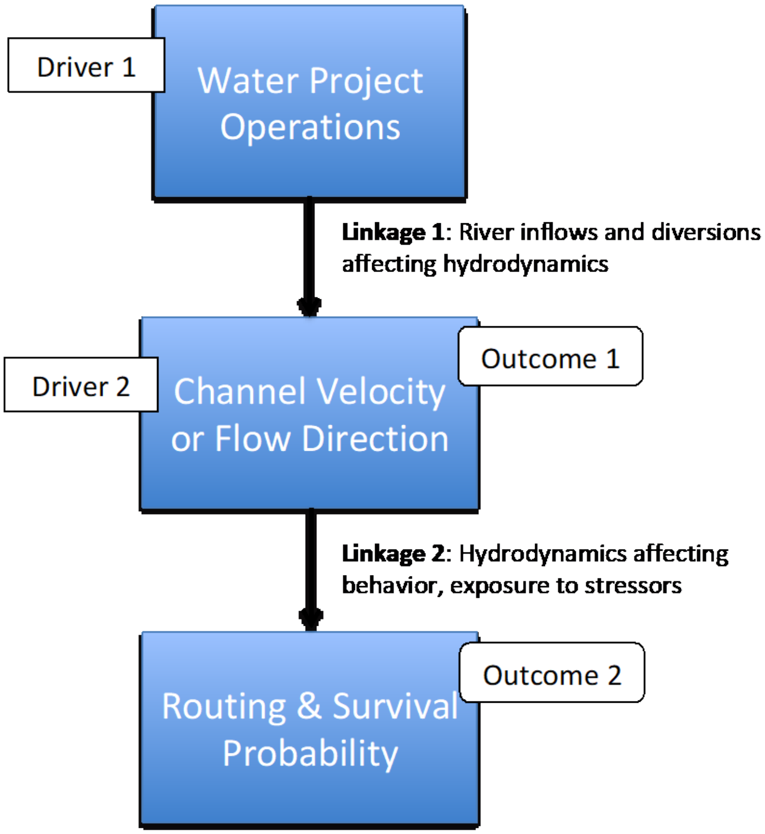

Figure O.3-105. Conceptual Model for Far-Field Effects of Water Project Operations on Juvenile Salmonids in the Delta. This CM is a Simplified Version of the Information Provided by the CAMT SST

To assess the potential for water project operations to influence survival and routing, Reclamation and DWR analyzed Delta hydrodynamic conditions by creating maps from DSM2 Hydro modeling. The maps are based on a comparative metric, proportion overlap (more below), to capture channel-level hydrodynamic details as a single number for color-scale mapping of Delta channels.

The objective of the comparative metric is to summarize the water velocity time series for each channel and scenario such the channel-level comparison is captured in a single number. For the proportion overlap metric, kernel density estimates are calculated on each time series. The kernel density estimates represent a non-parametric smoothing of the empirical distribution of time series values. The proportion overlap of two kernel density estimates is calculated with the following steps: 1) calculate the total area under the curve (AUC_t) as the sum of the AUC for each density estimate, 2) calculate the AUC of the overlapping portions (AUC_o) of the two density distributions being compared, and 3) calculate the overlapping proportion of the density distributions as AUC_o/AUC_t. Proportion overlap is naturally bound by zero and one; a value of zero indicates no overlap and a value of one indicates complete overlap. Lower values of proportion overlap identify channels demonstrating larger differences in a scenario comparison.

The proportion overlap metric is best applied over relatively short time periods because seasonal and annual variation in water velocity can overwhelm differences between scenarios. Thus, Reclamation calculated proportion overlap for every DSM2 channel for two seasons (December to Feburary and March to May) in each water year (1922–2003). DSM2 output was excluded from water year 1921 to allow for an extensive burn-in period. The proportion overlap was calculated based on hourly DSM2 output.

Because each season was roughly 90 days, each comparison involved roughly 4,300 DSM2 values (2 scenarios * 24 hours * 90 days) for each channel.

Because the proportion overlap was calculated for each channel in each water year, the proportion overlap values were summarized prior to mapping (i.e., not feasible to map proportion overlap for every comparison in every water year). To summarize, the minimum proportion overlap for each channel for each water year type for each comparison were found. The minimum values represent the maximum expected effect. Note that the year with the minimum proportion overlap for one channel might not be the same year as for another channel.

Entrainment

In the December through June period, the average total export rate, under Alternative 2, is higher than the export rate under No Action Alternative. Therefore, higher entrainment is expected compared to the No Action Alternative.

Zeug and Cavallo (2014) analyzed more than 1,000 release groups representing more than 28 million coded wire tagged juvenile fish including winter, late fall and Fall-Run Chinook Salmon. This data represents large release groups of tagged smolts where the number of fish representing each release group lost to entrainment at the export facilities has been estimated. Cavallo (2016) provided a supplemental assessment of Winter-Run Chinook Salmon entrainment risk (building upon Zeug and Cavallo 2014) that showed total CVP and SWP exports described entrainment risk better than OMR or other flow metrics. Entrainment loss results as reported below represents the proportion of coded wire tagged Winter-Run Chinook Salmon released upstream of the Delta which were entrained at South Delta export facilities. This proportion accounts for and includes expansion for sampling effort at the salvage facilities and also prescreen mortality. For December through February, Alternative 2 has an average total export rate greater than No Action Alternative (10,142 and 7,617 cfs respectively; Figure O1-1 in Appendix O, Attachment 1), and will therefore have greater entrainment risk. However, entrainment losses should average 0.8% and not exceed 2.2%. In the March through June period, total exports for Alternative 2 increase entrainment risk relative to No Action Alternative (6,851 vs. 4,164 cfs, respectively; Figure O1-2 in Appendix O, Attachment 1), but entrainment losses should average 0.4% and not exceed 1.6%.

Routing

Routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 2 were evaluated using DSM2. Juvenile Winter-Run Chinook Salmon are present in the Sacramento River at Sherwood Harbor upstream of the first distributary junctions between November and March with peak abundance in February and March (Reclamation 2019).

In the December to February period, velocity overlap between Alternative 2 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 89%, 83%, 68%, 71%, and 57% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-21 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 2 in below normal, above normal, and wet years and slightly lower in critically dry and dry years indicating routing into the interior Delta would be lower relative to No Action Alternative in normal and wet years and slightly higher relative to No Action Alternative in dry years (Perry et al. 2015; Figures O1-25 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 2 was more than

90%, 82%, 75%, 62%, and 86% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-22 in Appendix O, Attachment 1).

Abundance of juvenile Winter-Run Chinook Salmon at Chipps Island peaks in March and April but fish are collected between December and May (Reclamation 2019). During this time period, Winter-Run Chinook Salmon originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can potentially be exposed to hydrodynamic effects associated with the CVP and SWP that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 2 and the No Action Alternative (Figure in Appendix O, Attachment 1O1-23). Similar results were obtained when comparing Alternative 2 to the No Action Alternative in the March to May period (Reclamation 2019).

Through-Delta Survival

Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases.

To examine potential effects of Alternative 2, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, there are higher velocities under Alternative 2 than the No Action Alternative in wet, above normal, and below normal years. Velocities were lower in critically dry and dry years but overlap was high (>88%; Figure O1-25 in Appendix O, Attachment 1). At Steamboat Slough in the December through February period, there are higher velocities under Alternative 2 than the No Action Alternative in wet, above normal, and below normal years. Velocities were lower in critically dry and dry years but overlap was high (>90%; Figure O1-26). In the March through May period at Walnut Grove, when Alternative 2 was compared to the No Action Alternative, velocity overlap ranged from 80.2-92.8% with generally higher velocities under Alternative 2 (Figure O1-27 in Appendix O, Attachment 1). Velocity overlap at Steamboat Slough in the March through May period ranged from 84.2% to 94.6% with generally higher velocities under Alternative 2 (Figure O1-28 in Appendix O, Attachment 1).

Overall, Alternative 2 results in higher velocities in the Delta in the spring than under No Action Alternative, during the outmigrating juvenile time period. Survival probabilities are non-linear; however, the higher discharge at Freeport in the spring under Alternative 2 results in higher survival in the transition reaches. Higher flows also lead to lower probability of routing into the interior Delta, which has the lowest survival probability regardless of flow.

Potential changes to aquatic resources due to Delta Cross Channel operations

Under Alternative 2, the DCC may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Winter-Run Chinook Salmon in the Sacramento River at Sherwood Harbor, which is near the DCC, occurs from February through March (Reclamation 2019). Therefore, the DCC is closed for the majority of the juvenile Winter-Run Chinook Salmon migration period in the Sacramento River and as such the proportion of juvenile Winter-Run Chinook Salmon exposed to an open DCC would be negligible. Juvenile Chinook Salmon entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010; Perry et al. 2018).

Potential changes to aquatic resources due to the Temporary Barriers Project

Juvenile Winter-Run Chinook Salmon are not expected to co-occur in space or time with the agricultural barriers indicating no potential impacts.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 2 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a).

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory route for Winter-Run Chinook Salmon (NMFS 2017c), approximately 18 miles from the Sacramento River via the shortest route. Designated critical habitat for Winter-Run Chinook Salmon does not occur within Rock Slough, but is present further to the north in the Delta (NMFS 2017c, 2014). Salmonids are expected to avoid the area of the Rock Slough Intake during certain times of the year based on historical water temperatures.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Winter-Run Chinook Salmon presence near the Rock Slough Intake. Since 1994, fish monitoring has been conducted by CDFW and CCWD consistent with the separate biological opinions and permits that govern CCWD's operations. From 1994 through 1999, CDFW conducted fish monitoring at the Rock Slough Intake and in the Contra Costa Canal up to the first pumping plant. Over this 6-year period, CDFW captured a total of 13 juvenile Winter-Run Chinook Salmon from January through May (CDFG 2002c; NMFS 2017c). From 1999 to 2009, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected no juvenile or adult Winter-Run Chinook Salmon at the Rock Slough Headworks (Reclamation 2016; NMFS 2017c) and Contra Costa Canal Pumping Plant #1 (CCWD 2019).

Since construction of the RSFS, operation of the hydraulic rake cleaning system has been shown to trap and kill adult Chinook Salmon and other non-listed fish (Reclamation 2016). From 2011-2018, 47 Salmon were recovered at the RSFS (Reclamation 2016, Appendix A; Tenera Environmental 2018a), but none of the captured fish were identified as Winter-Run Chinook Salmon (NMFS 2017c).

NMFS issued a biological opinion in 2017 (NMFS 2017c) that considered improvements to the RSFS facility including the hydraulic rake cleaning system, operations and maintenance (O&M) of the RSFS and associated appurtenances, and administrative actions such as the transfer of O&M activities from Reclamation to CCWD. NMFS determined that the O&M of RSFS may result in the incidental take of juvenile Winter-Run Chinook Salmon and provided an incidental take limit based upon the number of listed fish collected in the pre and post-construction RSFS monitoring (NMFS 2017c). The incidental take provided in NMFS 2017c is five juvenile Winter-Run Chinook Salmon per year.

CCWD's Fish Monitoring Program also samples behind the fish screens at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Winter-Run Chinook Salmon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD’s operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD’s operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Winter-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Salmon can be “drawn” into the south Delta under reverse flows and high CVP and SWP pumping rates. One indicator of reverse flows is the net flow in Old and Middle Rivers (OMR). Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect OMR, and any effect that diversions at Rock Slough Intake would have in the Old and Middle River corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants.

However, diversions at the Rock Slough Intake could affect flows in the San Joaquin River at Jersey Point, which is approximately 14 river miles from the Rock Slough Intake (via the shortest route through Franks Tract). Mean velocity in a river channel can be calculated by dividing the flow rate by the cross-sectional area of the channel. The maximum effect of Rock Slough diversions on the channel velocity would be the maximum diversion rate (350 cfs) divided by the minimum cross-sectional area of the channel. This calculation assumes that all water diverted at Rock Slough comes from the San Joaquin River at Jersey Point, which is a conservative assumption (i.e., overestimates the effect on velocity). The cross-sectional area of the San Joaquin River at Jersey Point is approximately 60,500 square feet (sf), but varies depending on the tidal stage from approximately 56,000 sf (at low tide and low San Joaquin River flow) to 68,000 sf (at high tide and high San Joaquin River flow) as shown in Figure O.3-106.

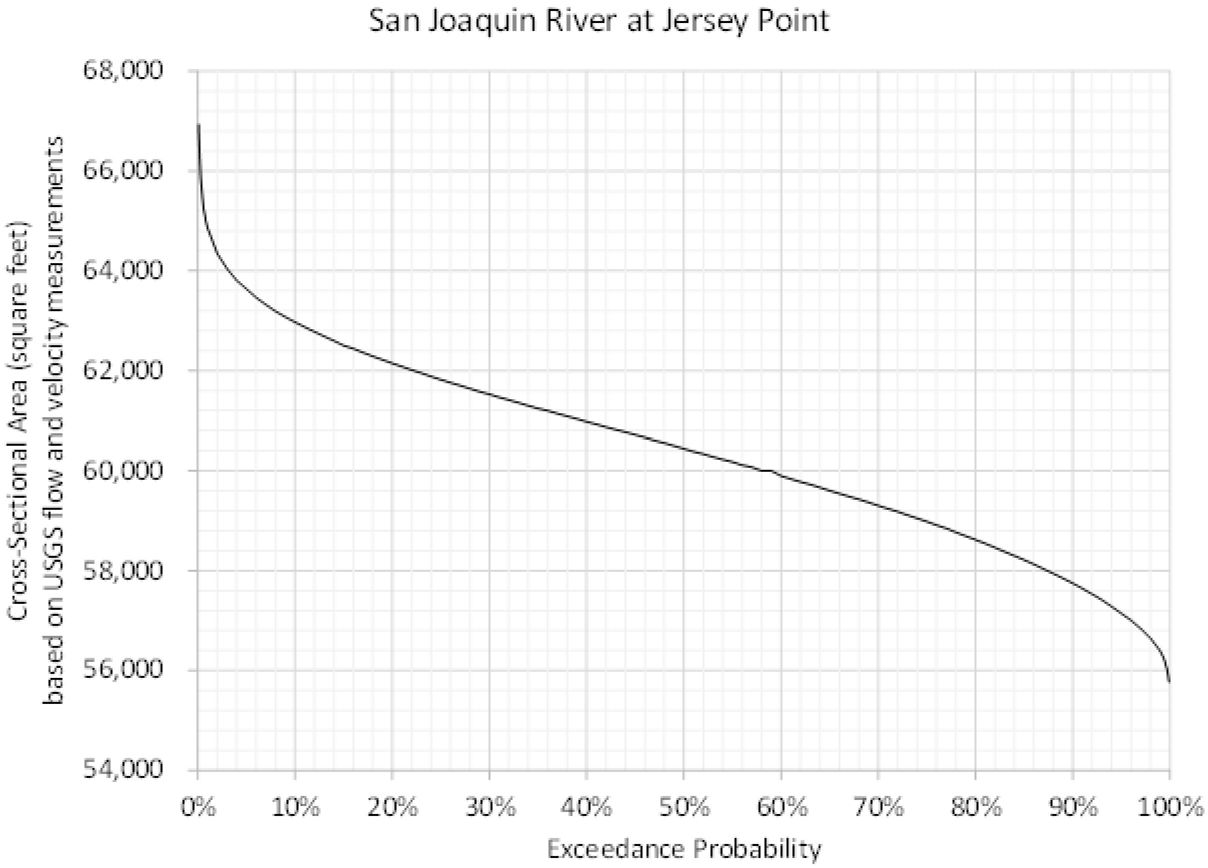

Figure O.3-106. Cross-sectional area of the San Joaquin River at Jersey Point (Station: 11337190) Calculated from USGS Measurements of Flow and Velocity every 15 Minutes for Water Years 2014 through 2018.

The maximum effect of water diversions at Rock Slough Intake on velocity in the San Joaquin River at Jersey Point is calculated as 350 cfs divided by 56,000 square feet; resulting in 0.00625 feet per second (ft/sec). For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from Rock Slough diversions. Furthermore, the actual effect is likely to be much lower than 0.00625 ft/sec because the water diverted at the Rock Slough Intake does not all come from the San Joaquin River west of Jersey Point.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, the combined effect of all three intakes is examined. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Winter-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant

particles such as phytoplankton. To examine the effect on neutrally buoyant particles, the distance that a particle would travel due to the maximum permitted Rock Slough diversions over the course of a day is calculated. A change in velocity of 0.00625 ft/sec could move a neutrally buoyant particle approximately 540 ft over the course of the day (0.00625 ft/sec * 86,400 sec/day). For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is not significant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 2 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources in North Bay Aqueduct operations

Alternative 2 includes the North Bay Aqueduct (NBA) intake in the North Delta and operation of the Barker Slough Pumping Plant. Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant (monitoring data is available at https://www.wildlife.ca.gov/Regions/3). There should be no discernable effect to the Winter-Run Chinook Salmon due to the operations of the Barker Slough Pumping Facility. This is due to the infrequent presence of Winter-Run Chinook Salmon in the monitoring surveys indicating a low risk of entrainment. Further, Barker Slough Pumping Facility fish screens are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment while greatly minimizing any impingement of fish against the screen.

Potential changes to aquatic resources due to water transfers

Under Alternative 2, Reclamation is extending the water transfer window until November, from the current July through September window. This extension could result in increased flows entering the Delta and increased pumping at Jones and Banks Pumping Plants.

Egg, alevin, and fry lifestages of Winter-Run Chinook Salmon do not occur in the Delta, and therefore would not be affected by this action. Winter-Run Chinook Salmon juveniles enter the Delta starting in December, and therefore would be unlikely to be exposed to increased pumping of water transfers through November. Adults returning from the ocean could possibly be in the Delta in July; however, they are strong swimmers, large fish that can avoid predators, and are unlikely to have impacts associated with direct entrainment of the pumping plants.

O.3.5.8.4 Central Valley Spring-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Reclamation and DWR propose to operate the C.W. Bill Jones Pumping Plant and the Harvey O. Banks Pumping Plant. These pumping plants affect the hydrodynamics of the south and central Delta resulting in effects to Spring-Run Chinook Salmon entrainment, routing and through Delta survival. Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to negatively impact juvenile Chinook Salmon in two distinct ways: 1) "near-field" mortality associated with entrainment to the export facilities, 2) "far-field" mortality resulting from altered hydrodynamics. See Winter-Run Chinook Salmon effects section for more detail concerning "far-field" and "near-field."

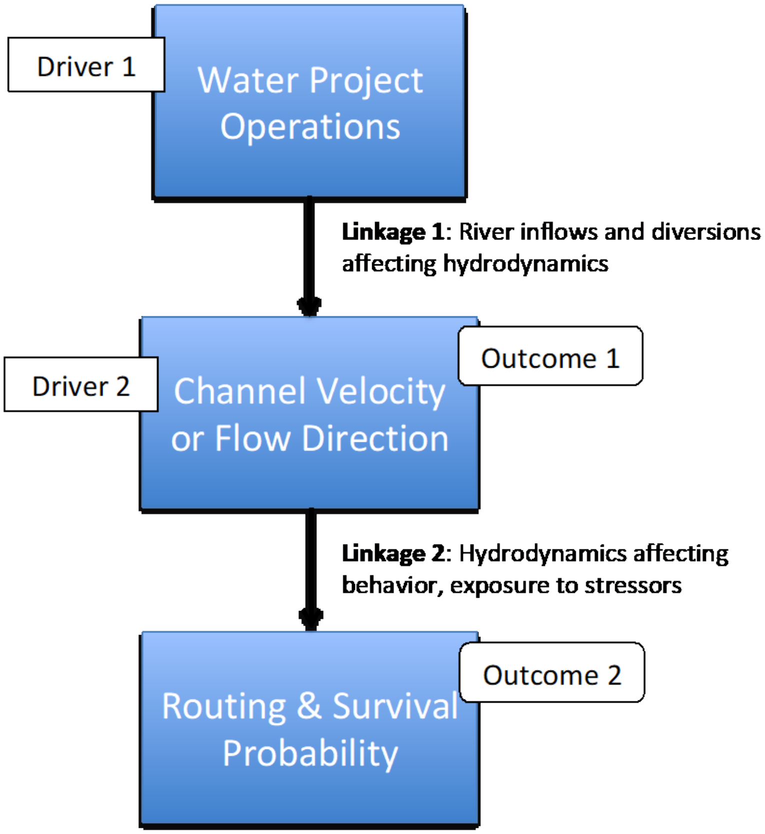

Figure O.3-107. Conceptual model for far-field effects of water project operations on juvenile salmonids in the Delta. This CM is a simplified version of the information provided by the CAMT SST.

Entrainment

Among 6.8 million tagged natural origin and 2.8 million tagged hatchery origin Spring-Run Chinook Salmon juveniles, entrainment loss averaged less than 0.0005% (Zeug and Cavallo 2014). Although data for juvenile Spring-Run Chinook Salmon originating from the San Joaquin River are limited, Zeug and Cavallo (2014) analyzed salvage of San Joaquin River-origin Fall-Run juvenile Chinook Salmon that are found in the Delta at a similar time as Spring-Run Chinook Salmon. Salvage of Fall-Run Chinook Salmon originating from the San Joaquin River averaged 1.4% and increased with export rate at the CVP and SWP (Zeug and Cavallo 2014). However, there were few observations at export rates greater than 3,000 cfs. Average mortality at the facilities represents < 5% total juvenile mortality for San Joaquin River-origin populations but can range as high as 17.5% (Zeug and Cavallo 2014).

In the December through February period, Alternative 2 proposes an average total export rate higher than No Action Alternative (2,525 cfs; Figure O1-1 in Appendix O, Attachment 1) and will, therefore, have a higher entrainment risk. Total exports proposed for Alternative 2 in March-June (2,687 cfs higher than No Action Alternative; Figure O1-2), when juvenile Spring-Run Chinook Salmon are most abundant in the Delta, will increase entrainment risk relative to No Action Alternative. Recent acoustic studies of juvenile Fall-Run Chinook Salmon in the San Joaquin River revealed that when the Head of Old River Barrier is out, >60% of fish detected at Chipps Island came through CVP, indicating that salvage is a higher survival route than volitional migration.

Routing

As stated in the Sacramento Winter-Run Chinook effects section, routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Juvenile Spring-Run Chinook Salmon are present in the Delta between November and early June with a peak in April (Reclamation 2019). In the December to February period, velocity overlap between Alternative 2 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 89%, 83%, 68%, 71%, and 57% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-21 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 2 in below normal, above normal, and wet years and slightly lower in critically dry and dry years indicating routing into the interior Delta would be lower relative to No Action Alternative in normal and wet years and slightly higher relative to No Action Alternative in dry years (Perry et al. 2015; Figures O1-25 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 2 was more than 90%, 82%, 75%, 62%, and 86% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-22 in Appendix O, Attachment 1).

Spring-Run Chinook Salmon originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can be exposed to hydrodynamic project effects that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 2 and both the No Action Alternative scenarios (Figure O1-23 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 2 to No Action Alternative in the March to May period (Figure O1-24 in Appendix O, Attachment 1).

Juvenile Spring-Run Chinook Salmon are present in the Delta between November and early June with a peak in April (Reclamation 2019). Early studies using coded wire tags indicated that survival of San Joaquin River-origin juvenile Chinook Salmon was lower in the Old River Route relative to the San Joaquin main stem (Newman 2008). This finding led to strategies designed to keep larger proportions of fish in the San Joaquin River main stem including the Head of Old River rock barrier and non-physical barriers. Recent studies using acoustic technology have indicated that differences in survival among the two routes are not significant (Buchanan et al. 2013; Buchanan et al. 2018). Thus, fish that enter Old River are unlikely to experience reduced survival.

Spring–run Chinook Salmon originating from the San Joaquin River that remain in the San Joaquin River main stem at the Head of Old River are exposed to additional junctions that lead into the interior Delta including; Turner Cut, Columbia Cut, Middle River, Old River, Fisherman's Cut and False River. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junctions with San Joaquin Rivers between Alternative 2 and No Action Alternative scenarios (Figure O1-23 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 2 to No Action Alternative in the March to May period (Figure O1-24 in Appendix O, Attachment 1).

In the December through February period, velocity overlap between Alternative 2 and No Action Alternative in the channel upstream of the Head of Old River was 95.1%, 84.0%, 57.3%, 67.7%, and 55.2% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-23 in Appendix O, Attachment 1). In the March to May period, velocity overlap was 84.0%, 62.7%, 61.6%, 65.2%, and 43.4% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-24 in Appendix O, Attachment 1).

Through-Delta Survival

To examine potential effects of Alternative 2, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this "transitional" region. During the December to February period at Walnut Grove, velocity distributions for Alternative 2 relative to No Action Alternative were most different in wet years (72.9%) with higher velocities in Alternative 2. Velocities were also greater for Alternative 2 relative to No Action Alternative in below normal and above normal years although overlap was greater (>76%; Figure O1-25 in Appendix O, Attachment 1). In critically dry and dry years, velocity distributions were more similar (>88%; Figure O1-25 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, there was a similar pattern where velocities under Alternative 2 were higher than No Action Alternative in wet, above normal, and below normal years and similar in dry and critically dry years (Figure O1-26 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 2 and No Action Alternative was >80% across all water year types with generally greater velocities under Alternative 2 (Figure O1-27 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 2 and No Action Alternative scenarios was high with all values ≥82% and generally greater velocities under Alternative 2 (Figure O1-28 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 2, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the "transitional" region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 2 relative to No Action Alternative exhibited high overlap in all water year types (≥81.9%; Figure O1-29 in Appendix O, Attachment 1). At the Head of Middle River during the December to February period, overlap was high between Alternative 2 and No Action Alternative in critically dry and dry water years (≥79%) and moderate in wet, above normal, and below normal years (66%; Figure O1-30 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 2 and No Action Alternative (≥80%; Figure O1-31 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-31). At the Head of Middle River in the March to May period, overlap between Alternative 2 and No Action Alternative was moderate in all water year types (41-65%) and higher in critically dry years >77% (Figure O1-32 in Appendix O, Attachment 1). Velocities were generally lower under Alternative 2 than No Action Alternative (Figure O1-32).

Potential changes to aquatic resources due to Delta Cross Channel operations

The Delta Cross Channel may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. Significant amounts of flow and many juvenile Spring-Run Chinook Salmon enter the DCC (when the gates are open) and Georgiana Slough, especially during increased Delta pumping. Mortality of juvenile Salmon entering the central Delta is higher than for those continuing downstream in the Sacramento River. Juvenile Chinook Salmon that are entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010) The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Spring-Run Chinook Salmon in the Sacramento River past Knights Landing, which is upstream of the DCC, occurs from March-April (Reclamation 2019). Therefore, the DCC is closed to protect the majority of the juvenile Spring-Run migration period in the Sacramento River and reduce the proportion of fish exposed to an open DCC.

Potential changes to aquatic resources due to the Temporary Barriers Project

The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30.

The proportion of juvenile Spring-Run Chinook Salmon exposed to the agricultural barriers (Temporary Barrier Program, TBP) depends on their annual timing of installation and removal. Due to their location, primarily migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Spring-Run Chinook Salmon in the Delta is March and April (Reclamation 2019). If the agricultural barriers are operating as early as April 15 then they have the potential to expose a large proportion of the juvenile Spring-Run Chinook Salmon migrating down the San Joaquin River. When the Head of Old River barrier is not in place, acoustically tagged juvenile Chinook Salmon have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). Flap gates tied up on agricultural barriers from May 16 to May 31 would help to reduce the negative effect of the barriers during this period. However, juveniles migrating before or after this period could be exposed to the agricultural barriers with flaps down which apparently decreases passage success and survival (DWR 2018).

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 2 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD's operations, including operation of the Rock Slough Intake, for Alternative 2 remain unchanged from the current operations.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory route for Central Valley Chinook Spring-Run (NMFS 2017c), approximately 18 miles from the Sacramento River and 10 miles from the San Joaquin River via the shortest routes. Designated critical habitat for Spring-Run Chinook Salmon does not occur within Rock Slough, but is present further to the north in the Delta (NMFS 2017c, 2014). Salmonids are expected to avoid the area of the Rock Slough Intake during certain times of the year based on historical water temperatures, which range from lows of about 45°F in winter (December and January) to over 70°F beginning in May and continuing to October (Reclamation 2016).

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Central Valley Spring-Run Chinook Salmon presence near the Rock Slough Intake. Since 1994, fish monitoring has been conducted by CDFW and CCWD consistent with the separate biological opinions and permits that govern CCWD's operations. From 1994 through 1999, CDFW conducted fish monitoring at the Rock Slough Intake and in the Contra Costa Canal up to the first pumping plant. Over this 6-year period, CDFW captured a total of 108 juvenile Central Valley Spring-Run Chinook Salmon from March through May (CDFG 2002c; NMFS 2017c). From 1999 to 2009, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected a total of 11 juvenile Central Valley Spring-Run Chinook Salmon from March through May at the Rock Slough Headworks (Reclamation 2016; NMFS 2017c) and 4 juvenile Central Valley Spring-Run Chinook Salmon at Pumping Plant #1 (CCWD 2019). No adult Spring-Run were collected in the vicinity of the Rock Slough Intake from 1994 through 2009 (CDFG 2002c; Reclamation 2016; NMFS 2017c). No juvenile or adult Central Valley Spring-Run Chinook Salmon have been collected in CCWD's Fish Monitoring Program at the Rock Slough Intake since 2008.

Since construction of the RSFS, operation of the hydraulic rake cleaning system has been shown to trap and kill adult Chinook Salmon and other non-listed fish (Reclamation 2016). From 2011-2018, 47 Salmon were recovered at the RSFS (Reclamation 2016, Appendix A; Tenera Environmental 2018a), but none of the captured fish were identified as Spring-Run Chinook Salmon (NMFS 2017c).

CCWD's Fish Monitoring Program also samples behind the fish screens at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Spring-Run Chinook Salmon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD's operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes (i.e., 10 miles from the San Joaquin River and 18 miles from the Sacramento River), juvenile Spring-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Spring-Run can be "drawn" into the south Delta under reverse flows and high CVP and SWP pumping rates.

One indicator of reverse flows is the net flow in OMR. Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect net reverse flow in OMR, and any effect that diversions at Rock Slough Intake would have in the OMR corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the OMR corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstem of the Sacramento River or the San Joaquin River and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run Chinook Salmon. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, we examine the combined effect of all three intakes. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Spring-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is insignificant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 2 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources in North Bay Aqueduct operations

Alternative 2 includes the North Bay Aqueduct (NBA) intake in the North Delta and operation of the Barker Slough Pumping Plant. Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant (monitoring data is available at https://www.wildlife.ca.gov/Regions/3)). The NBA is located within designated critical habitat for Spring-Run Chinook Salmon. There should be no discernable effect to the Spring-Run Chinook Salmon due to the operations of the Barker Slough Pumping Facility. This is due to the infrequent presence of Spring-Run Chinook Salmon in the monitoring surveys indicating a low risk of entrainment. Further, Barker Slough Pumping Facility fish screens are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment while greatly minimizing any impingement of fish against the screen.

Potential changes to aquatic resources due to water transfers

Under Alternative 2, Reclamation is expanding the transfer window to November from the current July to September. Expanding the transfer window could lead to increased pumping at Jones and Banks Pumping Plants, when capacity is available. The Figures below show when capacity is available under Alternative 1 and the No Action Alternative, in terms of exceedances, years in the model period of record, and average by water year types. These values are total available, and are not filtered for the pattern on which water might be acquired for transfer. The pattern of acquisition could decrease these values, as well as reoperation of storage that might be required, or the water cost of meeting D-1641. Prior estimates indicate that approximately 50% of the capacity in the figures below would be useful for water transfers given these timing and upstream considerations. In addition, a 20-30% surcharge on acquisition might be necessary to accommodate the salinity related inefficiencies that arise in operations. Based on the figures below and these additional estimates, expanding the water transfer window could result in an additional approximately 50 TAF of pumping in most yeartypes. As more stored water is available from CVP and SWP reservoirs to pump in wetter yeartypes, most of the available capacity for transfers is in drier yeartypes (Figures O.3-108 through O.3-110).

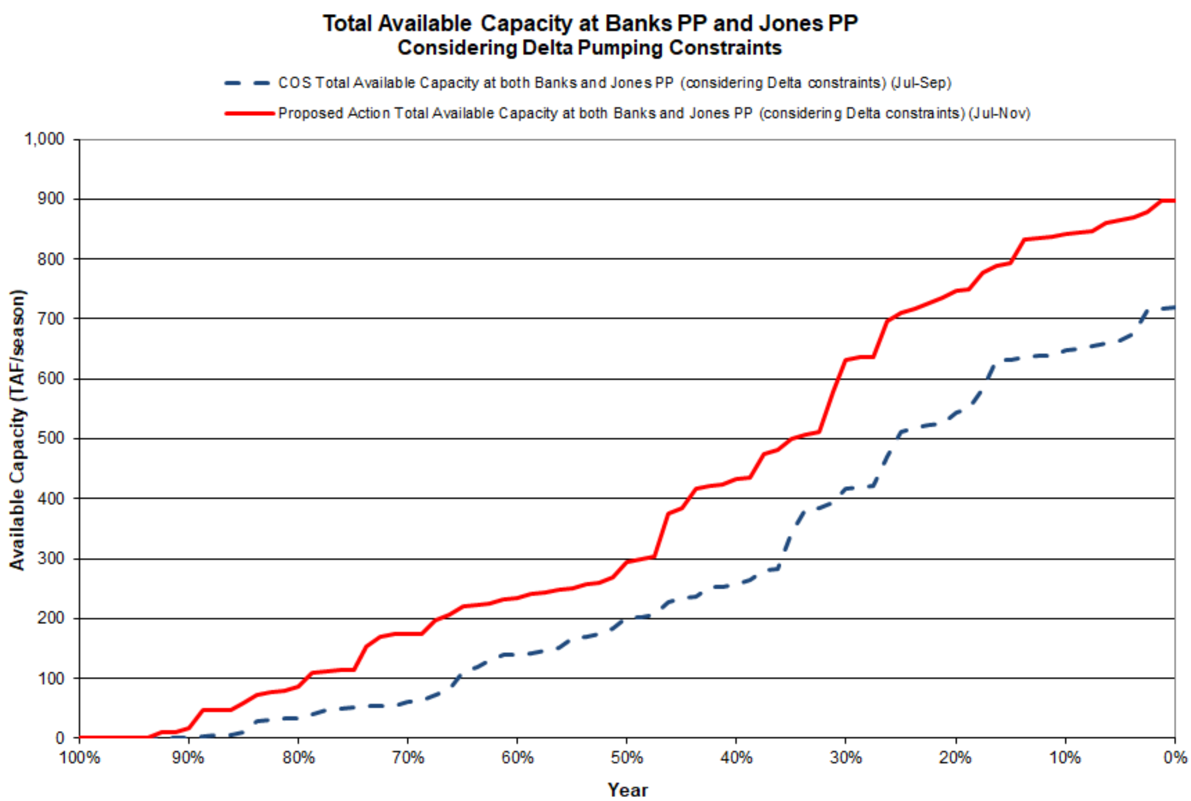

Figure O.3-108. Exceedance of Available Capacity for Transfers at Jones and Banks under the Alternative 1 and No Action Alternative

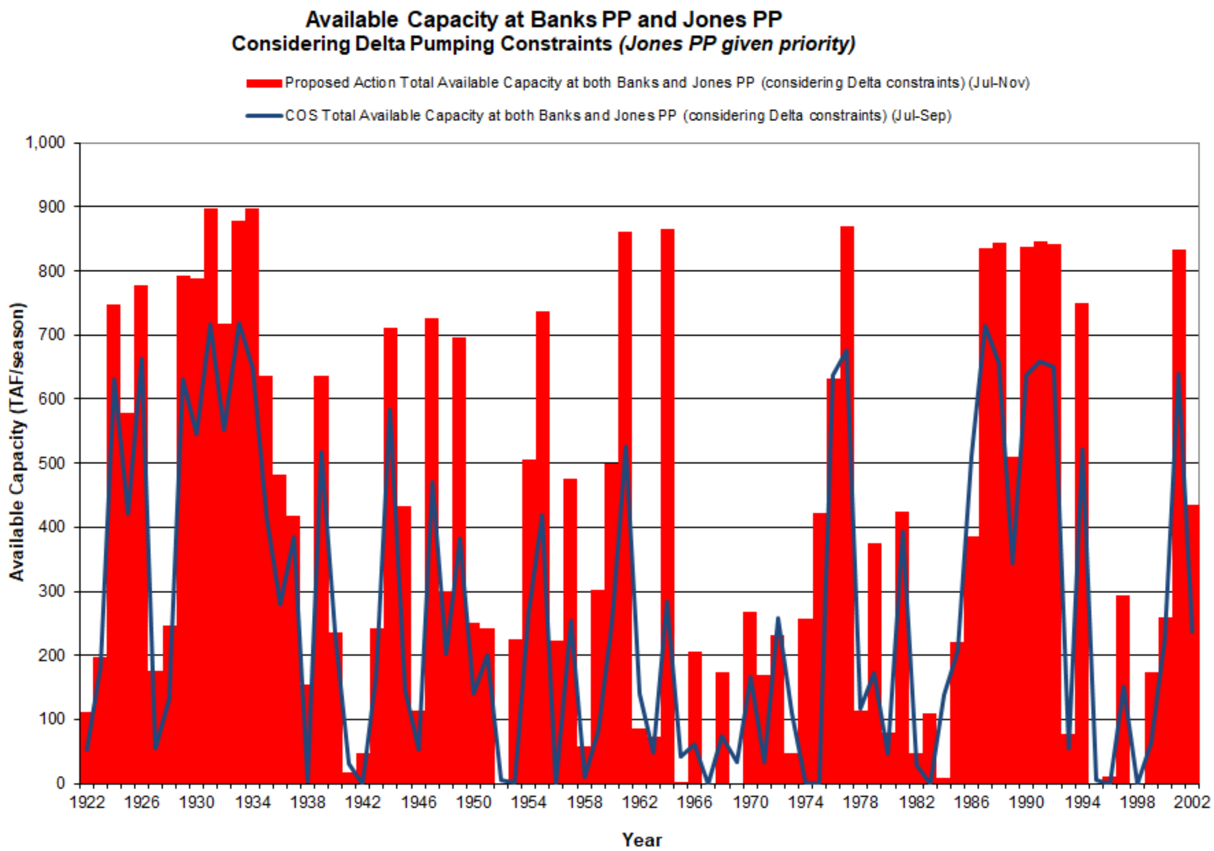

Figure O.3-109. Modeled annual maximum available capacity for transfers under Alternative 1 and No Action Alternative, CalSim period of record (1922–2003)

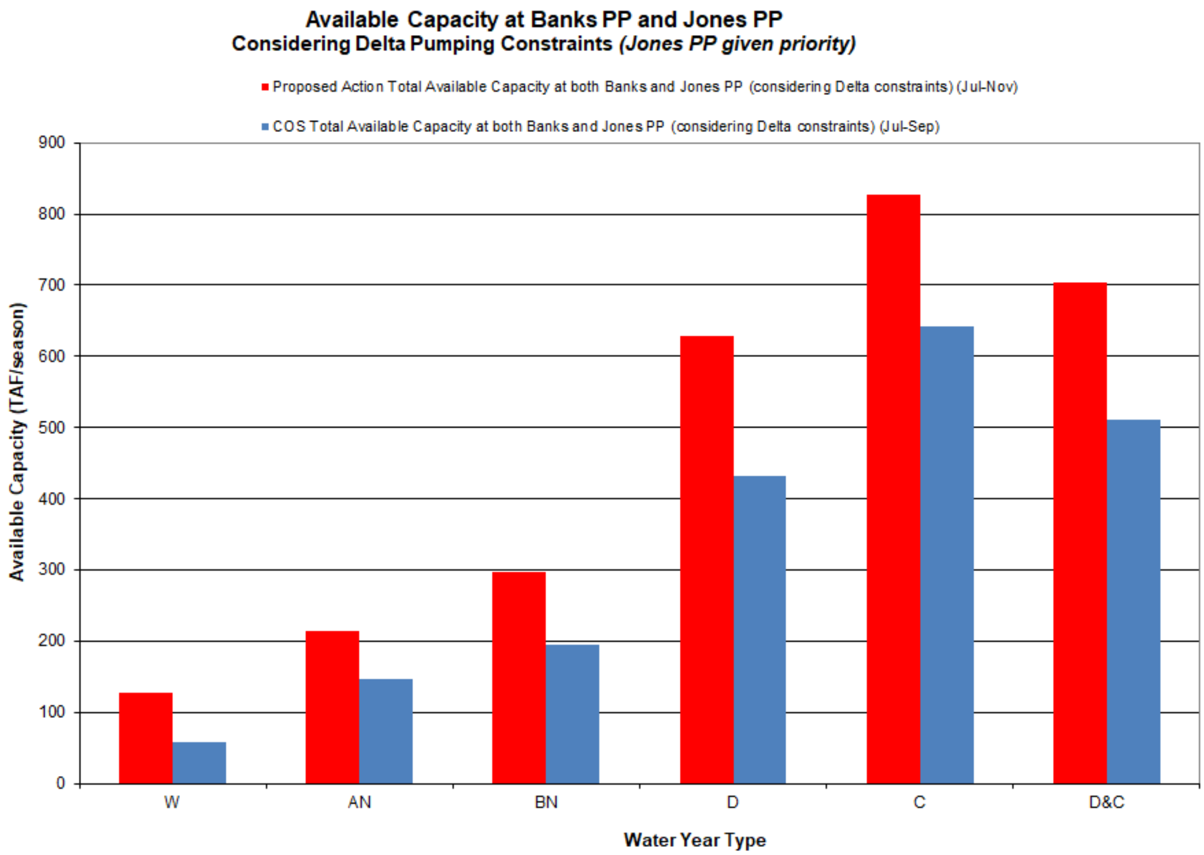

Figure O.3-10. Water Year Type average available capacity at Jones and Banks Pumping Plants

Egg, aelvin, fry, and adult lifestages of Spring-Run Chinook Salmon would not be exposed to the effects of increased water transfers as they do not occur in the Delta during July through November. Juvenile Central Valley Steelhead are detected at Chipps Island between December and July with the highest abundance in March to May (Reclamation 2019). Thus, only the very early or late migrants could potential be exposed to water transfers that occur during this time. These early or late migrant uvenile Spring-Run Chinook Salmon could be exposed to increased effects of entrainment, routing, and decreased Delta survival (see OMR management section) as a result of the expanded water transfer window. Increased flows during conveyance in the Sacramento River could provide small survival benefits to migrating juveniles (Perry et al. 2018).

O.3.5.8.5 Central Valley Fall-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Hydrodynamic changes associated with river inflows and South Delta exports have been hypothesized to adversely affect juvenile Chinook Salmon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, 2) “far-field” mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be most appropriately assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team's (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver- linkage-outcome (DLO) framework for specifying how water project operations (the "driver") can influence juvenile salmonid behavior (the "linkage") and potentially cause changes in survival or routing (the "outcome"). The SST concluded altered "Channel Velocity" and altered "Flow Direction" were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O.3-111 provides a simplified conceptual model of the DLO defined by the CAMT SST.

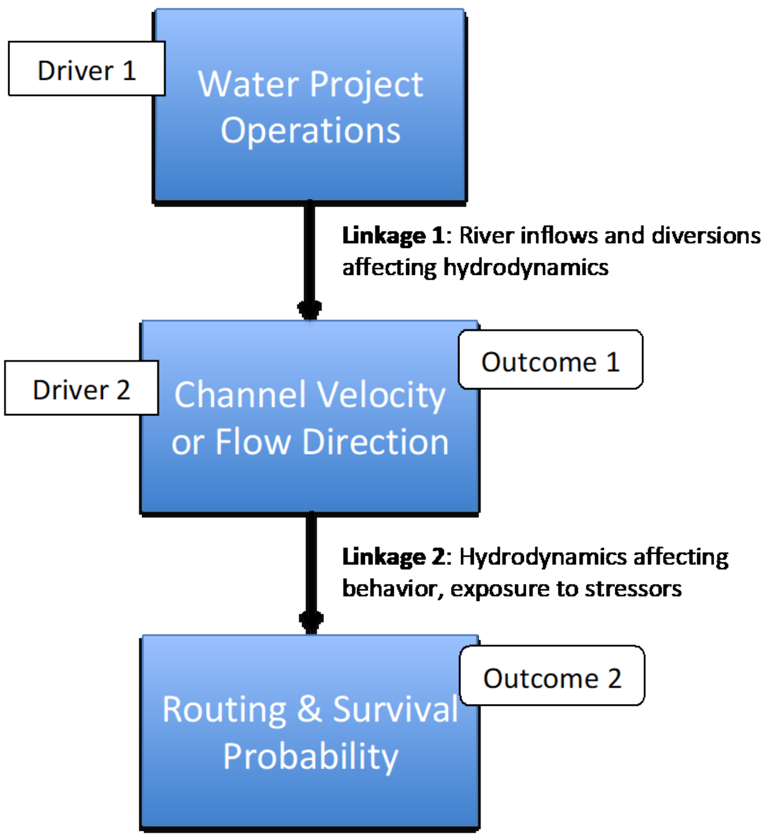

Figure O.3-111. Conceptual model for far-field effects of water project operations on juvenile salmonids in the Delta. This CM is a simplified version of the information provided by the CAMT SST.

Though many juvenile salmonid tagging studies have been conducted in the Delta, the focus has primarily been on estimating reach survival and routing- not assessing export-related hydrodynamic mechanisms defined by the SST's DLO. In fact, most tagging studies have targeted areas of the Delta where "Channel Velocity" and "Flow Direction" may not be appreciably affected by exports (e.g., Newman and Brandes 2010; Perry et al. 2010; Perry et al. 2012; Perry et al. 2015; Michel et al. 2013).

In order to assess the potential for water project operations to influence survival and routing, we analyzed Delta hydrodynamic conditions by utilizing outputs from DSM2 Hydro modeling. Our analysis of DSM2 output is based on our previous work creating map-based visualizations of spatial hydrodynamic patterns at the scale of the Delta. The map-based approach allows us to identify a 'footprint' of the hydrodynamic differences between scenarios. The maps are based on a comparative metric, proportion overlap (more below), to capture channel-level hydrodynamic details as a single number for color-scaled mapping of Delta channels. Our previous work made clear that spatial patterns were more easily discerned by mapping comparative metrics than by mapping descriptive metrics in multiple panels.

The objective of the comparative metric is to summarize the water velocity time series for each channel and scenario such the channel-level comparison is captured in a single number. For the proportion overlap metric, kernel density estimates are calculated on each time series. The kernel density estimates represent a non-parametric smoothing of the empirical distribution of time series values. The proportion overlap of two kernel density estimates is calculated with the following steps: 1) calculate the total area under the curve (AUC_t) as the sum of the AUC for each density estimate, 2) calculate the AUC of the overlapping portions (AUC_o) of the two density distributions being compared, and 3) calculate the overlapping proportion of the density distributions as AUC_o/AUC_t. Proportion overlap is naturally bound by zero and one; a value of zero indicates no overlap and a value of one indicates complete overlap. Lower values of proportion overlap identify channels demonstrating larger differences in a scenario comparison.

The proportion overlap metric is best applied over relatively short time periods because seasonal and annual variation in water velocity can overwhelm differences between scenarios. Thus, we calculated proportion overlap for every DSM2 channel for two seasons (Dec-Feb, May-Mar) in each water year (1922–2003). We excluded DSM2 output from water year 1921 to allow for an extensive burn-in period. We calculated proportion overlap based on hourly DSM2 output. Because each season was roughly 90 days, each comparison involved roughly 4,300 DSM2 values (2 scenarios * 24 hours * 90 days) for each channel.

Because we calculated proportion overlap for each channel in each water year, we summarized the proportion overlap values prior to mapping (i.e., not feasible to map proportion overlap for every comparison in every water year). To summarize, we found the minimum proportion overlap for each channel for each water year type for each comparison. The minimum values represent the maximum expected effect. Note that the year with the minimum proportion overlap for one channel might not be the same year as for another channel.

Entrainment

Zeug and Cavallo (2014) analyzed > 1000 release groups representing, more than 28 million coded wire tagged juvenile fish including winter, late fall and Fall-Run Chinook Salmon. This data is extremely useful because it represents large release groups of tagged smolts where the number of fish representing each release group lost to entrainment at the export facilities has been estimated. Estimating loss from “raw” salvage is problematic because the actual stock or basin of origin is often unknown (e.g., poor performance of length-at-date curves). Furthermore, with “raw” salvage, the number of smolts produced and potentially exposed to entrainment is unknown. The CWT salvage data analyzed by Zeug and Cavallo (2014) overcomes these deficiencies and provides the most appropriate basis for defining stock-specific categories of entrainment risk.

The average proportion Sacramento River-origin Fall-Run Chinook salvaged over a 15-year period was 0.0001 and the proportion of mortality accounted for by entrainment averaged 0.0003 (Zeug and Cavallo 2014). Salvage increased with increasing exports but loss never exceeded 1% regardless of export rate. Late Fall-Run Chinook Salmon juveniles were salvaged at a higher rate than any other race (0.02% of each release group) and entrainment related mortality accounted for almost 1% of total mortality on average (Zeug and Cavallo 2014). Proportional loss of Late-Fall remained low until exports exceeded ~9,000 cfs when proportional loss could approach 8% (Zeug and Cavallo 2014). In the December through February period when Late Fall-Run Chinook Salmon are most abundant, Alternative 2 proposes an average total export rate higher than No Action Alternative (2,525 cfs; Reclamation 2019) and will therefore have a higher entrainment risk. Total exports proposed for Alternative 2 in March-June (2,687 cfs higher than No Action Alternative; Figure O1-2) when juvenile Fall-Run are most abundant in the Delta, will increase entrainment risk relative to No Action Alternative, but entrainment losses for Fall-Run Chinook Salmon will be extremely low. Entrainment risk will also increase for Late Fall-Run Chinook Salmon and losses will likely be higher relative to Fall-Run.

Routing

Routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 1 were evaluated using DSM2 as described above. Juvenile Fall-Run Chinook Salmon abundance in the Delta is greatest between February and May and Late Fall-Run are present in the Delta between November and July with peaks in January through February and April through May (Reclamation 2019). In the December through February period, velocity overlap between Alternative 1 and No Action Alternative in the Sacramento River main stem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 89%, 83%, 68%, 71%, and 57% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-21 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 2 in below normal, above normal, and wet years and slightly lower in critically dry and dry years indicating routing into the interior Delta would be lower relative to No Action Alternative in normal and wet years and slightly higher relative to No Action Alternative in dry years (Perry et al. 2015; Figure O1-25 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 2 was more than 90%, 82%, 75%, 62%, and 86% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-22 in Appendix O, Attachment 1).

Fall-Run and Late Fall-Run Chinook Salmon juveniles originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can be exposed to hydrodynamic project effects that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 2 and the No Action Alternative (Figure O1-23 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 2 to the No Action Alternative in the March to May period (Figure O1-24 in Appendix O, Attachment 1).

Through-Delta Survival

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of the proposed project, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this "transitional" region. During the December to February period at Walnut Grove, velocity distributions for Alternative 2 relative to No Action Alternative were most different in wet years (72.9%) with higher velocities in Alternative 2. Velocities were also greater for Alternative 2 relative to No Action Alternative in below normal and above normal years although overlap was greater (>76%; Figure O1-25 in Appendix O, Attachment 1). In critically dry and dry years, velocity distributions were more similar (>88%; Figure O1-25 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, there was a similar pattern where velocities under Alternative 2 were higher than No Action Alternative in wet, above normal, and below normal years and similar in dry and critically dry years (Figure O1-26 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 2 and No Action Alternative was >80% across all water year types with generally greater velocities under Alternative 2 (Figure O1-27 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 2 and No Action Alternative scenarios was high with all values ≥82% and generally greater velocities under Alternative 2 (Figure O1-28 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 2, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the "transitional" region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 2 relative to No Action Alternative exhibited high overlap in all water year types (≥81.9%; Figure O1-29 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 2 and No Action Alternative in critically dry and dry water years (≥79%) and moderate in wet, above normal, and below normal years (66%; Figure O1-30 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 2 and No Action Alternative (≥80%; Figure O1-31 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-31 in Appendix O, Attachment 1). At the Head of Middle River in the March –May period, overlap between Alternative 2 and No Action Alternative was moderate in all water year types (41–65%) and higher in critically dry years >77% (Figure O1-32 in Appendix O, Attachment 1). Velocities were generally lower under Alternative 2 than No Action Alternative (Figure O1-32 in Appendix O, Attachment 1).

Potential changes to aquatic resources due to Delta Cross Channel operations

The Delta Cross Channel may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Fall-Run Chinook Salmon in the Sacramento River past West Sacramento, which is near the DCC, occurs from February through May (Reclamation 2019). Therefore, the DCC is closed for the majority of the juvenile Fall-Run Chinook Salmon migration period in the Sacramento River and as such the proportion of fish exposed to an open DCC would be low. Juvenile Fall-Run that are entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010).

Potential changes to aquatic resources due to the Temporary Barriers Project

The Temporary Barriers Project (TBP) consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions and one rock barrier to improve San Joaquin River salmonid migration in the south Delta. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, Grant Line Canal near Tracy Boulevard Bridge, and the head of Old River. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30. The head of Old River Barrier is only installed from September 16 to November 30 to improve flow and dissolved oxygenconditions in the San Joaquin River for the immigration of adult Fall-Run Chinook Salmon.

The proportion of juvenile Fall-Run Chinook Salmon exposed to the TBP depends on their annual timing of installation and removal. Due to their location, primarily migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Fall-Run Chinook Salmon in the Delta at Mossdale is February through May (Reclamation 2019). The Head of Old River Barrier would have no effect on juvenile Fall-Run Chinook Salmon if installed from September 16 to November 30 as juvenile Fall-Run Chinook Salmon are largely absent from this section of the San Joaquin River during this time period (Reclamation 2019). If the agricultural barriers are operating as early as April 15 then they have the potential to expose a large proportion of the juvenile Fall-Run migrating down the San Joaquin River. When the Head of Old River barrier is not in place, acoustically tagged juvenile Chinook Salmon have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). Flap gates tied up on agricultural barriers from May 16 to May 31 would help to reduce the negative effect of the barriers during this period. However, juveniles migrating before or after this period could be exposed to the agricultural barriers with flaps down which apparently decreases passage success and survival (DWR 2018). Therefore, the potential negative effects of the agricultural barriers depends on when they are installed and whether the flap gates are down or tied up but overall would be medium to high.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD’s operations in Alternative 2 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD’s operations, including operation of the Rock Slough Intake, under Alternative 2 would remain unchanged from the current operations.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Fall-Run/Late Fall-Run Chinook Salmon presence near the Rock Slough Intake. From 1999 to 2011, the 11 years prior to construction of the RSFS, CCWD’s Fish Monitoring Program collected 23 juvenile Fall-Run/Late Fall-Run Chinook Salmon at the Rock Slough Headworks and Contra Costa Pumping Plant #1. Since construction of the Rock Slough Fish Screen in 2012, no Fall-Run/Late Fall-Run Chinook Salmon have been collected behind the fish screen. CCWD’s Fish Monitoring Program also samples at CCWD’s other south Delta intakes. Since the intakes have been in operation, CCWD’s Fish Monitoring Program has never collected Fall-Run/Late Fall-Run Chinook Salmon at CCWD’s Old River Intake or Middle River Intake (CCWD 2019).

CCWD’s operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD’s operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD’s operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Central Valley Fall-Run/Late Fall-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Salmon can be "drawn" into the south Delta under reverse flows and high CVP and SWP pumping rates.

One indicator of reverse flows is the net flow in Old and Middle Rivers (OMR). Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect net reverse flow in Old and Middle Rivers (OMR), and any effect that diversions at Rock Slough Intake would have in the Old and Middle River corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the Old and Middle River corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstems of the Sacramento River or the San Joaquin River and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, we examine the combined effect of all three intakes. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Central Valley Fall-Run/Late Fall-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is not significant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 2 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources in North Bay Aqueduct operations

Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant, however several years of monitoring have failed to consistently capture any salmonids during the winter Delta Smelt surveys (1996 to 2004) in Lindsey Slough or Barker Slough. Captures of Chinook Salmon have usually occurred in the months of February and March and typically are only a single fish per net haul (http://www.delta.dfg.ca.goc/data/nba). Most Chinook Salmon captured have come from Miner Slough, which is a direct distributary from the Sacramento River via Steamboat and Sutter Sloughs. Few if any San Joaquin River-origin Fall-Run Chinook Salmon are expected to be exposed to the North Bay aqueduct because it is not on the migration route of this species.

O.3.5.8.6 Central Valley Steelhead

Potential changes to aquatic resources due to seasonal operations

Entrainment

ICF (2018) analyzed salvage of Central Valley Steelhead at the CVP and SWP between 2003 and 2017 and found that salvage increased with export rate and decreased with San Joaquin River flow. Salvage also decreased with OMR flow. However, OMR is a metric comprised of both exports and San Joaquin River flow which complicates attempts to understand individual effects.

In the December through February period, Alternative 2 proposes an average total export rate slightly higher than the No Action Alternative (2,525 cfs; Figure O1-1 in Appendix O, Attachment 1) and will therefore have higher entrainment risk. Total exports proposed for Alternative 2 in March-June (2,687 cfs higher than No Action Alternative; Figure O1-2 in Appendix O, Attachment 1) when juvenile Central Valley Steelhead are most abundant in the Delta at Chipps Island (Reclamation 2019), will increase entrainment risk relative to No Action Alternative.

Routing

Routing of juvenile Central Valley Steelhead into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 2 were evaluated using DSM2. Juvenile Central Valley Steelhead are present in the Sacramento River at Hood upstream of the first distributary junctions between November and early June with peak abundance from February to early June (Reclamation 2019). In the December to February period, velocity overlap between Alternative 2 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 89%, 83%, 68%, 71%, and 57% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-21 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 2 in below normal, above normal, and wet years and slightly lower in critically dry and dry years indicating routing into the interior Delta would be lower relative to No Action Alternative in normal and wet years and slightly higher relative to No Action Alternative in dry years (Perry et al. 2015; Figure O1-25 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 2 was more than 90%, 82%, 75%, 62%, and 86% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-22).

Through-Delta Survival

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 2, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, velocity distributions for Alternative 2 relative to No Action Alternative were most different in wet years (72.9%) with higher velocities in Alternative 2. Velocities were also greater for Alternative 2 relative to No Action Alternative in below normal and above normal years although overlap was greater (>76%; Figure O1-25 in Appendix O, Attachment 1). In critically dry and dry years, velocity distributions were more similar (>88%; Figure O1-25 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, there was a similar pattern where velocities under Alternative 2 were higher than No Action Alternative in wet, above normal, and below normal years and similar in dry and critically dry years (Figure O1-26 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 2 and No Action Alternative was >80% across all water year types with generally greater velocities under Alternative 2 (Figure O1-27 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 2 and No Action Alternative scenarios was high with all values ≥82% and generally greater velocities under Alternative 2 (Figure O1-28 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 1, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the “transitional” region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 2 relative to No Action Alternative exhibited high overlap in all water year types (≥81.9%; Figure O1-29 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 2 and No Action Alternative in critically dry and dry water years (≥79%) and moderate in wet, above normal, and below normal years (66%; Figure O1-30 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 2 and No Action Alternative (≥80%; Figure O1-31 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-31 in Appendix O, Attachment 1). At the Head of Middle River in the March –May period, overlap between Alternative 2 and No Action Alternative was moderate in all water year types (41-65%) and higher in critically dry years >77% (Figure O1-32 in Appendix O, Attachment 1). Velocities were generally lower under Alternative 2 than No Action Alternative (Figure O1-32 in Appendix O, Attachment 1).

Potential changes to aquatic resources due to Delta Cross Channel operations

Significant flow and many juvenile Central Valley Steelhead enter the central Delta when the DCC gates are open. Mortality of juvenile Central Valley Steelhead entering the central Delta is higher than for those continuing downstream in the Sacramento River. The peak migration of juvenile Central Valley Steelhead in the Sacramento River past Knights Landing, which is upstream of the DCC, occurs from January through February (Reclamation 2019). Therefore under Alternative 2, the continued operation of the DCC to protect the majority of the juvenile Central Valley Steelhead during their migration period in the

Sacramento River would reduce the proportion of fish exposed to an open DCC and result in beneficial impacts to this life stage when compared to the No Action Alternative.

Potential changes to aquatic resources due to the Temporary Barriers Project

The Temporary Barriers Project (TBP) consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions and one rock barrier to improve San Joaquin River salmonid migration in the south Delta. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, Grant Line Canal near Tracy Boulevard Bridge, and the head of Old River. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30. The Head of Old River Barrier is only installed from September 16 to November 30 to improve flow and dissolved oxygenconditions in the San Joaquin River for the immigration of adult Fall-Run Chinook Salmon.

The proportion of juvenile Central Valley Steelhead exposed to the TBP depends on their annual timing of installation and removal. Due to their location, primarily juvenile Central Valley Steelhead migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Central Valley Steelhead in the San Joaquin River in the vicinity of the TBP (Mossdale) occurs in April and May (Reclamation 2019). If the agricultural barriers are operating as early as April 15, there is potential exposure to a large proportion of the juvenile Central Valley Steelhead migrating down the San Joaquin River.

When the Head of Old River barrier is not in place, acoustically tagged juvenile Central Valley Steelhead have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Central Valley Steelhead migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Central Valley Steelhead passage past the agricultural barrier was improved (DWR 2018). Therefore, although Alternative 2 does not include HORB, which could result in negative impacts to Central Valley Steelhead juvenile migration, the improvements to the agricultural barriers (including flap gates tied up from May 16 to May 31) would help to reduce the negative effect of the barriers on migrating juvenile Central Valley Steelhead during this period relative to No Action Alternative. However, juvenile Central Valley Steelhead migrating before or after this period could be exposed to the agricultural barriers with flaps down, which apparently decreases passage success and survival (DWR 2018). Therefore, the potential negative effects of the agricultural barriers under Alternative 1 on juvenile Central Valley Steelhead depends on when they are installed and whether or not the flap gates are down.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD’s operations in Alternative 2 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD’s operations, including operation of the Rock Slough Intake, under Alternative 2 would remain unchanged from the current operations.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of presence near the Rock Slough Intake. From 1999 to 2011, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected 15 juvenile Central Valley Steelhead at the Rock Slough Headworks and Pumping Plant #1. Since construction of the Rock Slough Fish Screen, no Central Valley Steelhead have been collected behind the fish screen. CCWD's Fish Monitoring Program also samples at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Central Valley Steelhead at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD's operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Central Valley Steelhead are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile salmonids can be "drawn" into the south Delta under reverse flows and high CVP and SWP pumping rates. One indicator of reverse flows is the net flow in OMR. Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect OMR, and any effect that diversions at Rock Slough Intake under Alternative 2 would have in the OMR corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the Old and Middle River corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstems of the Sacramento or San Joaquin Rivers and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, the combined effect of all three intakes was examined. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Central Valley Steelhead.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is insignificant in comparison to the tidal excursion and mixing at this location. Although the diversions at Rock Slough Intake are not likely to impact juvenile Central Valley Steelhead, the aggregate effect of all water diversions in the Delta, including exports at Jones and Banks Pumping Plants can affect channel velocity.

In summary, CCWD's operations under Alternative 2 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is neglibible.

Potential changes to aquatic resources in North Bay Aqueduct operations

Under Alternative 2, there would be no changes to operational criteria at the NBA's BSPP relative to current operations. Juvenile Central Valley Steelhead could occur in the vicinity of the BSPP; however, the fish screens used at the facility are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment and greatly minimize impingement of fish against the screen itself (NMFS 2009). In addition, the location of the facility is well off the typical migration corridor of juvenile Central Valley Steelhead (NMFS 2009: 417). No juvenile Central Valley Steelhead have been captured during CDFW monitoring surveys from 1996 to 2004 (https://www.wildlife.ca.gov/Conservation/Delta/North-Bay-Aqueduct).

Potential changes to aquatic resources due to water transfers

Central Valley Steelhead juveniles could be exposed to increased entrainment, predation, and decreased through-Delta survival as a result of the expanded transfer window under Alternative 2, but as the peak of the juvenile out-migration is in the spring, effects are anticipated to be minimal. No other lifestages of Central Valley Steelhead would co-occur in time and space with water transfers from the Delta.

O.3.5.8.7 North American Green Sturgeon Southern DPS

Potential changes to aquatic resources due to seasonal operations

Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to negatively impact southern DPS Green Sturgeon in two distinct ways: 1) "near-field" mortality associated with entrainment to the export facilities, 2) "far-field" mortality resulting from altered hydrodynamics. The SST completed a thorough review of this subject and defined a driver- linkage-outcome (DLO) framework for specifying how water project operations (the "driver") can influence juvenile salmonid behavior (the "linkage") and potentially cause changes in survival or routing (the "outcome"). A similar analysis is not available for southern DPS Green Sturgeon.

Entrainment

As described by NMFS (2009: 386), impacts to the migratory corridor function of juvenile and subadult Green Sturgeon critical habitat from south Delta exports are less clear than for juvenile salmonids because Green Sturgeon spend 1 to 3 years rearing in the Delta environment before transitioning to their marine life history stage. During this Delta rearing phase, Green Sturgeon are free to migrate throughout the Delta. In the conceptual model, it is hypothesized that higher rates of exports may result in higher rates of entrainment. However, estimating entrainment risk from raw salvage data is not possible due to a lack of information on the number of juvenile Green Sturgeon potentially exposed to salvage.

Juvenile southern DPS Green Sturgeon (> 5 mo) are present in the Delta all year and subadults are most abundant from June through November. In the June through September period under Alternative 2 Reclamation proposes an average total export rate slightly higher than No Action Alternative (546 cfs; Figure O1-15 in Appendix O, Attachment 1) and are unlikely to measurably increase entrainment risk. Total exports proposed for Alternative 2 in September-November (969 cfs higher than No Action Alternative; Figure O1-16 in Appendix O, Attachment 1) are unlikely to measurably increase entrainment risk relative to No Action Alternative.

Juvenile White and Green Sturgeon are infrequent at the TFCF, but may occur in the facility salvage year-round. Salvage is expected to be similar and slightly higher than No Action Alternative under Alternative 2.

Routing

Juvenile Green Sturgeon (>5 mo) are present in the Delta all year and subadults are most abundant from June to November (Reclamation 2019). Juvenile Green Sturgeon swim and behave quite differently and have distinct body morphologies and habitat associations in the Delta compared to outmigrating salmonids, so it is hypothesized that juvenile Green Sturgeon have different routing-hydrology survival relationships. Per NMFS (2009: 338), Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways. It is highly uncertain how Green Sturgeon routing would change with Alternative 2.

Through-Delta Survival

Little is known about the relationship between survival of juvenile Green Sturgeon and Delta hydrology. Green Sturgeon reside in the Delta for 1 to 3 years suggesting they encounter a variety of daily, seasonal, and annual hydrological conditions. The majority of Green Sturgeon in the Delta are likely not surviving through the Delta per se, but using these habitats for rearing and foraging. Per NMFS (2009: 338), Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways. For juvenile outmigrating Green Sturgeon present in these regions, increasing negative velocities under Alternative 2 may result in lower survival. However, as described above, there is a lower probability of juvenile Green Sturgeon residing in this area.

Potential changes to aquatic resources due to Delta Cross Channel operations

Delta Cross Channel operations under Alternative 2 are changed to allow Reclamation to predict water quality exceedances and open the DCC if D-1641 criteria are predicted to be exceeded. This results in greater opening times of the DCC.

Little is known about the migratory behavior of juvenile Green Sturgeon in the Sacramento River basin. It is likely that juvenile Green Sturgeon (larger than the 75 mm) will not enter the Delta prior to their first winter and thus would not be exposed to the open DCC gates. If juvenile Green Sturgeon are exposed to the open DCC gates, they could be entrained into the central / south Delta and exposed to biological and physical conditions in this area, including potentially greater predation. It is likely that these fish will enter the Delta sometime in the winter or spring following their hatching upriver and encounter both types of gate configurations as they enter the Delta.

Potential changes to aquatic resources due to the Temporary Barriers Project

Agricultural Barriers (Temporary Barrier Project, TBP) are included in Alternative 2 and consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, and Grant Line Canal near Tracy Boulevard Bridge. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30.

Juvenile Green Sturgeon are present in the Delta in all months of the year. However, little is known about their spatial distribution. When the south Delta agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up (May 16 to May 31), outmigrating Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). It could be inferred that passage of outmigrating juvenile Green Sturgeon may also be improved when flap gates are tied up. Therefore, the potential negative effects of the agricultural barriers under Alternative 2 depends on when they are installed and whether the flap gates are down or tied up.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD’s operations in Alternative 2 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD operations, including operation of the Rock Slough Intake, for Alternative 2 remain unchanged from current conditions and the No Action Alternative.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory routes for southern DPS Green Sturgeon (NMFS 2017c), approximately 18 miles from the Sacramento River and 10 miles from the San Joaquin River via the shortest routes. Water temperatures in Rock Slough range from lows of about 40 degrees F in winter (December and January) to over 70 degrees F beginning in May and continuing through October (NMFS 2017c).

A review of the 24 years of fish monitoring data (1994–2018) near the Rock Slough Intake both pre- and post-construction of the Rock Slough Fish Screen (RSFS) showed that southern DPS Green Sturgeon have never been observed in Rock Slough (CDFG 2002c; Reclamation 2016; NMFS 2017c; Tenera Environmental 2018b, ICF 2018). CCWD’s Fish Monitoring Program also samples at CCWD’s other south Delta intakes. Since the intakes have been in operation, CCWD’s Fish Monitoring Program has never observed southern DPS Green Sturgeon at CCWD’s Old River Intake or Middle River Intake (CCWD 2019).

It is unlikely that juvenile, subadult, or adult Green Sturgeon would be present in Rock Slough due to the shallow depth, warm water temperatures, and low dissolved oxygenwhich make the area unsuitable habitat during most of the year. Therefore, it is unlikely that Green Sturgeon will be entrained at Rock Slough Intake and unlikely that Green Sturgeon would be impacted by CCWD operations.

Potential changes to aquatic resources in North Bay Aqueduct operations

Overall, the modeled exports in Alternative 2 represent a significant increase in export levels and, thus, a greater risk to Green Sturgeon in the waters adjacent to the pumping facility compared to their historical vulnerability (NOAA 2009). However, Green Sturgeon are expected to be fully screened out of the facilities by the positive barrier fish screen in place at the pumping facility.

Potential changes to aquatic resources due to water transfers

As discussed under the Spring-Run Chinook Salmon water transfer section, under Alternative 2 Reclamation proposes to expand the transfer window to November. This extended transfer window could result in approximately 50 TAF of additional pumping per year in most years, with associated entrainment, routing, and through-Delta survival impacts. Please see the OMR management section for a discussion of the effects of pumping.

Juveniles older than 5 months, subadults, and adult Green Sturgeon could be exposed to the effects of increased pumping due to water transfers. Although southern DPS Green Sturgeon are present in the Delta in all months of the year, Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways (NMFS 2009:338). Therefore, there are no negative impacts of increased pumping at Jones and Banks Pumping Plants due to water transfers under Alternative 2.

Juvenile southern DPS Green Sturgeon are present in the Delta in every month of the year (Reclamation 2019). Thus, some portion of the population would be exposed to this action. Increases in Delta inflow during water transfers may have benefits for juvenile Green Sturgeon. However, there is no information on relationships between flow and juvenile Green Sturgeon ecology.

O.3.5.9 *Nearshore Pacific Ocean on the California Coast*

Southern Resident Killer Whale

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

Under Alternative 2, water operations would not include many of the criteria currently in place as part of the NMFS (2009) SWP/CVP BO's RPA. Potential effects to Chinook Salmon, which as described in Section O.3.2.9, *Nearshore Pacific Ocean of the California Coast*, are important prey to Southern Resident Killer Whale, are analyzed above in Sections O.3.4.1.1 *Trinity River*, O.3.4.1.2 *Sacramento River*, O.3.4.1.3 *Clear Creek*, O.3.4.1.4 *Feather River*, O.3.4.1.5 *American River*, O.3.4.1.6 *Stanislaus River*, O.3.4.1.7 *San Joaquin River*, and O.3.4.1.8 *Bay Delta*. Given the NMFS (2009) BO's conclusion that the RPA would avoid jeopardy by not being likely to result in local depletion of Southern Resident Killer Whale prey (NMFS 2009, p.718), Alternative 2 may result in potential negative effects to Central Valley Chinook Salmon stocks and therefore Southern Resident Killer Whale, relative to the No Action Alternative. There is some uncertainty in this conclusion given that effects are potentially limited by the medium importance of Central Valley Chinook Salmon stocks to Southern Resident Killer Whale diet and the relatively high representation of hatchery-origin juvenile Chinook Salmon, many of which are released downstream of the Delta (Reclamation 2019).

O.3.6 Alternative 2 – Program-Level Effects

O.3.6.1 *Sacramento River*

Potential changes to aquatic resources from Battle Creek restoration

Acceleration of the Battle Creek restoration program will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from lower intakes near Wilkins Slough

Lowering intakes of diversions near Wilkins Slough will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources due to Shasta TCD Improvements

Improvement of the Shasta TCD will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from operation of the Livingston-Stone National Fish hatchery (Winter-Run Chinook Salmon)

Increased production of Winter-Run Chinook Salmon at the Livingston-Stone National Fish Hatchery will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from small screen program installation

Increased installation and improvements to screens on small diversions in the Sacramento River will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from spawning habitat restoration

Increased spawning habitat restoration will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from rearing habitat restoration

Increased rearing habitat restoration will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources due to adult rescue activities

Additional adult rescue (beyond what CDFW is currently doing, as noted for Alternative 1) will not occur under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 and the No Action Alternative are likely to have similar effects on aquatic resources.

Potential changes to aquatic resources due to trap and haul activities

The juvenile trap and haul strategy is not being implemented under either Alternative 2 or the No Action Alternative. Therefore, Alternative 2 is likely to have similar effects on aquatic resources as the No Action Alternative.

O.3.6.2 *Bay-Delta*

O.3.6.2.1 Delta Smelt

Potential changes to Delta Smelt from tidal habitat restoration

The effects of completion of 8,000 acres of tidal habitat restoration under Alternative 2 would be expected to be similar to those described for Alternative 1.

O.3.6.2.2 Longfin Smelt

Potential changes to Delta Longfin Smelt from tidal habitat restoration

The effects of completion of 8,000 acres of tidal habitat restoration under Alternative 2 would be expected to be similar to those described for Alternative 1.

O.3.6.2.3 Sacramento Winter-Run Chinook Salmon

Potential changes to aquatic resources due to changes to the Sacramento Deepwater Ship Channel food study

This action would hydrologically connect the Sacramento River with the Sacramento Deepwater Ship Channel (SDWSC) via the Stone Lock facility from mid-spring to late fall. Juvenile Winter-Run Chinook Salmon may be exposed to the Sacramento Deepwater Ship Channel (SDWSC) component of Alternative 2. This action would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018) to provide food web benefits to Delta Smelt. Juvenile Winter-Run Chinook Salmon abundance downstream of Stone Lock at Sherwood Harbor is highest in February and March, declines in April, and is moderate in November (Reclamation 2019). Juvenile Winter-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be routed into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, if survival rates are similar, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit associated with Alternative 2. A hydrologically connected SDWSC could potentially attract adult Winter-Run Chinook Salmon. If the connection is maintained there would likely not be impacts to adults. However, if the connection is not maintained there could be migratory delays and stranding.

Potential changes to aquatic resources due to changes to the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and therefore would have limited effects on Winter-Run Chinook Salmon, who are in the Delta between December and May for juveniles, and December to July for adults.

Potential changes to aquatic resources due to changes to the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 2, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Winter-Run Chinook Salmon, who are in the Delta between December and May for juveniles, and December to July for adults.

Potential changes to aquatic resources due to tidal habitat restoration

Although migration through the Delta represents a short period, a large proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to 8,000 acres of tidal habitat restoration in the Delta. Tidal habitat restoration is expected to benefit juvenile Winter-Run Chinook Salmon in several aspects represented by the Winter-Run Chinook Salmon conceptual model, (Reclamation 2019) including increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta. Reclamation and DWR will consult on future tidal habitat restoration with USFWS and NMFS on potential effects to fish from construction-related effects.

Potential changes to aquatic resources due to changes to predator hot spot removal

Predator hot spot removal is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Winter-Run Chinook Salmon. Although Alternative 2 would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Winter-Run Chinook Salmon. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016). Winter-Run Chinook Salmon juveniles in the Bay-Delta are unlikely to be exposed to the effects of construction at predator hot spot removal locations in the Sacramento River, as the in-water work window is in the summer and fall when, Winter-Run Chinook Salmon juveniles are generally in the upper river.

Potential changes to aquatic resources due to changes to Delta Cross Channel gate improvements

The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Winter-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. Few Winter-Run Chinook Salmon are expected to be exposed to improvements to the Delta Cross Channel. Seasonal closure periods would still be in place to protect migrating salmonids. Potential diurnal operation during closure periods could increase exposure of Winter-Run Chinook Salmon juveniles to entrainment into the interior Delta. Improved biological and physical monitoring associated with improvements would likely minimize potentially increased routing into the interior Delta and subsequent entrainment. Greater operational flexibility and increased gate reliability resulting from improvements would reduce the risk of gate failure that could result in higher rates of entrainment.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

A small proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility. Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements based on lack of observed salvage during the August to October in-water work window (see Figures F.2.7, F.2.8, and F.2.9 in Appendix F of the ROC LTO BA). However, a few early migrants could occur during the in-water work window based on occurrence in the north Delta (see Figures WR_Seines and WR_Sherwood in Appendix Fof the ROC LTO BA).

To the extent that the construction affects the ability of juvenile Winter-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Reclamation 2019), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12 (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Chinook Salmon entrained into CCF. It is important to note that only small proportions of Winter-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014).

Potential changes to aquatic resources due to changes to the small screen program

There may be some overlap Winter-Run Chinook Salmon with the main late spring-fall irrigation period for small diversions. Diversion screening could reduce entrainment of late migrating individuals. It is important to note that only a small proportion of the population would be exposed.

Few if any juvenile Winter-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Winter-Run Chinook Salmon primarily migrate from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources due to changes to the Delta fish species conservation hatchery

The operation of the Delta Fish Species Conservation Hatchery would not provide benefits to any life stage of Winter-Run Chinook Salmon. Potential negative effects of the Delta Fish Species Conservation Hatchery include inadvertent propagation and spread of invasive or nuisance species, which could affect juvenile Winter-Run Chinook Salmon through changes in food web structure, for example, in the case of invasive quagga and zebra mussels (Fera et al. 2017). Additional impacts could include reduced water quality resulting from hatchery discharge. Potential negative effects from discharged water are expected to be minimal due to the water treatment and the very small size of the discharge compared to flows in the Sacramento River near the hatchery location. Mitigation and minimization measures detailed in the

EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Winter-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Bay-Delta, few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of early migrants to in-water and shoreline construction of the hatchery intake and outfall, as illustrated by timing of occurrence in Sacramento seines and trawls (see Figures F.2.4 and F.2.5 in Appendix Fof the ROC LTO BAThe relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of construction of the Delta Fish Species Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

O.3.6.2.4 Central Valley Spring-Run Chinook Salmon

Potential changes to aquatic resources due to changes to the Sacramento Deepwater Ship Channel food study

This action would hydrologically connect the Sacramento River with the Sacramento Deepwater Ship Channel (SDWSC) via the Stone Lock facility from mid-spring to late fall. Juvenile Spring-Run Chinook Salmon abundance in the Delta is moderate in March and peaks in April (Reclamation 2019). Juvenile Spring-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be enter into the SDWSC. There are potential benefits to Spring-Run Chinook Salmon from this action. Fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar. However, estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. Also, there is potential for decreased migration time to the ocean and exposure to larger food sources of Liberty Island, but this is currently uncertain.

Potential changes to aquatic resources due to changes to the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and therefore would have limited effects on Spring-Run Chinook Salmon, who are in the Delta between January and February for adults, and November through June for juveniles, with a peak of juvenile migration from March to April.

Potential changes to aquatic resources due to changes to the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 2, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Spring-Run Chinook Salmon, who are in the Delta between January and February for adults, and November through June for juveniles, with a peak of juvenile migration from March to April.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Spring-Run Chinook Salmon are expected to benefit from continuing to construct the 8,000 acres of tidal habitat restoration in the Delta under Alternative 2. Benefits include increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of yearling migrants that enter the Delta in the fall. Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes the following: temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance, indirect impairment of aquatic ecosystem productivity, loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. Many of these are elements highlighted in the SAIL conceptual model (Reclamation 2019). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14 (Appendix E, *Mitigation Measures*).

Potential changes to aquatic resources due to changes to predator hot spot removal

Predator hot spot removal under Alternative 2 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Spring-Run Chinook Salmon. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Spring-Run Chinook. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016).

Potential changes to aquatic resources due to changes to Delta Cross Channel gate improvements

Greater operational flexibility and increased gate reliability resulting from improvements to the Delta Cross Channel under Alternative 2 would reduce the risk of gate failure that could result in higher rates of entrainment of Spring-Run Chinook Salmon, if left open. Few Spring-Run Chinook Salmon are expected to be exposed to in-water construction related improvements to the Delta Cross Channel due to observance of species protective work windows. Seasonal closure periods would still be in place to protect Spring-Run Chinook Salmon. The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Spring-Run

Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. However, improved biological and physical monitoring associated with improvements would likely minimize potentially increased entrainment.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

A number of programmatic actions are proposed to improve salvage efficiency of TFCF, including installing a carbon dioxide injection device to allow remote controlled anesthetization of predators in the secondary channels of the Tracy Fish Facility. These actions could potentially benefit juvenile Spring-Run Chinook Salmon through greater salvage efficiency.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see figures in Appendix Fof the ROC LTO BA*:* WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race). Risks to these few individuals would be minimized through appropriate mitigation measures (Appendix E, *Mitigation Measures*), the selected in-water work window, and the small scale of the in-water construction. For juvenile Spring-Run Chinook Salmon that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Predator control efforts at Skinner Fish Facility under Alternative 2 to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts.

Potential changes to aquatic resources due to changes to the small screen program

Few if any juvenile Spring-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Sacramento River Spring-Run Chinook Salmon primarily from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources due to changes to the Delta fish species conservation hatchery

The operation of the Delta Fish Species Conservation Hatchery would not provide benefits to any life stage of Winter-Run Chinook Salmon. Potential negative effects of the Delta Fish Species Conservation Hatchery include inadvertent propagation and spread of invasive or nuisance species, which could affect juvenile Winter-Run Chinook Salmon through changes in food web structure, for example, in the case of invasive quagga and zebra mussels (Fera et al. 2017). Additional impacts could include reduced water quality resulting from hatchery discharge. Potential negative effects from discharged water are expected to be minimal due to the water treatment and the very small size of the discharge compared to flows in the Sacramento River near the hatchery location. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Winter-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Bay-Delta, few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of early migrants to in-water and shoreline construction of the hatchery intake and outfall, as illustrated by timing of occurrence in Sacramento seines and trawls (see Figures F.2.4 and F.2.5 in Appendix Fof the ROC LTO BA). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of aquatic resourcesmitigation measures (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of construction of the Delta Fish Species Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

O.3.6.2.5 Central Valley Fall-Run Chinook Salmon

Potential changes to aquatic resources due to changes to the Sacramento Deepwater Ship Channel food study

Moderate to high proportions of juvenile Fall-Run Chinook Salmon are expected to be exposed to the Sacramento Deepwater Ship Channel (SDWSC) action. This action would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018). Juvenile Fall-Run Chinook Salmon abundance in the Delta is moderate in peaks in April and May (Reclamation 2019). Juvenile Fall-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be entrained into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar. The effect of this action on juvenile Fall-Run Chinook Salmon is moderate.

No San Joaquin River-origin Fall-Run Chinook Salmon are expected to be exposed to the Sacramento Deepwater Ship Channel.

Potential changes to aquatic resources due to changes to the North Delta food subsidies/Colusa Basin Drain study

This action is proposed to occur in July or September which is largely outside of the migration period for juvenile Fall-Run and Late FallRun Chinook Salmon in the Delta (Reclamation 2019). For fish that are exposed, increased food production could potentially enhance growth. The effect of this action is expected to be low.

Potential changes to aquatic resources due to changes to the Suisun Marsh Roaring River Distribution System food subsidies study

This action is proposed to occur in July or September which is largely outside of the migration period for juvenile Fall-Run and Late Fall-Run Chinook Salmon in the Delta (Reclamation 2019). For fish that are exposed, increased food production could potentially enhance growth. The effect of this action is expected to be low.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Fall-Run and Late Fall-Run Chinook Salmon are expected to be exposed to 8,000 acres of tidal habitat restoration in the Delta. Tidal habitat restoration is expected to benefit juvenile Chinook Salmon in several aspects represented by the Winter-Run Chinook Salmon conceptual model (Reclamation 2019) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta. Migration through the Delta represents a short period in the migration of juvenile Fall- and Late Fall-Run Chinook Salmon. Thus the total effect of this action is moderate.

Few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance (e.g., gill damage and reduced ability to take in oxygen, increasing metabolic cost), indirect impairment of aquatic ecosystem productivity (e.g., reduction in benthic macroinvertebrate production and availability), loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. Many of these are elements highlighted in the SAIL conceptual model (Reclamation 2019). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14 (Appendix E, Mitigation Measures).

Potential changes to aquatic resources due to changes to predator hot spot removal

Predator hot spot removal is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Fall-Run and Late Fall-Run Chinook Salmon. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Spring-Run Chinook. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016).

Potential changes to aquatic resources due to changes to Delta Cross Channel gate improvements

Greater operational flexibility and increased gate reliability resulting from improvements to the Delta Cross Channel under Alternative 2 would reduce the risk of gate failure that could result in higher rates of entrainment of Fall- and Late Fall-Run Chinook Salmon, if left open. Few Fall-Run or Late Fall-Run Chinook Salmon are expected to be exposed to in-water construction related improvements to the Delta Cross Channel due to observance of species protective work windows. Seasonal closure periods would still be in place to protect Chinook Salmon. The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Fall- and Late Fall-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. However, improved biological and physical monitoring associated with improvements would likely minimize potentially increased entrainment.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

A small proportion of juvenile Fall-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see Figures WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race in Appendix F of the ROC LTO BA). To the extent that the construction affects the ability of juvenile Fall-Run, and Late Fall-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; see Figure WR_CM4 of the ROC LTO BA), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, Mitigation Measures). Given the low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction, it is concluded that the negative population-level effects of Tracy Fish Facility Improvements construction would be low on this life stage.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Chinook Salmon entrined into Clifton Cout Forebay. However, given that only small proportions of Fall-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014), the population-level positive effect of this action would be low. Larger proportions of Late Fall-Run Chinook Salmon are lost at the facilities and this action would have a larger effect for this run.

Potential changes to aquatic resources due to changes to the small screen program

Although there may be moderate overlap Fall-Run Late Fall-Run Chinook Salmon with the main late spring-fall irrigation period for small diversions, and small diversion screening could reduce entrainment of late migraing individuals, the potential population-level positive effect would be low because only a small proportion of the population would be exposed.

Few if any juvenile Fall- /Late Fall-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Sacramento River Fall- /Late Fall-Run Chinook Salmon primarily migrate from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources due to changes to the Delta fish species conservation hatchery

Potential effects of the Delta Fishes Conservation Hatchery include inadvertent propagation and release of nuisance species and reduced water quality resulting from hatchery discharge. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Fall-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route. The overall impact of the operation of this facility is low.

As with the other proposed construction activities in the Bay-Delta, few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures will reduce effects, and the in-water construction is of a small scale.

O.3.6.2.6 Central Valley Steelhead

Potential changes to aquatic resources due to changes to the Sacramento Deepwater Ship Channel food study

Moderate to high proportions of Central Valley Steelhead are expected to be exposed to the Sacramento Deepwater Ship Channel (SDWSC) conservation measure under Alternative 2. This conservation measure would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018), allowing food to enter the Delta and an alternate migration pathway. Juvenile Central ValleyV Steelhead abundance in the Delta peaks in February through May (Reclamation 2019). Juvenile Central Valley Steelhead passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be entrained into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar.

No Central Valley Steelhead are expected to be exposed to the Sacramento Deepwater Ship Channel construction, as the in-water work window does not overlap with their occurrence in the Delta.

Potential changes to aquatic resources due to changes to the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall, and does not overlap in time or space with juvenile Central Valley Steelhead occurrence in the Delta. There would not be any effect to Central Valley Steelhead adults.

Potential changes to aquatic resources due to changes to the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 2, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Central Valley Steelhead juveniles, who are in the Delta between December and July. The action is not expected to have any effect on Central Valley Steelhead adults.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Central Valley Steelhead are expected to benefit from 8,000 acres of tidal habitat restoration in the Delta under Alternative 2. Tidal habitat restoration is expected to benefit juvenile Central Valley Steelhead in several aspects represented by the Winter-Run Chinook Salmon conceptual model (Figure 5.6-4) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta; however, the Delta only represents a small fraction of the total migration route.

Few if any juvenile Central Valley Steelhead would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be exposure of a few late migrants, as illustrated by timing of occurrence in Chipps mid-water trawls (Reclamation 2019). Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance (e.g., gill damage and reduced ability to take in oxygen, increasing metabolic cost), indirect impairment of aquatic ecosystem productivity (e.g., reduction in benthic macroinvertebrate production and availability), loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. The risk from these potential effects would be minimized through application of mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12 and MM-AQUA-14.

Potential changes to aquatic resources due to changes to predator hot spot removal

Predator hot spot removal under Alternative 2 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids, including Central Valley Steelhead. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of Central Valley Steelhead. All hotspots are limited in scale relative to overall available habitat, and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016). However, implementation of this action would likely improve conditions for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources due to changes to Delta Cross Channel gate improvements

Completion of DCC gate improvements would benefit Central Valley Steelhead of all life stages within the CVP watershed systems. The peak migration of juvenile Central Valley Steelhead in the Sacramento River past Hood, which is near the DCC, occurs from February through mid-June (Reclamation 2019). No San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the DCC. As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, few late migrants or early migrants have the potential to be exposed to potential construction from improvements to the DCC under Alternative 2.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

Small proportions of Sacramento River-origin Central Valley Steelhead and moderate proportions of Mokelumne River and San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the Tracy Fish Facility. However, for fish that arrive at the facility, the proposed improvements resulting in greater salvage efficiency under Alternative 2 are likely to increase survival of juvenile Central Valley Steelhead.

As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, none to a few late migrants or early migrants have the potential to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements. Risks of decrease Central Valley Steelhead juvenile salvage during construction would be minimized through appropriate mitigation measures.

Skinner Fish Facility improvements under Alternative 2 to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources due to changes to the small screen program

Fish screens under Alternative 2 would also benefit this lifestage in the same ways described above. Juvenile Central Valley Steelhead outmigrating in the Bay-Delta may be exposed to the effects of construction of screens since they migrate downstream during most months of the year, with a peak emigration period in the spring and a smaller peak in the fall (Hallock et al. 1961). Juvenile Central Valley Steelhead may be found in the work area of these projects; however, mitigation measures would minimize impacts.

Potential changes to aquatic resources due to changes to the Delta fish species conservation hatchery

Potential effects of the Delta Fishes Conservation Hatchery include inadvertent propagation and release of nuisance species and reduced water quality resulting from hatchery discharge. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Central Valley Steelhead would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Delta under Alternative 2, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) which means that none to a few late or early migrants of this life stage could be exposed to Delta Fishes Conservation Hatchery construction. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risk from these potential effects would be minimized through application of mitigation measures (Appendix E, *Mitigation Measures*).

O.3.6.2.7 North American Green Sturgeon Southern DPS

Potential changes to aquatic resources due to changes to the Sacramento Deepwater Ship Channel food study

As described above, juvenile Green Sturgeon may potentially be entrained into the DWSC. Fish entering the SDWSC would not, however, be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar between the SDWSC and the Sacramento main stem

Potential changes to aquatic resources due to changes to the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta or Suisun Marsh food subsidies by routing drain water would occur in summer/fall and therefore could provide food benefits to Green Sturgeon juveniles, who are in the Delta in the fall.

Potential changes to aquatic resources due to changes to the Suisun Marsh Roaring River Distribution System food subsidies study

Provision of north Delta or Suisun Marsh food subsidies by routing drain water would occur in summer/fall and therefore could provide food benefits to Green Sturgeon juveniles, who are in the Delta in the fall.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile southern DPS Green Sturgeon are expected to be exposed to continuing to implement the 8,000 acres of tidal habitat restoration in the Delta under Alternative 2. Tidal habitat restoration is expected to benefit juvenile Green Sturgeon in several aspects represented by the Green Sturgeon juvenile conceptual model (Reclamation 2019) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta.

Potential changes to aquatic resources due to changes to predator hot spot removal

Predator hot spot removal under Alternative 2 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids. It is currently unknown if predation on juvenile Green Sturgeon in the Delta is limiting their productivity. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the rearing and migratory corridors of juvenile Green Sturgeon.

Potential changes to aquatic resources due to changes to Delta Cross Channel gate improvements

Little is known about the migratory behavior of juvenile Green Sturgeon in the Sacramento River basin. It is likely that juvenile Green Sturgeon (larger than the 75 mm) will not enter the Delta prior to their first winter and thus would not be exposed to the open DCC gates. It is likely that these fish will enter the Delta sometime in the winter or spring following their hatching upriver and encounter both types of gate configurations as they enter the Delta. More information is required to accurately assess the migratory movements of juvenile Green Sturgeon in the river system, as well as their movements within the Delta during their rearing phase in estuarine/Delta waters. Greater operational flexibility and increased gate reliability resulting from improvements would reduce the risk of gate failure that could result in higher rates of entrainment.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

Upgrades to the TFCF will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

As previously described, juvenile Green Sturgeon can occur in the Delta year-round (Reclamation 2019) and, therefore, have the potential to be exposed to the effects of construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements. If construction affects the efficiency of Green

Sturgeon salvage (which is an element of entrainment risk; Reclamation 2019), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures (Appendix E, *Mitigation Measures*).

Skinner Fish Facility improvements under Alternative 2, which involve predator control efforts, can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently. Thus, Alternative 2 is not likely to negatively impact juvenile Green Sturgeon.

Potential changes to aquatic resources due to changes to the small screen program

Southern DPS Green Sturgeon are expected to be present in the Delta during the main irrigation period for small diversions (late spring-fall). Diversion screening under Alternative 2 could reduce entrainment of individual Green Sturgeon. However, there is currently no information on the proportion of juvenile Green Sturgeon that are entrained into small unscreened diversions. North American Green Sturgeon in the juvenile to subadult/adult life stage may be exposed to the effects of construction of screens since they are present in the Sacramento River year-round (Reclamation 2019). Effects are the same as described above for juveniles. Mitigation measures would minimize risk.

Potential changes to aquatic resources due to changes to the Delta fish species conservation hatchery

None of the Green Sturgeon life stages would benefit from the Delta Fish Species Conservation Hatchery under Alternative 2. As with the other proposed construction activities in the Delta, the year-round occurrence of juvenile Green Sturgeon in the Delta (Reclamation 2019) means that this life stage, as well as the timing of the adult Green Sturgeon occurring in the Delta during May to October, could be exposed to Delta Fish Species Conservation Hatchery construction under Alternative 2. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risks from these potential effects would be minimized with through the application of mitigation measures (Appendix E, *Mitigation Measures*).

O.3.6.3 *Nearshore Pacific Ocean on the California Coast*

O.3.6.3.1 Southern Resident Killer Whale

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

Following the logic provided in Alternative 1, given the medium priority of Central Valley Chinook Salmon stocks and the contribution of hatchery-origin Chinook Salmon released downstream of the potential proposed action influence, plus the fact that Alternative 2 includes almost none of the programmatic activities proposed under Alternative 1, Alternative 2’s programmatic activities would not be expected to have population-level effects to Southern Resident Killer Whale Chinook Salmon prey. This suggests limited effects of Alternative 2 programmatic activities on Southern Resident Killer Whale.

O.3.7 Alternative 3 – Project-Level Effects

O.3.7.1 *Trinity River*

O.3.7.1.1 <u>Seasonal Operations</u>

As described in the No Action Alternative and Alternative 1, the Trinity River system would be operated according to the Trinity River ROD with lower Klamath River augmentation flows.

Potential changes to aquatic resources due to changes in reservoir storage

Model results predict that under Alternative 3, storage volume in Trinity Lake would remain the same in most water year types compared to the No Action Alternative. On average, storage would be increased by 1 TAF under Alternative 3 compared to the No Action Alternative. The effects of changes in reservoir storage conditions as they relate to water temperature can be assessed by looking at temperatures in the Trinity River downstream of Trinity Dam. Average monthly water temperatures in the Trinity River downstream of Trinity Dam would remain similar under Alternative 3 compared to the No Action Alternative (Figure O.3-112). Maximum modeled water temperatures in the Trinity River downstream of Trinity Dam are generally similar under Alternative 3 compared to the No Action Alternative except in August when temperatures would be approximately 6°F higher and September when temperatures would be approximately 2°F higher under Alternative 3. October temperatures would be approximately 4°F lower under Alternative 3 compared to the No Action Alternative.

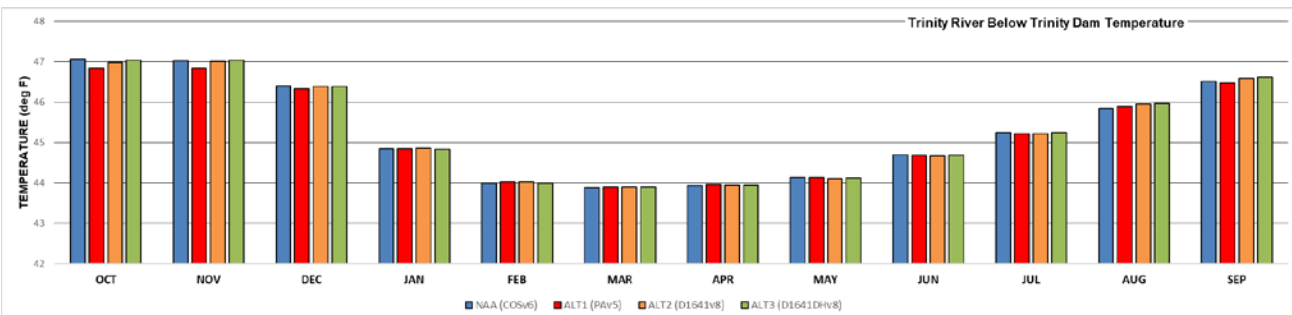

Figure O.3-112. Average Trinity River Water Temperatures below Trinity Dam for the Period October to September, Average of All Water Year Types

No focal fish species occur in Trinity Lake or in the Trinity River downstream of Trinity Dam. Effects of Trinity Reservoir storage on fish in the Trinity River downstream of Lewiston Dam are described below.

Potential changes to aquatic resources from variation in flow

Under Alternative 3 flows in the Trinity River downstream of Lewiston Dam would be similar to flows under the No Action Alternative in most months and water year types. However, in wet years flows would increase in December under Alternative 3 compared to the No Action Alternative (1,297 cfs versus 1,192 cfs). In above normal water years flows under Alternative 3 would decrease in November compared to the No Action Alternative (568 cfs versus 678 cfs) and increase in February compared to the No Action Alternative (801 cfs versus 528 cfs). In critically dry years, flows under Alternative 3 would decrease compared to the No Action Alternative in September and October from 870 cfs to 798 cfs and from 342 cfs to 321 cfs, respectively.

Coho Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 compared to the No Action Alternative. Minor differences (<10%) in November and December of some water year types and a larger difference (16%) in November of above normal water years may affect spawning and juvenile rearing habitat for Coho Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these changes in flow are not expected to result in a detectable effect on Coho Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in above normal water years in February would increase by approximately 52% under Alternative 3 (801 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Coho Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Spring-Run Chinook Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 compared to the No Action Alternative. Minor differences (<10%) in November and December of some water year types and a larger difference (16%) in November of above normal water years may affect spawning and juvenile rearing habitat for Spring-Run Chinook Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these changes in flow are not expected to result in a detectable effect on Spring-Run Chinook Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in above normal water years in February would increase by approximately 52% under Alternative 3 (801 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Spring-Run Chinook Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Fall-Run Chinook Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 compared to the No Action Alternative. Minor differences (<10%) in November and December of some water year types and a larger difference (16%) in November of above normal water years may affect spawning and juvenile rearing habitat for Fall-Run Chinook Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these changes in flow are not expected to result in a detectable effect on Fall-Run Chinook Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in above normal water years in February would increase by approximately 52% under Alternative 3 (801 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Fall-Run Chinook Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Steelhead (Winter- and Summer-Run)

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 compared to the No Action Alternative. Minor differences (<10%) in November and December of some water year types and a larger difference (16%) in November of above normal water years may affect juvenile rearing habitat for Steelhead. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these changes in flow are not expected to result in a detectable effect on Steelhead juvenile rearing habitat (USFWS 1999). Flows in above normal water years in February would increase by approximately 52% under Alternative 3 (801 cfs) compared to the No Action Alternative (528 cfs).

This increase in flow may reduce the amount of spawning habitat for Steelhead. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999: 123), increasing flows from 500 cfs to 800 cfs showed little change in the amount of spawning habitat for Steelhead in the Trinity River from downstream of Lewiston Dam to the confluence with Dutch Creek.

Green Sturgeon

Green Sturgeon occur within the lower 43 miles of the Trinity River, approximately 70 miles downstream of Lewiston Dam. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in flow under Alternative 2 would not affect Green Sturgeon.

White Sturgeon

White Sturgeon are not likely to be affected by changes in reservoir operations under Alternative 2 compared to the No Action Alternative due to their limited distribution in the lower Klamath River, primarily in the estuary.

Pacific Lamprey

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 compared to the No Action Alternative. However, minor differences (<10%) in November and December of some water year types and a larger difference in November (16%) and February (52%) of above normal water years are expected. Increased flows in February overlap with the Pacific Lamprey adult migration period but are not expected to affect migration because Pacific Lamprey migration spans multiple seasons and associated flows. Although previous flow habitat relationship studies in the Trinity River (USFWS 1999) did not focus on Pacific Lamprey, results for salmonids suggest that changes in flow under Alternative 3 would not result in a detectable effect on juvenile rearing or adult holding habitat for Pacific Lamprey compared to the No Action Alternative.

American Shad

American Shad are primarily found in the lower Klamath River but may occur in the lower sections of the Trinity River up to approximately RM 24 at the town of Willow Creek. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in flow under Alternative 3 would not affect American Shad.

Potential changes to aquatic resources due to variation in temperature

Modeling results indicate that changes in monthly average water temperature in the Trinity River downstream of Lewiston Dam would be similar between Alternative 3 and the No Action Alternative. Changes in monthly average temperature between Alternative 3 and the No Action Alternative would be less than 0.5°F different for all months of the year (Figure O.3-113). Modeled maximum temperatures in the Trinity River would be higher under Alternative 3 compared to the No Action Alternative in August, September, and November when the maximum temperature would be approximately 2°F to 5°F higher and lower in February when the maximum temperature would be approximately 1°F lower. Maximum temperatures would be similar in the remaining months (Figure O.3-113 and Table O.3-42).

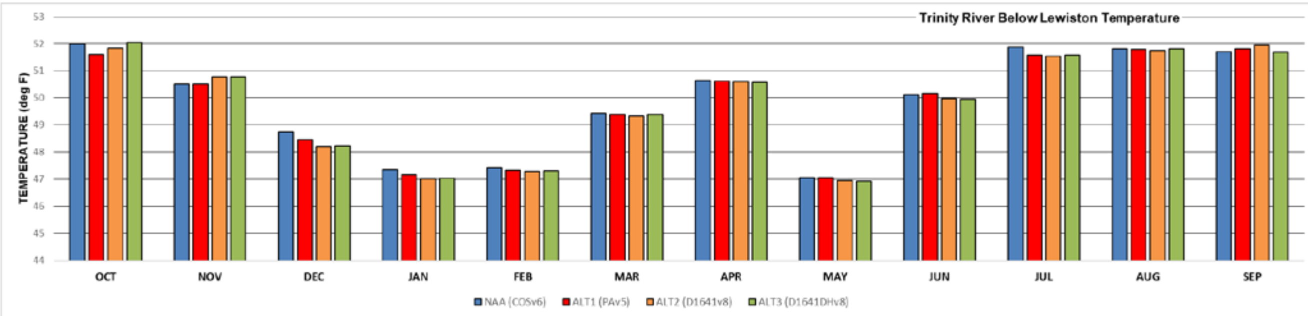

Figure O.3-113. Average Trinity River Water Temperatures below Lewiston Dam for the Period October to September, Average of All Water Year Types

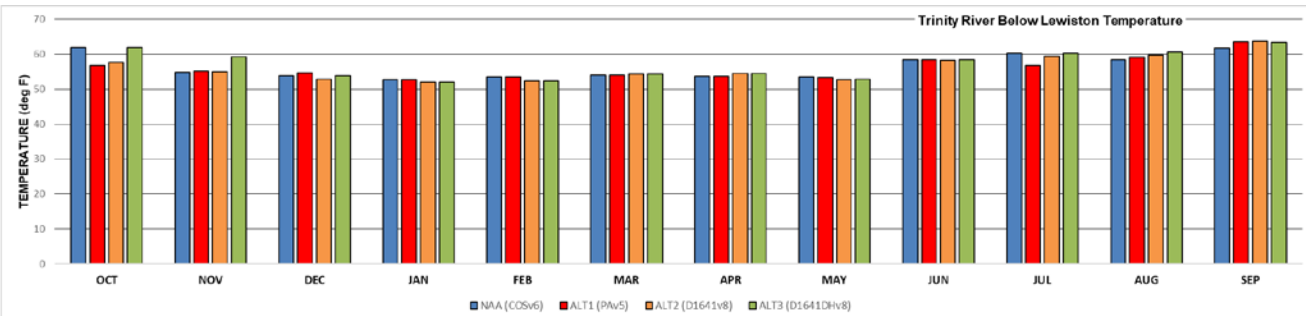

Figure O.3-114. Maximum Trinity River Water Temperatures below Lewiston Dam for the Period October to September, Average of All Water Year Types

Table O.3-42. Maximum Trinity River Water Temperatures below Trinity Dam for the Period October–September, Average of All Water Year Types (Differences >1°F Are Highlighted)

Alt	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
No Action Alternative	61.8	54.8	53.8	52.7	53.4	54.1	53.7	53.5	58.4	60.3	58.4	61.8
ALT 1	56.7	55.2	54.6	52.6	53.5	54.0	53.7	53.4	58.4	56.9	59.1	63.5
ALT 2	57.6	55.1	52.8	52.0	52.4	54.4	54.5	52.7	58.4	59.4	59.7	63.8
ALT 3	61.9	59.3	53.9	52.0	52.4	54.4	54.5	52.9	58.4	60.3	60.6	63.4

In a previous study that looked at flow and water temperatures in the Trinity River (USFWS 1999), results indicated that flows do not have a significant influence on water temperatures from mid-October through early April when cooler air temperatures help maintain cold water temperatures even when flow releases drop below 150 cfs. Once tributary influence begins to decrease and meteorological conditions warm from May to mid-July, flow releases become more influential on downstream temperatures, particularly during hot-dry conditions. Maintaining a flow of 450 cfs during the summer and early fall was found to meet the water temperature objectives for the Trinity River when water released from Lewiston Dam was 53°F or less (USFWS 1999: 203). Water temperatures are most influenced by flow releases from May through mid-October. Flows from May to October would be similar under Alternative 3 compared to the No Action Alternative in most water year types with the exception of critically dry water years. In critically dry years, flows in September would decrease by approximately 6% under Alternative 3 compared to the No Action Alternative, from 870 cfs to 798 cfs. Based on modeling results, changes in flow under Alternative 3 are not likely to have a detectable change in water temperature in the Trinity River downstream of Lewiston Dam.

Coho Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 3 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 3 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-113). Modeled maximum temperatures in the Trinity River in July, September, and November would be approximately 2°F to 5°F higher under Alternative 3 compared to the No Action Alternative and approximately 1°F lower in February with similar maximum temperatures in the remaining months (Figure O.3-114). Maximum temperatures under Alt 3 from August to October exceed the NCRWQCB (2018) objectives for the Trinity River and may reduce juvenile Coho Salmon rearing success compared to conditions under the No Action Alternative.

Spring-Run Chinook Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 3 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 3 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-113). Modeled maximum temperatures in the Trinity River in July, September, and November would be approximately 2°F to 5°F higher under Alternative 3 compared to the No Action Alternative and approximately 1°F lower in February, with similar maximum temperatures in the remaining months. Spring-Run Chinook Salmon spawning usually peaks in October but typically ranges from the third week of September through November. Maximum August to October temperatures under Alternative 3 would exceed the NCRWQCB (2018) objectives for the Trinity River and may limit the success of adult migration, spawning, and juvenile rearing of Spring-Run Chinook Salmon compared to conditions under the No Action Alternative.

Fall-Run Chinook Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 3 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 3 and the No Action Alternative would be less than 0.5°F different for all months of the year (Figure O.3-113). Modeled maximum temperatures in the Trinity River in July, September, and November would be approximately 2°F to 5°F higher under Alternative 3 compared to the No Action Alternative and approximately 1°F lower in February with similar maximum temperatures in the remaining months (Figure O.3-114). Fall-Run Chinook Salmon spawning usually occurs between October and December with peak spawning activity occurring in November. Maximum August to October temperatures under Alternative 3 exceed the NCRWQCB (2018) objectives for the Trinity River and may limit the success of adult migration and spawning of Fall-Run Chinook Salmon compared to conditions under the No Action Alternative.

Steelhead (Winter- and Summer-Run)

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 3 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 3 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-113). Modeled maximum temperatures in the Trinity River in July, September, and November are approximately 2°F to 5°F higher under Alternative 3 compared to the No Action

Alternative and approximately 1°F lower in February, with similar maximum temperatures in the remaining months. Maximum temperatures under Alternative 3 from August to October exceed the NCRWQCB (2018) objectives for the Trinity River and may limit the success of juvenile rearing Steelhead compared to conditions under the No Action Alternative.

Green Sturgeon

Green Sturgeon occur within the lower 43 miles of the Trinity River, approximately 70 miles downstream of Lewiston Dam. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Results of previous water temperature modeling for the Trinity River (USFWS 1999) predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43 with smaller temperature differences expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers. Therefore, changes in water temperature under Alternative 2 would not affect Green Sturgeon.

White Sturgeon

White Sturgeon would not be affected by changes in reservoir operations under Alternative 2 compared to the No Action Alternative due to their limited distribution in the lower Klamath River, primarily in the estuary.

Pacific Lamprey

Model results predict that water temperatures in the Trinity River below Lewiston Dam would be similar under Alternative 3 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 3 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-113). Modeled maximum temperatures in the Trinity River in July, September, and November would be approximately 2°F to 5°F higher under Alternative 3 compared to the No Action Alternative and approximately 1°F lower in February, with similar maximum temperatures in the remaining months. Maximum temperatures under Alternative 3 from August to October exceed the NCRWQCB (2018) objectives for the Trinity River. Under the No Action Alternative and Alternative 3 water temperatures exceed the NCRWQCB objectives during this time. However, larger increases in temperature that would occur under Alternative 3 may further reduce Pacific Lamprey juvenile rearing success compared to the No Action Alternative.

American Shad

American Shad are primarily found in the lower Klamath River but may occur in the lower sections of the Trinity River up to approximately RM 24 at the town of Willow Creek. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Results of previous water temperature modeling for the Trinity River (USFWS 1999) predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 24 with smaller temperature differences expected downstream to the confluence of the Trinity and Klamath Rivers. Therefore, changes in water temperature under Alternative 3 would not affect American Shad.

O.3.7.1.2 Trinity River Record of Decision

The Trinity River ROD is being implemented under both Alternative 3 and the No Action Alternative. Therefore, implementation of the variable annual flow regime, restoration actions, and monitoring and adaptive management, per the Trinity River ROD under Alternative 3 would have similar effects as the No Action Alternative on Coho Salmon, Chinook Salmon (Spring- and Fall-Run), Steelhead (Winter- and Summer-Run), Green Sturgeon, White Sturgeon, Pacific Lamprey, and American Shad.

O.3.7.1.3 Grass Valley Creek Flows

Grass Valley Creek Flows are being implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources.

O.3.7.2 *Sacramento River*

Potential changes to aquatic resources in the Sacramento River from seasonal operations.

Under all the Project alternatives, flows in the upper Sacramento River result from controlled releases from Shasta and Keswick reservoirs, as well as transfers from the Trinity River and natural accretions. Dry hydrologic conditions often lead to inadequate storage in Shasta Reservoir for operators to provide suitable conditions for salmonids and other native species in the upper Sacramento River. In most cases, water temperature rather than flow is the limiting factor creating unsuitable conditions, as discussed below. The primary differences between the No Action Alternative (No Action Alternative) and Alternative 3 for the Sacramento River flow and water tempearture management upstream of the Delta is that the No Action Alternative includes NMFS's 2009 BO RPAs to operate Shasta Reservoir for management of cold water in the reservoir and river to protect anadromous salmonids, and includes requirements for Fall X2 flow releases, but Alternative 3 includes neither requirement. A minimum flow of 3,250 cfs is required from Keswick Dam to the RBDD during October through March under the No Action Alternative and during October through February under Alternative 3 (NCWA 2014).

CalSim II modeling indicates that average flow released at Keswick Dam under Alternative 3 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 3 flows would be substantially lower than the No Action Alternative flows (Table Sac-3-1). The higher September and November flows under the No Action Alternative result from Fall X2 releases, which are not included in Alternative 3. Table O.3-43 shows that the highest mean monthly flows for both alternatives occur primarily during winter of wet and above normal water years and during summer of all water year types. Flow releases are high during summer to satisfy downstream demands of water users and Delta water quality and to meet water temperature requirements of incubating Winter-Run Chinook Salmon eggs and alevins downstream of Keswick Dam.

Table O.3-43. CalSim II Monthly Average Flow (cfs) by Water Year Type and Month below Keswick Dam for No Action Alternative, Alternative 3 and Differences between Them

Alternative[1,2,3] Water Year Type[4]	Monthly Flow (cfs)											
	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
No Action Alternative												
Wet (32%)[5]	7,908	9,796	7,444	17,876	19,288	16,127	8,458	8,662	8,940	13,440	10,474	14,063
Above Normal (16%)	7,054	10,124	6,406	7,629	16,401	8,534	5,221	7,925	10,359	15,316	10,494	9,972
Below Normal (13%)	5,842	4,960	7,558	3,285	7,149	3,925	3,803	7,867	10,930	14,421	10,624	5,493
Dry (24%)	5,660	5,111	8,652	3,697	3,564	3,961	3,719	7,014	10,368	12,658	8,608	4,995
Critically Dry (15%)	4,829	3,755	3,251	3,392	3,580	3,509	4,065	6,895	8,984	10,947	7,793	4,729

6 Bold green font indicates greater than 5% increase in flow; bold red font indicates greater than 5% reduction in flow.

HEC-5Q modeling was used to compare water temperature effects of the No Action Alternative and Alternative 3. Based on recent investigations of Winter-Run Chinook Salmon mortality in the upper Sacramento River (Martin et al. 2017; Anderson 2018), this effects analyses uses an upper water temperature threshold of 53.5°F for suitable salmonid spawning and egg and alevin incubation in the Sacramento River. An important caution regarding the HEC-5Q water temperature modeling results, particularly with regard to meeting water temperature criteria (e.g., 56°F water temperature at Bend Bridge criterion), relates to the time step used in the modeling. HEC-5Q, like the CalSim II model on which it relies for flow data, has a monthly time step and provides estimates of monthly mean water temperatures. However, most of the regulatory requirements to meet water temperature criteria apply to daily mean (or shorter duration) water temperatures. Daily means are almost always much more variable than monthly means and, therefore, the monthly mean water temperature estimates provided by HEC-5Q are not directly comparable to the regulatory criteria. For example, even with constant flows releases, downstream daily water temperatures would fluctuate around the mean in response to variation in solar radiation and other meteorological conditions within a given month. In view of this limitation, it is helpful to consider the comparisons of temperature effects among the alternatives as indicating the relative likelihoods of exceeding temperature criteria, rather than whether or not the criteria are actually met.

These considerations apply to the CalSim II flow data as well, but are less important for flow because there are fewer regulatory criteria for flow and, except during storm events, flow tends to be less variable than water temperature.

During the summer and much of the fall, water released from Keswick Dam warms downstream resulting in warmer water temperatures in more downstream habitats. Therefore, the effects of the alternatives on fish populations depend on the habitat distributions of the populations as well as the results of temperature management operations. Winter-Run Chinook Salmon mostly spawn from Keswick Dam to about 6 miles downstream of the Clear Creek temperature gage, Spring-Run Chinook Salmon from Keswick Dam to about Balls Ferry, Fall-Run Chinook Salmon from Keswick Dam to about RBDD, Late Fall-Run Chinook Salmon spawning distribution is similar to that of Winter-Run, and Green Sturgeon spawn downstream of the Cow Creek confluence to the GCID oxbow near Hamilton City (NMFS 2018b). Steelhead spawning areas in the upper Sacramento River are poorly known.

Based on the HEC-5Q modeling, the mean monthly water temperatures at Keswick Dam are roughly equal under the No Action Alternative and Alternative 3, except for September of above normal water years, which has a 1.2°F higher mean water temperatures under Alternative 3 than under the No Action Alternative (Table O.3-44). Summer mean monthly water temperatures are consistently below the 53.5°F temperature threshold, except in critically dry water years during July through September. The October and November mean water temperatures under Alternative 3 are similar to those under the No Action Alternative and are just above the 53.5°F temperature threshold, except for critically dry water years, when those for both alternatives are well above the threshold (Table O.3-44). For October, the mean water temperature for critically dry water years is 1.0°F higher under Alternative 3 than that under the No Action Alternative. Although the difference in mean October critically dry water year water temperatures between the No Action Alternative and Alternative 3 is not large, it occurs under highly stressful temperature conditions for salmonids eggs and alevins. The largest predicted increase in mean water temperature under Alternative 3 is 1.2°F for September of above normal water years (Table O.3-44). This increase occurs over a range well below the critical temperature threshold and is therefore unlikely to have a large effect on the salmonids. The differences between the No Action Alternative and Alternative 3 in September water temperatures at Keswick Dam are small (Figure O.3-20) relative to those at more downstream locations, as described below.

The HEC-5Q results indicate that late spring through early fall water temperatures in the Sacramento River at Clear Creek are slightly warmer than those at Keswick Dam, with larger increases in September water temperature differences between the No Action Alternative and Alternative 3 (Table O.3-45). Summer mean monthly water temperatures are below the 53.5°F temperature threshold, except in drier water years, especially in August and September. All mean temperatures for October and November are above the threshold for both alternatives. At Balls Ferry, the temperatures are warmer still and the September increases are larger (Table O.3-46). The mean September water temperatures for wet and above normal water years at Balls Ferry exceed the critical water temperature threshold under Alternative 2, but not under the No Action Alternative (Table O.3-46). As discussed previously, the monthly mean water temperatures provide a rough estimate of the probability of mean daily water temperatures exceeding a temperature threshold. Because the mean monthly water temperatures are higher under Alternative 3, the probability or frequency of the threshold being exceeded in September of wet and above normal water years is expected to be higher under Alternative 3 than under the No Action Alternative.

The downstream trends in water temperature conditions noted for Keswick Dam, Clear Creek and Balls Ferry continue to RBDD, with little difference in water temperatures between the alternatives, except for substantially warmer temperatures in September of wet and above normal water years under Alternative 3 (Table O.3-47). The growing downstream differences in wet and above normal water year temperatures for September can be seen in Figures O., 3-20, O.3-31 and O.3-22. The temperature differences are largely limited to the cooler 50% of years. Under both the No Action Alternative and Alternative 3, the mean water temperatures at RBDD for April through October are above the 53.5°F critical water temperature threshold in all water year types. The pattern of increasing water temperatures differences in September of wet and above normal water years between the No Action Alternative and Alternative 3 continues downstream to Hamilton City and Knights Landing, (Tables O.3-48 and O.3-49; Figures O.3-23 and O.3-24). However, at these locations there are also water temperature reductions of 1°F to 2°F between the No Action Alternative and Alternative 3 during May, June, and September of above normal, below normal or dry water years, depending on the month (Table O.3-48 and O.3-49; Figure O.3-23 and O.3-24). These reductions result from increases in flow under Alternative 3 relative to the No Action Alternative (Tables O.3-51 and O.3-52).

The reduced downstream warming of the river in September of wet and above normal under the No Action Alternative relative to the Alternative 3 is due, at least in part, to the much higher flow releases for Fall X2, as noted above (Table O.3-43). Note that November Fall X2 flow releases under the No Action Alternative do not result in higher water temperatures under Alternative 3 (e.g., Table O.3-49), presumably because November air temperatures would, on average, be similar to or lower than the water temperatures.

It is expected that, in general, water temperatures between the No Action Alternative and Alternative 3 would be largely similar, with the exception of September of wet and above normal water years, when water temperatures are warmer under the Alternative 3 because this alternative would not include the Fall X2 flows that reduce downstream warming under the No Action Alternative, and with the exception of May, June, and September of various water year types at the most downstream locations, when water temperatures are cooler under Alternative 3 because of higher flows.

O.3.7.2.1 Sacramento River Winter-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Winter-Run Chinook Salmon adults spawn from May through August with peak spawning during June and July (Section O.2.4.2.1, *Winter-Run Chinook Salmon*). Fry emergence occurs up to 3 months after eggs are spawned, so effects of flow and water temperature on Winter-Run eggs and alevins may occur from May through November, but primarily occur during June through October.

As previously noted, CalSim II modeling indicates that mean monthly flow released at Keswick Dam under Alternative 3 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 3 flows would be substantially lower than the No Action Alternative flows (Table O.3-43). By September in most years, a large proportion of Winter-Run Chinook Salmon redds still contain incubating alevins. Assuming flows are stable enough to avoid dewatering the redds, which is generally true in September, the most important effect of flows on alevins is to transport dissolved oxygen to the developing alevins and to flush potentially toxic metabolites out of the redds. Although the mean September wet and above normal water year flows are substantially lower under Alternative 3 than under the No Action Alternative, the flows under Alternative 3 flows remain moderately high (>6,000 cfs) (Figure O.3-25). Flows at this level are expected to provide sufficient flow velocity to keep the redds clean and well oxygenated. With regard to redd dewatering, there are some reductions in mean monthly flows below Keswick Dam during the fall under Alternative 3, but these are similar to the fall reductions expected under the No Action Alternative (Table O.3-43). Therefore, differences in flow between the No Action Alternative and Alternative 3 are expected to have little effect on Winter-Run Chinook Salmon spawning and incubation habitat.

As noted in the previous section, there are few differences between the No Action Alternative and Alternative 3 in the HEC-5Q water temperature results for the Winter-Run Chinook Salmon spawning period (Table O.3-44). The largest difference for the Keswick Dam location, a 1.2°F increase in September of above normal water years under Alternative 3, would occur within a range of temperature well below the 53.5°F water temperature threshold, and therefore would not affect Winter-Run eggs or alevins. The mean October water temperatures at Keswick are predicted to be above the water temperature threshold in about 85% of years under both the No Action Alternative and Alternative 3 (Figure O.3-18). September mean monthly water temperatures exceed the threshold in critically dry water years under both alternatives (Table O.3-44). At the more downstream Winter-Run Chinook Salmon spawning locations, the September water temperatures exceed the threshold for more of the water year types (Tables O.3-45 and O.3-46). At these locations, water temperature increases between the No Action Alternative and Alternative 3 for September of wet and above normal water years result in water temperatures approaching or exceeding the 53.5°F temperature threshold under Alternative 3, but not under the No Action Alternative, which would result in adverse effects on Winter-Run Chinook Salmon eggs and alevins under Alternative 3.

Recent investigations of Winter-Run Chinook Salmon mortality in the upper Sacramento River (Martin et al. 2017; Anderson 2018) yielded models for estimating mortality of Winter-Run Chinook Salmon eggs and alevins under different water temperature conditions. These models, referred to hereinafter as the Martin and Anderson models, were used to compare water-temperature-related mortality of Winter-Run Chinook Salmon eggs and alevins under Alternative 3 and the No Action Alternative. The modeling was based on the HEC-5Q water temperature estimates for the years used in the HEC-5Q modeling (1922 to 2002). The results for all water year types combined show no consistent differences in egg/alevin mortality between Alternative 3 and the No Action Alternative (Figure O.3-115). Figure O.3-115 combines results for all water year types, including wet years, when there is little temperature-related mortality. This obscures the modeling results for drier years, when egg/alevin mortalities are especially high. For critically dry water years, the mortality modeling shows similar mortality between Alternative 3 and the No Action Alternative or slightly higher mortality under Alternative 3 (Figure O.3-116).

The flow effects resulting from Alternative 3 would have a less-than-significant effect relative to the No Action Alternative on Winter-Run Chinook Salmon spawning and the egg and alevin life stages, but the water temperature effects would have a significant adverse impact relative to the No Action Alternative because of the temperature increases in September of wet and above normal water years.

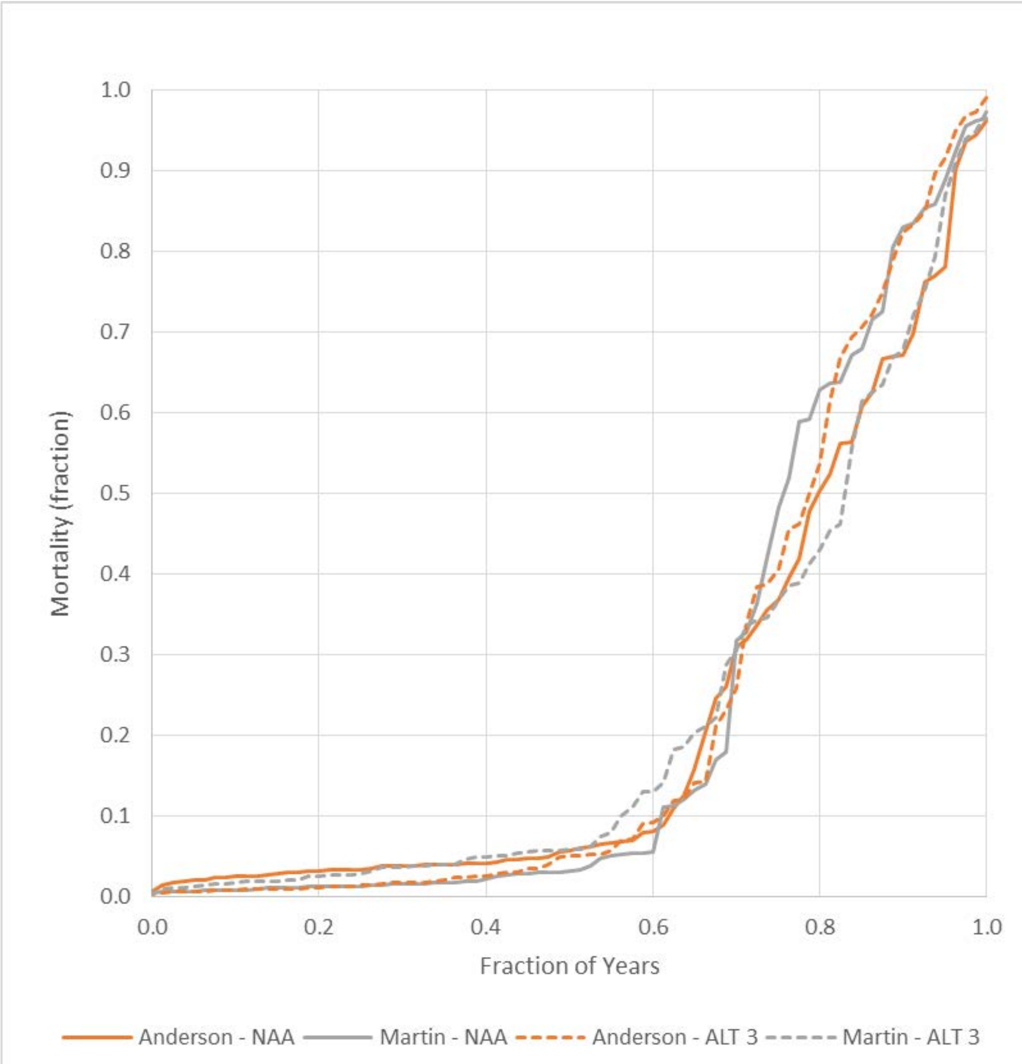

Figure O.3-115. Exceedances of Winter-Run Chinook Salmon Temperature-Dependent Egg Mortality, Alternative 3 vs. No Action Alternative; All Water Year Types.

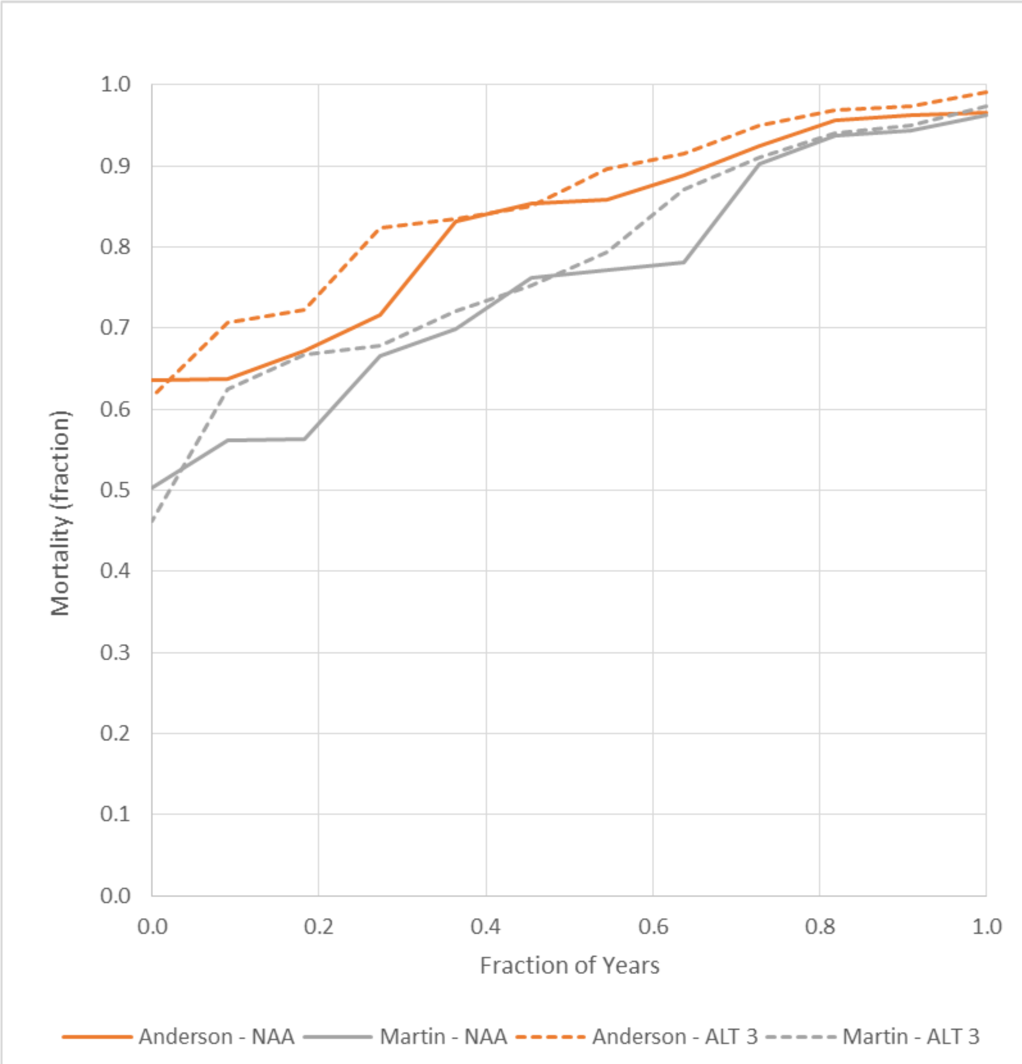

Figure O.3-116. Exceedances of Winter-Run Chinook Salmon Temperature-Dependent Egg Mortality, Alternative 3 vs. No Action Alternative; Critically Dry Water Years

Juvenile Rearing and Emigration

Winter-Run Chinook Salmon juveniles rear in the Sacramento River primarily from late summer to late winter, and emigrate from the river to the Delta beginning in November (see Section O.2.4.2.1, *Winter-Run Chinook Salmon*). The proportion of juveniles surviving to emigrate to the Delta depends largely on habitat conditions, including flow and water temperature. Inundated floodplain habitat has been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Sacramento River flow during the Winter-Run juvenile rearing and emigration period differs substantially between the No Action Alternative and Alternative 3, especially during September and November of wet and above normal water years (Tables O.3-43, O.3-50 through O.3-52). The juveniles rear primarily in the upper and middle Sacramento River until about October, when they begin to appear in the lower river (e.g., Knights Landing) (del Rosario et al. 2013). As noted previously, because the No Action Alternative includes Fall X2 releases but not Alternative 3 does not, the mean monthly flows during September and November are much lower under Alternative 3 than under the No Action Alternative, which would potentially reduce suitable rearing habitat for juveniles (Tables O.3-43 and O.3-50 through O.3-52; Figures O.3-25, O.3-28 and O.3-29).

Emigration of juvenile Winter-Run Chinook Salmon from the Sacramento River is triggered by pulse flows of about 14,000 cfs and above (at Wilkins Slough) (del Rosario et al. 2013). CalSim II September flows at Wilkins Slough exceed this threshold in about 18% of years under the No Action Alternative and never exceed it under Alternative 3, but September is too early for juvenile Winter-Run Chinook Salmon to emigrate to the Delta (del Rosario et al. 2013). For November, when Winter-Run juveniles are ready to emigrate, monthly mean flow at Wilkins Slough is much higher under the No Action Alternative than under Alternative 3, but remains below the 14,000 cfs threshold for both alternatives, except for the highest 9% of flows (Figure O.3-29). There are no differences between the alternatives at these highest flows. An important limitation with this analysis is that the CalSim II flow estimates are monthly averages and Winter-Run Chinook Salmon emigration can be triggered by flow pulses that exceed 14,000 cfs for only a few days (del Rosario et al. 2013), so the flow differences in Figure O.3-29 incompletely represent the likelihood of triggering pulse flows occurring under the two alternatives.

Results from a more recent analysis suggest that the reduction in November flows from the No Action Alternative to Alternative 3 during wet and above normal water years could adversely affect Winter-Run Chinook Salmon juveniles emigrating at that time. The NMFS Southwest Fisheries Science Center ran statistical models using 2012-2017 tagging data from Spring-Run Chinook Salmon and Fall-Run Chinook Salmon and found a significant increase in smolt survival when Sacramento River flow at Wilkins Slough was above 9,100 cfs during the smolts out-migration period (Cordoleani et al. 2019). The CalSim II results for November at Wilkins Slough indicate that, under the No Action Alternative, 50% of years would have mean monthly flows that exceed the 9,100 cfs threshold, but that under Alternative 3 only 20% of years would exceed the threshold (Figure O.3-29). If these results apply to Winter-Run juveniles emigrating in November, they indicate a potential adverse effect of Alternative 3 on emigrating Winter-Run juveniles. The applicability of the results to Winter-Run Chinook Salmon are currently unknown, so the effect on Winter-Run is uncertain.

The USEPA (2003) gives 61°F as the critical 7 day average daily maximum (7DADM) water temperature for Winter-Run Chinook Salmon juveniles rearing in the upper Sacramento River and 64°F (7DADM) for those rearing in the middle Sacramento River (Knights Landing). Under the No Action Alternative, NMFS's RPA 1.2.4 requires Reclamation to maintain water temperature from May 15 through October 31 in the Sacramento River at no more than 56°F at compliance locations between Ball's Ferry and Red Bluff Diversion Dam. Under Alternative 3, SWRCB's WRO 90-5 has similar but more flexible water temperature requirements for Reclamation. Therefore, under both alternatives, juveniles rearing in the upper Sacramento River are likely to be well protected from water temperature extremes through the end of October in all but the driest years.

Under the No Action Alternative and Alternative 3, mean monthly water temperatures at Keswick exceed the 61°F threshold in only about 5% of years in September and October, with no appreciable water temperatures differences between the alternatives for water temperatures greater than the 61°F threshold (Figures O.3-18 and O.3-20). The monthly average temperatures for these months should reasonably estimate daily mean temperatures because operations at Shasta and Keswick dams create relatively stable summer and fall flow and water temperature conditions in the upper Sacramento River. From November through March, by which months most juvenile Winter-Run Chinook Salmon have emigrated to the Delta, there are only minor differencs in mean water temperatures at all locations from Keswick Dam to Knights Landing (Tables O.3-26 through O.3-31).

The water temperature effects on juvenile Winter-Run Chinook Salmon rearing in or emigrating from the Sacramento River resulting from Alternative 3 would be less-than-significant relative to the No Action Alternative, but the flow effects are potentially significant because the reductions in September flows in wet and above normal water years could reduce rearing habitat and the reductions November flows in wet and above normal water years could reduce smolt survival.

Adult Upstream Migration and Holding

Winter-Run Chinook Salmon adults enter the Sacramento River from the Delta and make their way to the upper Sacramento River, beginning as early as December. They hold in the upper River within 10 to 15 miles of Keswick Dam until they are ready to spawn, which may extend through August (Windell et al. 2017).

There are no flow or temperature requirements for the middle Sacramento River designed to protect fish. However, releases from Shasta Reservoir during November through early May may be reduced to conserve water for the May through October Winter-Run and Spring-Run Chinook Salmon spawning and incubation periods, resulting in reduced flow in the middle river (NMFS 2011: RPA I.2.2; SWRCB 1990: WRO 90-5). Lower flow in the Sacramento River relative to flow from the lower Yolo and Sutter bypasses and agricultural drains may affect navigation cues and straying of Winter-Run adults into canals and behind weirs, increasing their stranding risk. Once the adults reach holding habitat in the upper Sacramento River, they are more directly affected by Shasta and Keswick reservoir operations designed to preserve cold water for the Winter-Run and Spring-Run Chinook Salmon spawning and incubation periods. During the December through August period of adult Winter-Run Chinook Salmon immigration and holding, the mean monthly flows under Alternative 3 at Keswick Dam, RBDD, Hamilton City and Wilkins Slough would generally be similar to or greater than flows under the No Action Alternative, except during December of below normal and dry water years at Keswick and December of below normal water years at RBDD (Tables O.3-43, O.3-50). The mean monthly CalSim II flows in December of below normal water years are greater than 6,500 cfs at all four sites for both alternatives, which is much higher than needed enough to allow upstream passage.

The USEPA (2003) gives 68°F as the critical 7DADM water temperature for Winter-Run Chinook Salmon adults migrating upstream in the Sacramento River and 61°F for adult Winter-Run Chinook Salmon holding in the upper river. There are no major differences in HEC-5Q water temperature estimates between the No Action Alternative and Alternative 3 during any of the months that adult Winter-Run Chinook Salmon migrate upstream in the Sacramento River or hold in the upper river (Tables O.3-44 through O.3-49). However, the monthly mean water temperatures are moderately cooler under Alternative 3 at Hamilton City and Knights Landing sites during May and June in some of the water year types (Tables O.3-48 and O.3-49). Under both alternatives, the mean monthly water temperatures in the middle Sacramento River (Knights Landing) would be below the 68°F threshold for immigrating adults from December through April, but would exceed the threshold in May of critically dry water years and June through August of all water year types (Table O.3-49). Most Winter-Run Chinook Salmon adults have migrated upstream of RBDD by late May (see Section O.2.4.2.1, *Winter-Run Chinook Salmon*) and would therefore not be adversely affected by the elevated downstream summer water temperatures. In the upper Sacramento River from Keswick to Balls Ferry, the mean water temperatures would be well below the 61°F threshold for holding adults from December through August under both alternatives (Table O.3-44, O.3-45, and O.3-46).

Alternative 3 is expected to have a less-than-signficant effect on Winter-Run Chinook Salmon adult upstream migration and holding relative to the No Action Alternative.

O.3.7.2.2 Central Valley Spring-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Spring-Run Chinook Salmon adults spawn from August through October with peak spawning in September (see Section O.2.4.2.2, *Spring-Run Chinook Salmon*). Monitoring Spring-Run spawning in the mainstem Sacramento River is complicated due to lack of spatial/geographic segregation and temporal isolation from Fall-Run Chinook Salmon. Most spring-sun spawning occurs between the Keswick Dam and Ball Ferry Bridge (NMFS 2017b). Fry emergence occurs up to 3 months after eggs are spawned (Moyle 2002), so effects of flow in the upper Sacramento River on incubating Spring-Run eggs and alevins potentially occur from August through January, peaking in December.

As previously noted, CalSim II modeling indicates that mean monthly flow released at Keswick Dam under Alternative 3 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 3 flows would be substantially lower (up to 44% lower) than the No Action Alternative flows (Table O.3-43). The higher September and November flows under the No Action Alternative result from Fall X2 releases, which are not included in Alternative 3. Spawning and incubating eggs and alevins could be negatively or positively affected by the flow reductions. Assuming flows are stable enough to avoid dewatering the redds, which as noted previously is an important criterion for operators of Shasta and Keswick dams, the most important effect of flows on eggs and alevins is to transport dissolved oxygen to the developing eggs and alevins and to flush potentially toxic metabolites out of the redds. Although the mean September and November wet and above normal water year flows are substantially lower under Alternative 3 than under the No Action Alternative, the flows under Alternative 3 flows remain sufficiently high (>6,000 and >7,400 cfs for September and November, respectively) to provide the flow velocity needed to keep most redds clean and well oxygenated (Figure O.3-25). Therefore, differences in flow between the No Action Alternative and Alternative 3 are expected to have little effect on Spring-Run Chinook Salmon spawning and incubation habitat.

Differences in water temperature during the Spring-Run Chinook Salmon spawning period may be important. As described previously, HEC-5Q mean October water temperatures at Keswick Dam under Alternative 3 are predicted to be largely similar to the No Action Alternative and above the 53.5°F water temperature threshold most years (Figure O.3-18; Tables O.3-44). Summer mean monthly water temperatures at Keswick Dam are roughly equal under the No Action Alternative and Alternative 3, except for September of above normal water years, which has a 1.2°F higher mean water temperatures under Alternative 3 than under the No Action Alternative (Table O.3-44). Summer mean monthly water temperatures are consistently below the 53.5°F temperature threshold, except in critically dry water years during July through September. The October and November mean water temperatures under Alternative 3 are similar to those under the No Action Alternative and are just above the 53.5°F temperature threshold, except for critically dry water years, when those for both alternatives are well above the threshold (Table O.3-44). For October, the mean water temperature for critically dry water years is 0.95°F higher under Alternative 3 than that under the No Action Alternative. Although the difference in mean October critically dry water year water temperatures between the No Action Alternative and Alternative 3 is not large, it occurs under highly stressful temperature conditions for salmonids eggs and alevins. The largest predicted increase in mean water temperature under Alternative 3 is 1.2°F for September of above normal water years (Table O.3-44). This increase occurs over a range well below the critical temperature threshold and is therefore unlikely to have a large effect on the salmonids. The differences between the No Action Alternative and Alternative 3 in September water temperatures at Keswick Dam are small in relation to downstream areas as described below (Figure O.3-20).

Between the Clear Creek confluence and Balls Ferry, where more of the Spring-Run Chinook Salmon spawning occurs, late spring through early fall water temperatures in the Sacramento River at Clear Creek are slightly warmer than those at Keswick Dam, with larger increases in September water temperature differences between the No Action Alternative and Alternative 3 (Table O.3-45). Summer mean monthly water temperatures are below the 53.5°F temperature threshold, except in drier water years, especially in August and September. At Balls Ferry, the temperatures are warmer still and the September increases are larger (Table O.3-46). The mean September water temperatures for wet and above normal water years at Balls Ferry exceed the critical water temperature threshold under Alternative 3 but not under the No Action Alternative (Table O.3-46). Because the mean monthly water temperatures are higher than the threshold under Alternative 3, the probability or frequency of the threshold being exceeded by daily mean temperatures in September of wet and above normal water years is expected to be higher under Alternative 3 than under the No Action Alternative. The critical temperature threshold for spawning adult Chinook Salmon in the Sacramento River is the same as that for eggs and alevins, 53.5°F (Martin et al. 2017) or 55.4°F (USEPA 2003).

The HEC-5Q modeling results, which show an increased exceedance of the 53.5°F water temperature threshold during September under Alternative 3 relative to the No Action Alternative, suggest that Alternative 3 would have a significant adverse impact on Spring-Run spawning and egg and alevin incubation. It is concluded that Alternative 3 would have a less-than-significant impact on Spring-Run Chinook Salmon spawning and egg and alevin incubation with respect to flow and water temperature.

Juvenile Rearing and Emigration

Spring-Run Chinook Salmon juveniles rear in the Sacramento River primarily from November through early May and most emigrate to the Delta during December and again in March and April (see Section O.2.4.2.2, *Spring-Run Chinook Salmon*). Migratory cues, such as increased flow and/or turbidity from runoff, may spur emigration of juveniles from the upper Sacramento River basin when they have reached the appropriate stage of maturation (NMFS 2009). Inundated floodplain habitats have been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Based on the CalSim II modeling results, during most of the Spring-Run juvenile rearing and emigration period, Sacramento River flow would be higher under Alternative 3 than under the No Action Alternative and many of the increases would be greater than 5% (Tables O.3-43 and O.3-50 through O.3-52). However, the mean monthly flows for November of wet and above normal water years would be much lower under Alternative 3, because of the Fall X2 flows that are included in the No Action Alternative but not Alternative 3. Despite the reductions, the wet and above normal water year November flows under Alternative 3 remain relatively high (Tables O.3-43, O.3-50 through O.3-52; Figures O.3-28 and O.3-29), so they are not expected to substantially affect rearing juveniles. Furthermore, as noted above, emigration occurs primarily in December and in the spring. Mean monthly flows would also be lower under Alternative 3 in December of below normal and dry water years and February and March of dry water years (Tables O.3-43 and O.3-50 through O.3-52).

Results from a recent study suggest that for Spring-Run Chinook Salmon that do emigrate as early as November, the Alternative 3 flow reductions in November of wet and above normal water years would have a potentially adverse effect. The NMFS Southwest Fisheries Science Center ran statistical models using 2012-2017 tagging data from Spring-Run Chinook Salmon and Fall-Run Chinook Salmon and found a significant increase in smolt survival when Sacramento River flow at Wilkins Slough was above 9,100 cfs during the smolts emigration period (Cordoleani et al. 2019). The CalSim II results for

November at Wilkins Slough indicate that 50% of years would have mean monthly flows that exceed the 9,100 cfs threshold under the No Action Alternative, and 20% of years would have flows that exceed the threshold under Alternative 3 (Figure (O.3-29). As shown by recent sampling at RBDD (Figure O.3-31-A), almost all Spring-Run juveniles emigrate from the upper Sacramento River after November, so the percentage of Spring-Run juveniles that would be affected by the expected reductions in November flows at Wilkins Slough would be small. Therefore changes in flow resulting from Alternative 3 are not expected to substantially affect rearing and emigrating juvenile Spring-Run Chinook Salmon.

The USEPA (2003) gives 61°F as the critical 7 day average daily maximum (7DADM) water temperature for Spring-Run Chinook Salmon juveniles rearing in the upper Sacramento River and 64°F (7DADM) for those rearing in the middle Sacramento River (Knights Landing). Under the No Action Alternative and Alternative 3, HEC-5Q estimates of mean monthly water temperatures from Keswick to RBDD do not exceed the 61°F threshold during any month and water year type during the November through May rearing period (Tables O.3-44 through O.3-47). The mean monthly water temperatures for Hamilton City do not exceed the 64°F threshold for the middle Sacramento River during any of the months, but the mean monthly water temperatures for May exceed the middle river threshold at Knights Landing in all water year types under both alternatives. However, the May temperatures are generally lower under Alternative 3 than the No Action Alternative, especially in below normal and dry water years (Table O.3-49). These results indicate that water temperature conditions would be too warm for juvenile Spring-Run Chinook Salmon rearing and emigrating in the middle Sacramento River during May, but would be modestly improved under Alternative 2 relative to the No Action Alternative. It should be noted that May is the last month during spring or summer that Spring-Run Chinook Salmon juveniles are found in the middle river, and it is likely that when water temperatures are too high they emigrate to the ocean before May. However, early emigration could have other adverse effects.

The flow and water temperature effects resulting from Alternative 3 would have a less-than-significant effect relative to the No Action Alternative on juvenile Spring-Run Chinook Salmon in the Sacramento River.

Adult Upstream Migration and Holding

Spring-Run Chinook Salmon adults enter the Sacramento River from the Delta as early as January and make their way to the upper Sacramento River beginning in February, where they hold until ready to spawn in late summer and early fall (Windell et al. 2017). Adults may continue migrating upstream until August, and holding continues until October when spawning is complete. There are no flow or temperature requirements for the middle Sacramento River designed to protect fish. Once the adults reach holding habitat in the upper Sacramento River, they are more directly affected by Shasta and Keswick reservoir operations designed to preserve cold water for the Winter-Run and Spring-Run Chinook Salmon spawning and incubation periods.

During the January through August period of adult Spring-Run Chinook Salmon immigration, the mean monthly CalSim II flows under Alternative 3 at Keswick, RBDD, Hamilton City, and Wilkins Slough would generally be similar to or greater than those under the No Action Alternative, except during February and March of dry water years (Tables O.3-43 and O.3-50 through O.3-52). During the holding period, September flow would be much lower under Alternative 3 than under the No Action Alternative (Tables O.3-43 and O.3-50 through O.3-52; Figure O.3-25), but the mean September Alternative 2 flows at Keswick Dam would not fall below 6,000 cfs over the range of flows for which the alternatives have major flow differences (i.e., upper 50% in Figure O.3-25). A flow of 6,000 cfs would presumably be sufficient to maintain good water quality conditions in the Spring-Run holding habitats. Note that monthly mean flows for these months should reasonably estimate daily mean flows because operations at

Shasta and Keswick dams create relatively stable summer and fall flow and water temperature conditions in the upper Sacramento River.

The USEPA (2003) gives 68°F as the critical 7DADM water temperature for Spring-Run Chinook Salmon adults migrating upstream in the Sacramento River and 61°F for adult Spring-Run Chinook Salmon holding in the upper river. Throughout the January through August period of Spring-Run upstream migration, HEC-5Q water temperatures for Alternative 3 are similar to or slightly lower than those for the No Action Alternative, including greater than 1°F reductions in mean monthly water temperature for May and June in various water year types at Hamilton City and t Knights Landing (Tables O.3-44 through O.3-49). Under both alternatives, the mean monthly water temperatures in the middle Sacramento River (Knights Landing) would be below the 68°F threshold for immigrating adults from December through April, but would exceed the threshold in May of critically dry water years and in June through August of all water year types (Table O.3-49). The high May through August water temperatures would be likely to adversely affect any Spring-Run Chinook Salmon adults that were migrating upstream in those months. High water temperatures were found to cause adult Spring-Run Chinook Salmon in Butte Creek to terminate their upstream migrations, which made them more susceptible to mortality from rising water temperatures (Mosser et al. 2012). The June temperature reductions under Alternative 3 occur in a range slightly above the 68°F threshold and, therefore, would likely have a beneficial effect on upstream migrating adults. In the upper Sacramento River at Keswick Dam to Balls Ferry, the mean water temperatures under both alternatives would be well below the 61°F threshold for holding adults from February through October (Tables O.3-44 through O.3-46). As previously noted, flow below Keswick Dam is relatively stable during the summer and fall months, so monthly mean flows and temperatures are likely to be fairly representative of daily means in those months.

May through August water temperature reductions under Alternative 3, especially in the middle Sacramento River, are expected to have a beneficial effect on adult Spring-Run Chinook Salmon migrating upstream to spawn. Temperatures in the upper River under Alternative 3 and changes in flow in the upper and middle River are expected to have a less-than-significant impact on migrating and holding adults. Therefore, Alternative 3 is expected to have a less-than-significant effect relative to the No Action Alternative on Spring-Run Chinook Salmon with respect to flow, and a minor beneficial effect with respect to water temperature.

O.3.7.2.3 Central Valley Steelhead

Spawning and Egg Incubation

CV steelhead adults spawn from November through April with peak spawning from January through March. Based on the general timing of hatching and fry emergence, eggs and alevins may occur from November through May. Little is known about steelhead spawning locations in the Sacramento River, but it is generally assumed that spawning occurs primarily between Keswick Dam and RBDD.

During the steelhead spawning and incubation period, CalSim II modeling indicates that Alternative 3 flows in wet and above normal years would be substantially lower in November, and generally higher during the winter and spring months (Table O.3-43). Based on PHABSIM results (flow versus weighted usable area [WUA]) developed by the USFWS (2003) for the Sacramento River between Keswick Dam and Battle Creek, changes in flow in wet and above normal years would result in a 14% increase in spawning WUA in November, and less than a 10% decrease in spawning WUA in subsequent months (Figure WUA-SH-S). The differences in flow in other water years would have relatively small, variable effects on the availability of spawning habitat. Therefore, changes in flows under Alternative 3 would have both positive and negative effects on the availability of steelhead spawning habitat relative to the No Action Alternative.

HEC-5Q modeling for Alternative 3 indicates that the water temperatures in the upper Sacramento River during the steelhead spawning and incubation period (November through May) would be similar to those under the No Action Alternative (Tables O.3-44 through O.3-47). Based on the steelhead spawning and incubation threshold of 53°F (see O.3.3 Alternative 1, Central Valley Steelhead Spawning and Egg Incubation), both alternatives would maintain suitable water temperatures for spawning and incubation through April or May in the reach between Keswick Dam and Clear Creek, and there would be no major differences in the frequency and magnitude of water temperatures exceeding 53°F in other months or locations with the primary spawning (Keswick Dam to RBDD). Therefore, changes in water temperatures under Alternative 3 would not likely have significant effects on spawning adults, eggs, and alevins relative to the No Action Alternative.

Juvenile Rearing and Emigration

CV steelhead rear year-round in the Sacramento River, and use the river downstream from spawning areas as both a rearing and migration corridor. The timing of downstream migration is variable but generally peaks in the upper river at RBDD in spring and summer (March through June) and in the lower river at Knights Landing in winter and spring (January through May) (NMFS 2009). The peak migration of yearling and older juveniles through the Delta occurs in March and April (NMFS 2009).

CalSim II modeling indicates that the largest differences in Sacramento River flows between Alternative 3 and the No Action Alternative would occur in the late summer and fall (September and November) of above normal and wet years, and in late spring (most notably May and June) of most water year types, potentially affecting fry and juvenile rearing habitat (Table O.3-43). Based on the flow-habitat relationships for Late Fall-Run Chinook Salmon fry and juvenile life stages (see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration), lower flows under Alternative 3 in the fall of wet and above normal water years would increase the amount of juvenile rearing habitat (as measured by WUA), while higher flows in spring of most water year types would have variable effects on fry and juvenile rearing habitat (Figures O.3-39 and O.3-40). For example, in wet years, reductions in average flows of approximately 6,100 cfs in September and 3,500 cfs in November would increase juvenile WUA by 30% to 40% relative to the No Action Alternative. In below normal years, increases in average flows of approximately 1,600 cfs in May and 2,200 cfs in June would reduce juvenile WUA by approximately 10% relative to the No Action Alternative. These same flow increases would reduce fry WUA by 4% in May and increase fry WUA by 6% in June. Therefore, changes in flows under Alternative 3 would have both positive and negative effects on the availability of steelhead rearing habitat relative to the No Action Alternative.

In the upper Sacramento River, HEC-5Q modeling for Alternative 3 and the No Action Alternative indicates that average water temperatures between Keswick Dam and RBDD would be maintained at or below the "core rearing area threshold" of 61°F (see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration) throughout the year except in summer (July through September) of critically dry water years (Tables O.3-44 through O.3-47). During summer, water temperatures under Alternative 3 would be similar to those under the No Action Alternative except in September of wet and above normal years when average water temperatures would be 0.7 to 3.2°F higher (Tables O.3-44 to O.3-47); however, there would be no major differences in the frequency and magnitude of temperatures above 61°F (Figure O.3-22). Similarly, water temperatures during the steelhead emigration season (January through June) are expected to similar or cooler than those under the No Action Alternative (Table O.3-47 to O.3-49). For example, although water temperatures at Knights Landing would frequently exceed the 64°F "non-core rearing area" threshold in May under both alternatives (e.g., Figure O.3-41), higher spring flows under Alternative 3 would reduce average water temperature by up to 1.2°F (dry water years) (Table O.3-49). Therefore, changes in water temperature under Alternative 3 would not likely have significant effects on rearing and emigrating steelhead relative to the No Action Alternative.

Adult Upstream Migration and Holding

Adult steelhead immigration into Central Valley streams potentially occurs during all months of the year but typically begins in August and continues through March or April (McEwan 2001; NMFS 2014a). In the Sacramento River, adults migrate upstream past RBDD during all months of the year, but primarily during September and October (NMFS 2009). Adults may hold until the spawning season which generally extends from November through April.

During the steelhead immigration and holding period, lower flows in September and November of wet and above normal water years under Alternative 3 could affect immigrating and holding adults. However, mean monthly flows would be maintained at a minimum of 3,250 under both alternatives, and would not differ substantially in frequency and magnitude between the alternatives until flows exceed approximately 5,000 cfs (Figures O.3-25, O.3-27, and O.3-29). Within this flow range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Under both Alternative 3 and the No Action Alternative, HEC-5Q modeling indicates that suitable water temperatures for steelhead immigration in the Sacramento River (based on the immigration threshold of 68°F; see O.3.3 Alternative 1, Central Valley Steelhead Adult Upstream Migration and Holding) would generally not occur until September or October (Table O.3-49). However, under Alternative 3, substantially lower flows in September of wet and above normal water years would increase the frequency of water temperatures exceeding this threshold, resulting in potential delays in migration or adverse physiological effects on migrating adults relative to the No Action Alternative. For example, at Knights Landing, mean monthly water temperatures in September exceeded 68°F approximately 80% of the time compared to 52% of the time under the No Action Alternative (Figure O.3-24). Therefore, changes in water temperatures under Alternative 3 in September would have a potentially adverse effect on immigrating adult steelhead in the Sacramento River relative to the No Action Alternative. Lower flows in September would also result in higher water temperatures in the upper Sacramento River, potentially affecting holding adults. However, no major differences would be expected to occur in the frequency and magnitude of water temperatures exceeding the threshold for holding adults (61°F; see O.3.3 Alternative 1, Central Valley Steelhead Adult Upstream Migration and Holding) (Figure O.3-22).

O.3.7.2.4 <u>Southern DPS Green Sturgeon</u>

Spawning and Egg Incubation

Green Sturgeon spawn in deep pools (averaging about 28 feet deep) (NMFS 2018b). Eggs from spawning Southern DPS Green Sturgeon have been found in the middle and upper Sacramento River from the GCID oxbow (RM 207) to Inks Creek (RM 265) and spawning is believed to extend upstream to the confluence with Cow Creek (RM 277) (Heublein et al. 2017b). Green Sturgeon spawn primarily from April through July, although they periodically spawn in late summer and fall (as late as October) (Heublein et al. 2009, 2017b, NMFS 2018b). Eggs hatch about a week after fertilization (at 60ºF) (Heublein et al. 2017b). Because the incubation time for Green Sturgeon is so short, the effects analysis period for incubating eggs is considered to be the same as the spawning period. Based on laboratory studies for Northern DPS Green Sturgeon, Heublein et al. 2017b) concluded that the optimal range for normal embryo development of Southern DPS Green Sturgeon is 53 to 64°F, and impaired fitness occurs below 52°F and above 71°F.

During the April through July Green Sturgeon spawning period, CalSim II estimates of mean monthly flows at RBDD (RM 244) under the No Action Alternative and Alternative 3 range from about 5,000 cfs for April of critically dry water years to about 14,300 cfs in July of above normal water years (Table O.3-50). Mean flows during most of this period are moderate (~8,000 cfs to ~12,000 cfs). These flow levels are likely to be suitable for Green Sturgeon spawning and egg incubation, and no adverse effects are expected to result.

Differences in flows between Alternative 3 and the No Action Alternative are small in most months, but flows are moderately higher for Alternative 3 in May and June of all water years, except May of wet years (Table O.3-50). During the August through October period, when Green Sturgeon spawning occurs in occasional years, the flows under both alternatives tend to be lower than those in April through July, but the mean flows would be close to or above 5,000 cfs for all water year types in all three months, which is expected to be adequate for Green Sturgeon spawning and egg incubation. Large reductions in mean flows from the No Action Alternative to Alternative 3 are predicted for September of wet and above normal water years and, although the resulting Alternative 3 mean flows are greater than 5,000 cfs, the flow reductions are so large (45 and 41%, respectively) that conditions for Green Sturgeon spawning and egg incubation are likely to be adversely affected (Table O.3-50). However, September spawning occurs only sporadically so any effect on the Green Sturgeon population would be minor (NMFS 2018b). Therefore, the September flow reductions are expected to have a minor adverse impact on Green Sturgeon.

Based on the HEC-5Q modeling, mean water temperatures during the April through July primary spawning period of Green Sturgeon are below the 53°F and 52°F lower temperature thresholds for Green Sturgeon egg development at Clear Creek and Balls Ferry during many of the months and water year types (Tables O.3-45 and O.3-46). As discussed previously, daily water temperatures are likely to be more variable than monthly mean temperatures, so the reductions of the mean temperatures below the 52 and 53°F thresholds probably underestimate the largest daily reductions below the thresholds.

The HEC-5Q modeling results show little difference in Clear Creek confluence mean water temperatures between Alternative 3 and the No Action Alternative during the April through July primary Green Sturgeon spawning and incubation period (Table O.3-45). Therefore, Alternative 3 is unlikely to cause a reduction in water temperatures relative to the No Action Alternative and thereby would not adversely affect Green Sturgeon spawning and egg incubation.

Larval and Juvenile Rearing and Emigration

As discussed under Alternative 1 (Section O.3.3, *Alternative 1*), the larval period for Green Sturgeon is considered to be April through September. The downstream distribution of Green Sturgeon larvae in the Sacramento River is uncertain, but is estimated to extend to the Colusa area, at RM 157 (Heublein et al. 2017b). The upstream limit is the Cow Creek confluence. Green Sturgeon juveniles rear in the Sacramento River from about May through December (NMFS 2017b). During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near the Cow Creek confluence to the Delta.

CalSim modeling for the Sacramento River at RBDD indicates that mean monthly flows during the April through September period of larval rearing are generally similar between the No Action Alternative and Alternative 3 in April, July and August but would be greater in May (all water years except wet), June (all water years) and September (below normal and dry years) (Table O.3-50). The September reductions in flow from the No Action Alternative to Alternative 3 during wet and above normal years would potentially affect Green Sturgeon larvae adversely because, as discussed above, there appears to be a positive relationship between annual outflow and abundance of White Sturgeon larvae and juveniles, but the applicability of the relationship to Green Sturgeon is uncertain.

CalSim modeling for the Sacramento River at Hamilton City indicates that mean monthly flows during the period of juvenile rearing and emigration, May through December, are generally similar between the No Action Alternative and Alternative 3 except for higher flows under Alternative 3 during May (all years except wet), June (all years), and September (below normal to critically dry) (Table O.3-50). Reductions in flows occur in September and November (wet and above normal years). These reductions in flow could adversely affect Green Sturgeon juveniles under Alternative 3 because, as noted above, there may be a positive relationship between annual outflow and abundance of Green Sturgeon.

There are few notable differences in the HEC-5Q mean monthly water temperature estimates at RBDD or Hamilton City between the No Action Alternative and Alternative 3 during the Green Sturgeon larval and juvenile rearing and emigration period in any month, except for September (Tables O.3-47 and O.3-48). During over half of the years in September, the Alternative 3 water temperature at RBDD is greater than the No Action Alternative temperature, with a maximum difference of about 3°F (Figure O.3-22). Over the range of years for which there are temperature differences, the water temperatures of both the No Action Alternative and Alternative 3 are under the 63°F lower limit of the optimal range for larvae. However, the Alternative 3 water temperatures are closer to the optimal range and therefore would potentially provide more favorable conditions for larval growth and survival. For the juveniles at RBDD, the September water temperatures under the No Action Alternative are below the 59°F lower limit of the optimal temperature range in about half of the years, and under Alternative 3 they are below the optimal range in about a third of the years (Figure O.3-22). The September HEC-5Q temperature estimates for Hamilton City also fall within or are closer to the optimal ranges of Green Sturgeon larvae and juveniles in more years under the Alternative 3 than the No Action Alternative, however overall temperatures are slightly lower in the other months (Table O.3-48; Figure O.3-23).

The CalSim II flow results indicate that Alternative 3 would have a less-than-significant impact on rearing larval and juvenile southern DPS Green Sturgeon relative to the No Action Alternative, and the HEC-5Q water temperature modeling results indicate that Alternative 3 would provide a minor potential benefit to rearing larval and juvenile Green Sturgeon relative to the No Action Alternative.

Adult Upstream Migration and Holding

Green Sturgeon adults enter the Sacramento River from the Delta as early as February and ultimately make their way upstream to spawn in deep pools from the GCID oxbow (near Hamilton City) to the Cow Creek confluence (Heublein et al. 2017b). After spawning, the adults hold in the river for varying amounts of time, but typically emigrate back to the San Francisco Estuary and the ocean from about October through December (Heublein et al. 2017b).

Flows during the February through December period of Green Sturgeon immigration, spawning and holding would generally be similar between Alternative 3 and the No Action Alternative at RBDD, Hamilton City, and Wilkins Slough (Tables O.3-50 through O.3-52). Exceptions include moderately higher mean monthly flows under Alternative 3 at all locations during May and June, and in September during below normal to critically dry years. Substantially lower flows under Alternative 3 occur during September and November during wet and above normal years. All of the more notable flow differences occur within a range of river flows (~5,000 cfs to 14,000 cfs) that are not expected to substantially affect upstream passage of migrating Green sturgeon, but the September and November flow reductions under Alternative 3 at Hamilton City and RBDD could result in reduced habitat quality in holding pool habitats, adversely affecting holding adults.

There are few major differences in mean monthly water temperatures between the No Action Alternative and Alternative 3 in the Sacramento River at Knights Landing during the February through April period that most adult Green Sturgeon migrate upstream or during the later months (through December) when the sturgeon migrate downstream after spawning (Table O.3-49). Temperatures are lower during May and June which would benefit migrating adults by bringing temperatures closer to the 66 degree threshold. However, increases of more than 4°F are expected in September of wet and above normal water years. The means exceed the 66°F threshold for migrating Green Sturgeon adults in both water year types under Alternative 3 and in neither water year type under the No Action Alternative. The mean monthly water temperatures at Knights Landing also exceed the 66°F threshold under both alternatives during June through August of all water year types and May of all but wet years (Table O.3-49). Adults migrating downstream from May through September would potentially be adversely affected by the high water temperatures. However, adults migrating upstream would be less affected because most upstream immigration occurs before late spring (Heublein et al. 2009), when water temperatures are below the 66°F threshold.

During the May through December spawning and post-spawn holding period for Green Sturgeon, the HEC-5Q mean monthly water temperatures at Hamilton City are generally similar between the No Action Alternative and Alternative 3, except for higher temperatures under Alternative 3 in September (Table O.3-48). The mean monthly water temperatures during the hottest months of this period, July through September, range from 58 to 68°F (both in September). The temperatures frequently exceed the 63°F threshold for spawning adults and the 61°F threshold for holding adults during these months. During September, the mean water temperatures only exceed the 63 and 61°F thresholds in wet and above normal years under Alternative 3 but not under the No Action Alternative and the mean water temperatures in the remaining water years are slightly lower under Alternative 3 than under the No Action Alternative. September water temperatures are cooler at RBDD and there is no difference at this location between Alternative 3 and the No Action Alternative in the frequency of the threshold exceedances (Figure O.3-22). During October through December, the mean monthly water temperatures stay below both thresholds in every water year type.

The CalSim II modeling results indicate that for adult southern DPS Green Sturgeon holding in September or November, reduced flows under Alternative 3 would have a potentially significant adverse impact on holding habitat relative to the No Action Alternative. The HEC-5Q modeling results indicate that the water temperatures for September of wet and above normal water years would be substantially higher under Alternative 3 than under the No Action Alternative and would exceed the 61°F thresholds for migrating, spawning and holding adult Green Sturgeon only under Alternative 3. In conclusion, the HEC-5Q results for Alternative 3 are expected to result in substantially less favorable water temperatures for Green Sturgeon in September of wet and above normal water years and moderately more favorable water temperatures in a number of other water year types and months. In combination, the reduced flows in September and November of wet and above normal water years and increased water temperatures in September of wet and above normal water years are expected to have a significant adverse impact on southern DPS Green Sturgeon adults.

O.3.7.2.5 Fall-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Fall-Run Chinook Salmon migrate upstream past RBDD on the Sacramento River between July and December, typically spawning in upstream reaches from October through January, with a peak in October and November. Eggs and alevins are present from October through April. The primary spawning area used by Fall-Run Chinook Salmon in the Sacramento River is the area from Keswick Dam downstream to RBDD. Spawning densities for all Chinook Salmon runs are highest in this reach, but the distribution of spawning fall-run generally extends downstream to spawning areas below RBDD (Gard 2013).

During the Fall-Run Chinook Salmon spawning and incubation period, relatively large reductions in flows in November of wet and above normal water years under Alternative 3 (averaging over 3,000 cfs lower than No Action Alternative flows) would increase the amount of available spawning habitat, while moderate increases in flow in subsequent months (averaging 500 to 2,000 cfs higher than No Action Alternative flows) would decrease available spawning habitat. For example, in wet years, a reduction in average flow of approximately 3,500 cfs in November would increase the amount of available spawning habitat (as measured by WUA) by 72%, while an increase in average flow of approximately 2,000 cfs in December would decrease available spawning habitat by 26% (Figure O.3-35). In above normal years, a reduction in average flow of approximately 3,100 cfs in November would increase the amount of available spawning habitat by 63%, while increases in average flow of 600 cfs in December and 900 cfs in January would decrease available spawning habitat by 8% and 13%, respectively. Therefore, changes in flows under Alternative 3 would have both positive and negative effects on the availability of spawning habitat relative to the No Action Alternative.

HEC-5Q modeling indicates that Alternative 3 would not substantially affect the frequency of water temperatures exceeding the 53.5°F threshold (see O.3.3.1.2, Sacramento River, *Potential changes to aquatic resources in the Sacramento River from seasonal operations*) during the fall-run Chinook Salmon spawning and incubation period (Table O.3-44). Both alternatives would maintain suitable water temperatures for spawning and incubation through April in the reach between Keswick Dam and Clear Creek, and there would be little or no difference in the frequency and magnitude of water temperatures exceeding 53.5°F in other months or locations within the primary spawning area (Keswick Dam to RBDD) (e.g., Figure O.3-117). Therefore, changes in water temperatures under Alternative 3 are not likely to have significant effects on steelhead spawning and incubation relative to the No Action Alternative.

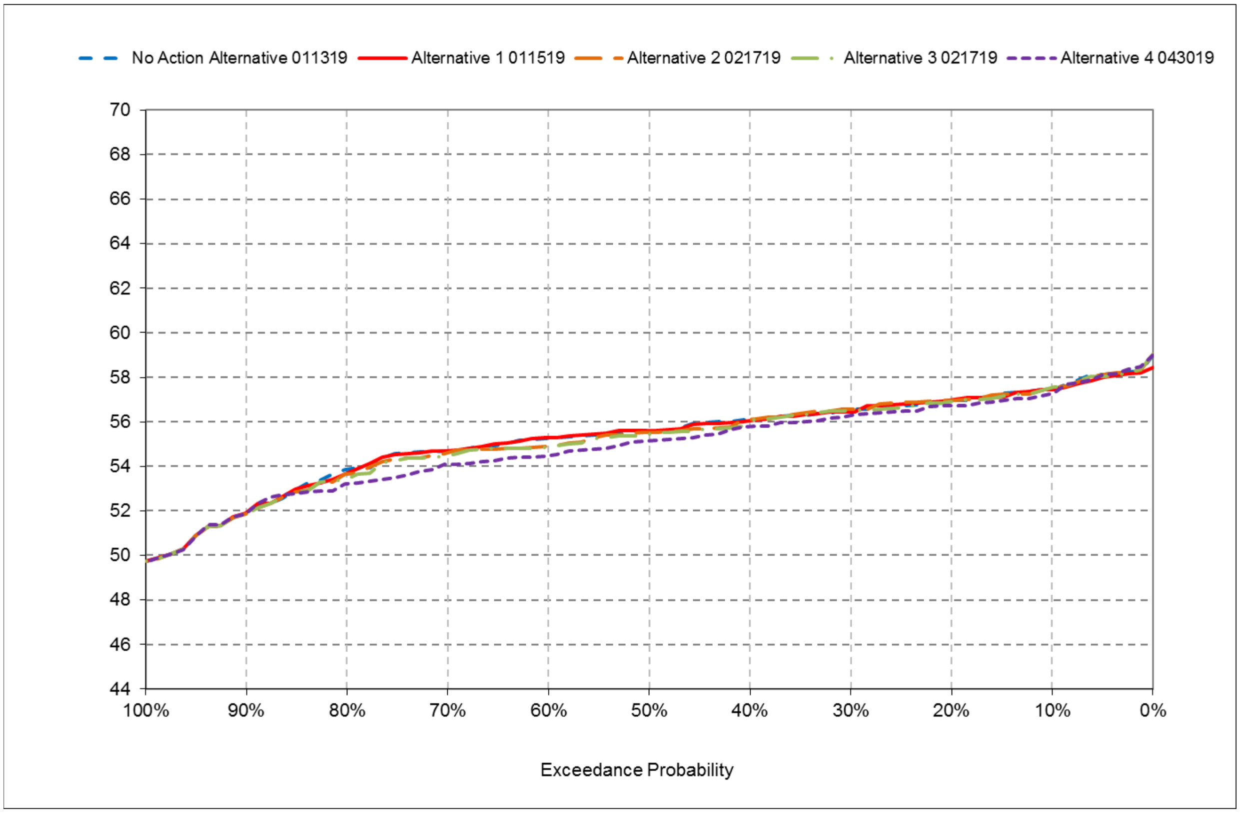

Figure O.3-117. HEC-5Q Sacramento River Water Temperatures at Red Bluff Diversion Dam under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3 and Alternative 4; April

Juvenile Rearing and Emigration

Fall-Run Chinook Salmon juveniles rear in the Sacramento River primarily from December through May. Following emergence, juveniles rear for variable lengths of time in the Sacramento River before entering the Delta and estuary, and may emigrate as fry, parr, or smolts. The timing of emigration is variable but generally peaks in the upper river from January through April and in the lower river from January through May (NMFS 2009).

Under Alternative 3, higher winter and spring flows in the Sacramento River relative to the No Action Alternative could affect rearing and emigrating fall-run Chinook Salmon. Based on the flow-habitat relationships for Fall-Run Chinook Salmon fry and juvenile life stages (see O.3.3 Central Valley Fall-Run Chinook Salmon, Juvenile Rearing and Emigration), higher winter and spring flows under Alternative 3 would generally reduce the amount of available fry and juvenile rearing habitat in the upper Sacramento River (Figures O.3-39 and O.3-40). CALSIM II modeling indicates that the largest differences in flows between Alternative 3 and the No Action Alternative would occur in December of wet years (averaging approximately 2,000 cfs) and in May of below normal and dry water years (averaging approximately 1,500 cfs). Based on the flow-habitat relationships, these flow increases correspond to a 7% reduction in fry WUA in December of wet years, a 13% reduction in juvenile WUA in May of below normal years, and a 12% reduction in juvenile WUA in May of dry years. While these results indicate that Alternative 3 would potentially reduce the availability of suitable rearing habitat for Fall-Run Chinook Salmon relative to the No Action Alternative, uncertainty exists in the importance of this reduction relative to other factors that affect the quantity and quality of rearing habitat for juvenile Chinook Salmon in the Sacramento River.

In the upper Sacramento River, HEC-5Q modeling for Alternative 3 and the No Action Alternative indicates that both alternatives would maintain suitable water temperatures (≤ 61°F; see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration) between Keswick Dam and RBDD during the Fall-Run Chinook Salmon fry and juvenile rearing period (December through May) (Tables O.3-44 through O.3-47). Farther downstream, mean monthly water temperatures in the lower river at Knights Landing would be similar or slightly cooler under Alternative 4 (Table O.3-49), but there would be no differences in the frequency and magnitude of temperatures exceeding the 64°F “non-core rearing area threshold” (Table O.3-49). Therefore, changes in Sacramento River water temperatures under Alternative 3 would not likely have significant effects on rearing and emigrating juvenile Fall-Run Chinook Salmon relative to the No Action Alternative.

Adult Upstream Migration and Holding

Fall-Run Chinook Salmon migrate upstream past RBDD on the Sacramento River between July and December. Adults may hold until the spawning season, which occurs primarily from October through January.

CALSIM II modeling indicates that mean monthly flows in the Sacramento River under Alternative 3 would be substantially lower in September and November of wet and above normal water years relative to the No Action Alternative (Tables O.3-43, O.3-50, and O.3-51), potentially affecting immigrating and holding adults. However, flows under both alternatives would be maintained at or above 3,250 cfs throughout the immigration and holding period. Although flows would differ substantially in September and November, the differences would be limited to flows exceeding approximately 5,000 cfs (Figures O.3-25, O.3-27, and O.3-29). Within this range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Under both Alternative 3 and the No Action Alternative, HEC-5Q modeling indicates that suitable water temperatures for Fall-Run Chinook Salmon immigration in the Sacramento River (based on the immigration threshold of 68°F; see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding) would generally not occur until September or October (Table O.3-49). However, under Alternative 3, substantially lower flows in September would increase the frequency of water temperatures exceeding this threshold, resulting in potential delays in migration or adverse physiological effects on migrating adults relative to the No Action Alternative. For example, at Knights Landing, mean monthly water temperatures in September exceeded 68°F approximately 80% of the time under Alternative 3 compared to 52% of the time under the No Action Alternative (Figure O.3-24). Therefore, changes in water temperatures under Alternative 3 in September would have a potentially adverse effect on immigrating adult Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative. Lower flows in September would also result in higher water temperatures in the upper Sacramento River, potentially affecting holding adults. However, no major differences would be expected to occur in the frequency and magnitude of water temperatures exceeding the threshold for holding adults (61°F; see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding) (Figure O.3-22).

O.3.7.2.6 Late Fall-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Late Fall-Run Chinook Salmon spawn primarily from December through April, and eggs and alevins are present in the gravel from December through June. In the Sacramento River, most adults spawn upstream of Red Bluff Diversion Dam, with the majority spawning between Keswick Dam and the ACID Dam.

CALSIM II modeling indicates that Sacramento River flows under Alternative 3 would generally be higher than or similar to the flows under the No Action Alternative during the Late Fall-Run Chinook Salmon spawning and incubation period (December through June) (Table O.3-43). The largest increases in flow are expected to occur in the winters of wet, above normal, and below normal years, averaging approximately 1,000 cfs to 2,000 cfs higher than flows under the No Action Alternative. Based on PHABSIM results (flow-habitat relationships) developed by the USFWS for the Sacramento River between Keswick Dam and Battle Creek (USFWS 2003a), higher flows under Alternative 3 would reduce the amount of available spawning habitat for Late Fall-Run Chinook Salmon (as measured by WUA) (Figure O.3-38). For example, spawning habitat WUA would be reduced by approximately 16% in December of wet years and 10% in January and February of above normal years. While these results indicate that Alternative 3 would potentially reduce the availability of suitable spawning habitat for Late Fall-Run Chinook Salmon relative to the No Action Alternative, uncertainty exists in the importance of this reduction relative to other factors that affect the quantity and quality of spawning and incubation habitat for Late Fall-Run Chinook Salmon in the Sacramento River.

Similar to Alternative 1, HEC-5Q modeling for Alternative 3 indicates that the water temperatures in the upper Sacramento River during the Late Fall-Run Chinook Salmon spawning and incubation period (December through June) would be similar to those under the No Action Alternative (Tables O.3-44 through O.3-47). Based on the spawning and incubation threshold of 53.5°F (see O.3.3.1.2, Sacramento River, *Potential changes to aquatic resources in the Sacramento River from seasonal operations*), both alternatives would maintain suitable water temperatures from spawning and incubation through May or June in the primary spawning reach (Keswick Dam and Clear Creek), and there would be no major differences in frequency and magnitude of water temperatures exceeding this threshold (Table O.3-44 to O.3-45). Therefore, changes in water temperatures under Alternative 3 are unlikely to have significant effects on spawning adults, eggs, and alevins relative to the No Action Alternative.

Juvenile Rearing and Emigration

Late fall–run Chinook Salmon fry generally emerge from March through June, and juveniles rear in the Sacramento River through the summer before emigrating at a relatively large size (150- to 170-mm fork length) primarily from November through May.

CalSim II modeling indicates that Sacramento River flows under Alternative 3 would generally be higher than or similar to flows under the No Action Alternative during the Late Fall-Run Chinook Salmon rearing period except in September and November of wet and above normal water years when flows would be substantially lower (Table O.3-43). Based on PHABSIM results (flow-habitat relationships) for Late Fall-Run Chinook Salmon fry (<60 mm) and juveniles (≥60 mm) in the upper Sacramento River between Keswick Dam and Battle Creek (USFWS 2005), higher flows during spring and summer would generally reduce the amount of available fry and juvenile rearing habitat (Figures O.3-39 and O.3-40). For example, in below normal water years, higher spring flows under Alternative 3 would reduce fry WUA by 4% to 10% (March to May), increase fry WUA by 8% in June, and reduce juvenile WUA by 9% to 12% in May and June. In September and November of wet and above normal water years, substantially lower flows under Alternative 3 would increase juvenile WUA by 30% to 40% relative to the No Action Alternative. Therefore, changes in flows under Alternative 3 would have both positive and negative effects on the availability of rearing habitat relative to the No Action Alternative.

In the upper Sacramento River, HEC-5Q modeling for Alternative 3 and the No Action Alternative indicates that average water temperatures between Keswick Dam and RBDD would be maintained at or below the "core rearing area threshold" of 61°F (see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration) throughout the year except in the summer (July through September) of critically dry water years (Tables O.3-44 through O.3-47). During summer, water temperatures under Alternative 3 would be similar or cooler than those under the No Action Alternative except in September of wet and above normal years when average water temperatures would be 0.7°F to 3.2°F higher (Tables O.3-44 to O.3-47); however, there would be no major differences in the frequency and magnitude of temperatures above 61°F (Figure O.3-22). Similarly, water temperatures during the Late Fall-Run Chinook Salmon emigration season (November through May) are expected to similar or cooler than those under the No Action Alternative (Table O.3-47 to O.3-49). Although water temperatures would frequently exceed the 64°F "non-core rearing area" threshold by May under both alternatives (e.g., Figure O.3-41), water temperatures at Hamilton City and Knights Landing would average up to 1.2°F cooler in May (Tables O.3-48 and O.3-49). Therefore, changes in water temperature under Alternative 3 would not likely have significant effects on rearing and emigrating Late Fall-Run Chinook Salmon relative to the No Action Alternative.

Adult Upstream Migration and Holding

In the Sacramento River, adult Late Fall-Run Chinook Salmon migrate from October through April, with a peak during January through March (NMFS 2009). Adults hold for 1 to 3 months prior to spawning, which occurs primarily from December through April.

Under Alternative 2, CALSIM II modeling indicates that flows in the Sacramento River during the Late Fall-Run Chinook Salmon immigration period would be similar or higher than those under the No Action Alternative except in November of wet and above normal water years when flows would be substantially reduced relative to the No Action Alternative (Tables O.3-43, O.3-50, and O.3-51). However, flows under both alternatives would be maintained at or above 3,250 cfs throughout the immigration and holding period. Although flows would differ substantially in November, the differences would be limited to flows exceeding approximately 5,000 cfs (Figures O.3-25, O.3-27, and O.3-29). Within this range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Based on the water temperature thresholds for immigration (68°F) and holding (61°F) (see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding), Alternative 3 and the No Action Alternative would maintain suitable water temperatures for Late Fall-Run Chinook Salmon throughout the immigration and holding period (October through April) (Tables O.3-47 and-O.3-49). Therefore, changes in water temperatures under Alternative 3 would not likely have significant effects on immigrating and holding Late Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative.

O.3.7.2.7 White Sturgeon

Spawning and Egg Incubation

White sturgeon spawn in deep water in the middle and lower Sacramento River from Verona (RM 80) to just upstream of Colusa (~RM 156) from late February to early June, but primarily during March and April, (Moyle et al. 2015; Heublein et al. 2017). The adults typically return promptly to the Delta/Estuary after spawning.

During the March and April spawning and egg incubation period of White Sturgeon, CalSim II estimates of mean monthly flows at Wilkins Slough under the No Action Alternative and Alternative 3 range from about 5,300 cfs for April of critically dry water years to about 17,800 cfs for March of wet water years (Table O.3-34). These flow levels are likely to be adequate for White Sturgeon spawning and egg incubation, so no adverse effects are expected to result. Differences in flows between Alternative 3 and the No Action Alternative are small in both months, but flows are moderately higher for Alternative 3 in March of below normal and critically dry water years and April of below normal years (Table O.3-34). It is concluded that Alternative 2 would have no flow effect on White Sturgeon eggs and embryos relative to the No Action Alternative.

The HEC-5Q water temperature modeling results for March and April indicate that mean monthly water temperatures at Knights Landing are below the 63°F threshold for optimal temperatures (see Section O.3.3.1.2, *Sacramento River*), except in April of critically dry water years (Table O.3-49). As noted earlier, the mean monthly water temperatures for water year types combine water temperatures for many years and therefore mask individual year variations. The monthly means for individual years show that April water temperatures exceed the 63°F threshold in 15% of years, but lie below the 68°F lethal temperature in all years (Figure O.3-43). There are no appreciable differences in water temperatures between Alternative 3 and No Action Alternative in March or April (Table O.3-31; Figures O.3-43).

During June, the warmest month of the full spawning and egg incubation period, the mean monthly water temperatures are predicted to exceed the 68°F lethal temperature in all water year types, but the water temperatures are lower for Alternative 3 than for the No Action Alternative, especially in drier water years (Table O.3-49). It is concluded that Alternative 3 would have no water temperature effect on White Sturgeon eggs and embryos relative to the No Action Alternative.

Larval and Juvenile Rearing and Emigration

During the March through June larval period, water temperature modeling indicates that water temperatures frequently exceed water temperature thresholds (61 and 68°F, see Section O.3.3.1.2, *Sacramento River*) at Knights Landing under the No Action Alternative and Alternative 3 (Table O.3-31), especially in June. Such high levels of temperature threshold exceedances suggest that typical water temperature conditions in the lower Sacramento River may be highly stressful for White Sturgeon larvae. In any case, the water temperatures, especially in June, are lower under Alternative 3 than under the No Action Alternative (Table O.3-31). It is concluded that Alternative 3 compared to the No Action Alternative will not have an adverse effect on larval and juvenile rearing.

During the of White Sturgeon juvenile emigration period, approximately April to July, CalSim II results indicate that flows at Wilkins Slough during May and June would increase with Alternative 3 compared to No Action Alternative (Table O.3-14). Alternative 3 may have a beneficial effect on juvenile White Sturgeon.

Adult Upstream Migration and Holding

White Sturgeon adults to initiate their upstream spawning migrations during late winter and early spring, presumably in response to elevated flows (Heublein et al. 2017). CalSim II flows at Wilkins Slough for December through February are not much different between Alternative 3 and No Action Alternative for all water year types. There are a few months and water year types when flows are higher under Alternative 3, such as December during wet years and January during below normal years. Increased flows potentially benefit White Sturgeon migration, but all flows are between 7,700 and 18,900 cfs, which are suitable for migration. There are no temperature differences from December through February for Knights Landing. Alternative 3 would have no flow or water temperature effects on White Sturgeon adults.

O.3.7.2.8 <u>Sacramento Splittail</u>

Sacramento Splittail occur in the Sacramento River upstream of the Delta from about December through May. The adults spawn in river-margin and inundated floodplain habitats in February through April (Feyrer et al. 2005, 2006; Sommer et al. 2007; Moyle et al. 2015). The larvae hatch several days after spawning then rear for about a month in habitat similar to the spawning habitat (Moyle et al. 2004). The juveniles rear upstream and then begin their downstream migration during April and May, as the river level recedes back to the channel (Moyle et al. 2004; Feyrer et al. 2005). Floodplain spawning in wet years overwhelmingly dominates production, but spawning in side channels and channel margins is important during low-flow years when floodplains are not inundated. In the Sacramento River drainage, splittail spawn from Colusa to Knights Landing, but the most important spawning areas are the inundated floodplains of the Yolo and Sutter bypasses (Feyrer et al. 2005).

High flows benefit adults migrating upstream (Feyrer et al. 2006), and greatly enhance spawning and rearing habitat for larvae and early juveniles (Crain et al. 2004). Mean monthly flows at Wilkins Slough during January through March of wet and above normal water years consistently equal or exceed 17,000 cfs under both alternatives (Table O.3-43). Figure O.3-44 shows the expected mean February flows for each year of the CalSim II record. About 15% of the years have mean February flows greater than 22,500 cfs, which is the approximate flow at which the Tisdale Weir begins to spill into the Sutter Bypass (DWR 2010b). In any case, differences between Alternative 3 and the No Action Alternative in flows at Wilkins Slough during December through May are relatively minor, and generally result from higher flow under the Alternative 3, especially in May during all water year types except wet years (Table O.3-52). It is concluded that Alternative 3 would have no flow effects on Sacramento Splittail relative to the No Action Alternative.

Preferred water temperature for Sacramento splittail ranges from about 66°F for adults to about 75°F for juveniles, and the “upper limit of safe temperatures” ranges from about 75°F for adults and 81°F for juveniles (Young and Cech 1996). Mean monthly water temperatures during December through May at Knights Landing, which is at the approximate downstream limit of splittail spawning in the Sacramento River, range up to 68°F under both alternatives in May of critically dry water years (Table O.3-49). There are no meaningful water temperature differences between the alternatives at Knights Landing during the December through May period that Sacramento Splittail occupy the river upstream of the Delta, except in May of below normal and dry water years when water temperatures are just over 1°F lower under Alternative 3 than the No Action Alternative (Table O.3-49). There is evidence that some juvenile splittail remain in the Sacramento River well upstream of the Delta through the entire year (Feyrer et al. 2005), but summer water temperatures in the more upstream locations where they have been found are considerably cooler than those at Knights Landing (compare Tables O.3-48 and O.3-49). Therefore, Alternative 3 is considered to have no adverse water temperature effects on splittail relative to the No Action Alternative.

The CalSim II flow results for Wilkins Slough and the HEC-5Q water temperature results for Knight Landing indicate that Alternative 3 would not have an adverse impact on Sacramento Splittail relative to the No Action Alternative.

O.3.7.2.9 Pacific Lamprey

Sacramento River Pacific Lamprey adults enter the Sacramento River from the Delta primarily during about March through June and hold in the river for about a year prior to spawning (Moyle et al. 2015). Spawning occurs in gravel redds in the upper river from March through July. The eggs and pro-larvae incubate for about 1 to 1.5 months. After the larvae (ammocoetes) emerge, they drift downstream and burrow into fine sediments primarily in off-channels habitats, where they rear (Schultz et al. 2014; Moyle et al. 2015). After 5 or more years, the ammocoetes metamorphose to the macropthalmia (juvenile) stage and migrate downstream to the Delta and ocean, typically migrating from March through June during pulse flow events (Moyle et al. 2015).

River flow potentially affects survival of Pacific Lamprey eggs and larvae, and migratory habitat of the juveniles and adults. Pacific lamprey build their spawning redds in shallow water (about 0.5 to 3.5 feet) (Gunckel et al. 2009; Schultz et al. 2014; Moyle et al. 2015), so reductions in water level can dewater the redds. The larvae select habitats, often off-channel, with fine sediments, low flow velocity, and shallow depths (~1 ft), so they are vulnerable to stranding by reductions in water level. Migrations of the juveniles and adults may be triggered by surges in flow (Moyle et al. 2015).

The types of variations in flow that potentially affect Pacific Lamprey, as described above, often occur on a time scale of hours or days, and therefore may not be detectable using the CalSim II monthly time-step modeling results. However, the CalSim II results mostly show no large difference in Sacramento River flow between the No Action Alternative and Alternative 3, so there is no reason to expect much difference in short period flow fluctuations between the alternatives. The biggest differences in monthly mean flows occur in September and November of wet and above normal water years, when flows are much lower under Alternative 3 than the No Action Alternative because Alternative 3 operations do not include releases for Fall X2 flows (Table O.3-50; Figures O.3-25 and O.3-28). Pacific lamprey are generally done spawning by late July and the prelarvae have finished emerging from their redds by early September. In contrast, the larvae are present in the river yearround and so could be vulnerable to flow reductions during September and November. However, water levels during these months are generally relatively stable because they are largely determined by Shasta and Keswick dam releases rather than runoff. The adults and juveniles carry out their migrations primarily during March through June. CalSim II modeling flow results for these months are generally higher under Alternative 3 than under the No Action Alternative (Tables O.3-13 and O.3-14). Therefore, Alternative 3 and the No Action Alternative are expected to similarly affect Pacific Lamprey with respect to flow in the Sacramento River.

As described for Alternative 1, laboratory studies conducted on Columbia River Pacific Lamprey indicated that survival of incubating eggs and pre-larvae and of young larvae was greatest at a water temperature of 64°F and lowest at the highest water temperature included in the study, 72°F (Meeuwig et al. 2005). HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River between Keswick and RDBB during the March through August spawning and egg/prelarvae incubation period would be consistently below 64°F, with minor differences between the alternatives (Tables O.3-26 through O.3-29). During September, when Pacific Lamprey larvae would be present in the river, mean water temperatures would exceed the 64°F optimal temperature at RBDD in critically dry water years. September has the highest water temperatures of the year upstream of RBDD. Mean September water temperatures at RBDD for individual years exceed 64°F in about 7% of years for both alternatives, but are below 72°F for all years (Figure O.3-22). The downstream distribution of Pacific Lamprey larvae is uncertain, but if the larvae drift well downstream of RBDD or enter the Sacramento River from downstream tributaries, they would be subject to higher water temperatures, especially during July and August. However, there are few differences between July and August water temperatures at the lower temperature modeling sites, except in below normal water years when water temperatures are about 1°F cooler under Alternative 3, which would likely benefit the larvae (Table O.3-48 and O.3-49; Figure O.3-45). There are no biologically meaningful differences in water temperature conditions for Pacific Lamprey between the No Action Alternative and Alternative 3.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 3 would have a less-than-significant impact on Pacific Lamprey relative to the No Action Alternative.

O.3.7.2.10 River Lamprey

River Lamprey adults migrate from the ocean to spawning areas during the fall and late winter (Beamish 1980). Spawning is believed to occur from February through May in small tributary streams (Moyle 2002). The redds are built at the upstream end of small riffles (Moyle 2002). After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juvenile (macrothalmia) migrate downstream in the following year from May to July (Moyle 2002).

River flow potentially affects survival of River Lamprey eggs and larvae, and migratory habitat of the juveniles and adults. River lamprey build their spawning redds in shallow water (Moyle et al. 2015), so reductions in water level can dewater the redds. Assuming River Lamprey larvae habitat requirements are similar to those of Pacific Lamprey, the larvae select habitats, often off-channel, with low flow velocity and shallow depths, so they are vulnerable to stranding by reductions in water level.

The types of variations in flow likely to cause redd dewatering and stranding of larvae often occur on a time scale of hours or days and, therefore, may not be detectable using the CalSim II monthly time-step modeling results. However, the CalSim II results mostly show no large differences in Sacramento River flow between the No Action Alternative and Alternative 2, so there is no reason to expect much difference in short period flow fluctuations between the alternatives. The biggest differences in monthly mean flows occur in September and November of wet and above normal water years, when flows are lower under Alternative 3 than the No Action Alternative because Alternative 3 operations do not include releases for Fall X2 flows (Table O.3-50; Figures O.3-25 and O.3-28). River lamprey are generally done spawning by May and, assuming their incubation times are similar to those of Pacific Lamprey, the prelarvae complete their emergence from redds by June or July. In contrast, the larvae are present in the river yearround and so could be vulnerable to flow reductions during September and November. However, water levels during these months are generally relatively stable because they are largely determined by Shasta and Keswick dam releases rather than runoff.

The juveniles carry out their migrations during May through July. CalSim II modeling flow results for May and June at Hamilton City and Wilkins Slough are higher under Alternative 3 than under the No Action Alternative, except in May of wet years, but flows for July are generally slightly lower (Tables O.3-51 and O.3-52). The adults migrate upstream primarily in the fall and winter and could be adversely affected by the September and November reductions in flow under Alternative 3 relative to the No Action Alternative (Table O.3-52), but little is know about flow needs of migrating adult River Lamprey.

Overall, Alternative 3 and the No Action Alternative are expected to similarly affect River Lamprey with respect to flow in the Sacramento River.

The water temperature requirements of River Lamprey have not been studied, but they are assumed to be similar to those of Columbia River Pacific Lamprey with 64°F for maximum survival of eggs and prelavae and 72°F and above for minimum survival (Meeuwig et al. 2005). HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River between Keswick and RDBB during the February through May spawning and egg/prelarvae incubation period would be consistently below 64°F, with minor differences between the alternatives (Tables O.3-44 through O.3-47). It should be noted that River Lamprey are believed to spawn in tributary streams rather than the mainstem, but this is uncertain (Moyle et al. 2015). During September, when River Lamprey larvae would be present in the river, mean water temperatures would exceed the 64°F optimal temperature at RBDD in critically dry water years. September has the highest water temperatures of the year upstream of RBDD. Mean September water temperatures at RBDD for individual years exceed 64°F in about 7% of years for both alternatives, but are below 72°F for all years (Figure O.3-22). The downstream distribution of River Lamprey larvae is uncertain, but if the larvae drift well downstream of RBDD or enter the Sacramento River from downstream tributaries, they would subject to higher water temperatures, especially during July and August. However, there are few differences between July and August water temperatures at the downstream temperature modeling sites, except in below normal water years when water temperatures are about 1 dgree Fahrenheit cooler under Alternative 3, which would likely benefit the larvae (Table O.3-48 and O.3-49; Figure O.3-45). There are no biologically meaningful differences in water temperature conditions for River Lamprey between the No Action Alternative and Alternative 3.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 1 would have a less-than-signficant impact on River Lamprey relative to the No Action Alternative.

O.3.7.2.11 Hardhead

Hardhead are believed to spawn in riffles, runs, and heads of pools, primarily during April and May (Moyle et al. 2015). Most spawning probably occurs in tributaries rather than in the Sacramento River mainstem (Moyle et al. 2015). Larvae and juveniles likely inhabit stream margins with abundant cover, and move into deeper habitats as they grow larger. Adults occupy the deepest part of pools. Juvenile and adult Hardhead are present in the Sacramento River year-round. They tend to prefer water temperatures near 67°F (Thompson et al. 2012), but have been captured at RBDD, where water temperatures are generally much cooler (USFWS 2002) (Table O.3-9).

Spawning success of Hardhead in the lower Tuolumne River is highest when there are higher flows during in April and May (Brown and Ford 2002), which is likely true for the Sacramento River Hardhead as well. The CalSim II results for Keswick, Red Bluff, Hamilton City, and Wilkins Slough indicate that monthly mean flow would be moderately higher under Alternative 3 than under the No Action Alternative during the April and May peak spawning months (Tables O.3-43, O.3-50 through O.3-52). During most of the other months, flows would generally be similar between Alternative 3 and the No Action Alternative, but, from Keswick Dam to Wilkins Slough, they would be 9 to 33% higher under Alternative 3 in June of all water year types and would be 25% to 36% lower in September and November of wet and above normal water years. The large flow reductions in September and November would likely have little effect on hardhead because they are predicted for wet and above normal years, when flows are generally high, and because by September and November, hardhead hatched in the spring would be well developed and have gravitated to deeper water. Similarly, the large flow increases in June would likely have little effect because June flows are adequate under both alternatives. The flow effects of Alternative 3 are not expected to substantially affect hardhead.

Hardhead juveniles and adults performed well in laboratory tests at water temperatures from about 61 to 70°F (Thompson et al. 2012). They consistently preferred a mean water temperature of 67°F and avoided temperatures above about 79°F. HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River would be below 79°F at all locations under both alternatives (Tables O.3-44 through O.3-49). There would be only minor differences in mean water temperatures between the alternatives, except for moderate increases under Alternative 3 during September of wet and above normal water years. However, these mean water temperatures would be only slightly warmer than the Hardhead preferred temperature, and only at Knights Landing (Table O.3-49). There are no biologically meaningful differences in water temperature conditions for Hardhead between the No Action Alternative and Alternative 3.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 3 would have no impact on Hardhead relative to the No Action Alternative.

O.3.7.2.12 Central California Roach

Given that most Central California Roach inhabit tributary streams rather than the mainstem Sacramento River and have a broad range of habitat types and temperature tolerances, as discussed under Alternative 1, it is unlikely that flow or water temperature conditions under Alternative 3 would adversely affect California Roach. Therefore, Alternative 3 is expected to have no impact on Central California Roach relative to the No Action Alternative.

O.3.7.2.13 Striped Bass

Striped Bass spawn in the Sacramento River primarily between about Verona (RM 78) and Wilkins Slough (RM 121) during April through June (Moyle 2002). No spawning occurs until water temperature reaches 57 degrees Fahrenheit (Moyle 2002). The eggs are free-floating and negatively buoyant and hatch in about two days after spawning (at 66°F) as they drift downstream. Low flows can result in eggs settling on the bottom, which they cannot survive for long. The larvae may inhabit shallow, open water of the lower river from April to mid-June and then are carried by flows to the Delta and Suisun Bay (Stevens 1966; Moyle 2002). Adult striped bass are found in the upper Sacramento River at RBDD and upstream, primarily from late spring through early fall, where they forage heavily on juvenile salmon and other fish (Tucker et al. 1998).

High flows in April through June benefit striped bass eggs because they help prevent them from settling to the river bottom. High flows likely also accelerate transport of Striped Bass larvae to their nursery habitats in the Delta and Suisun Bay (Moyle 2002). CalSim II flow results for Wilkins Slough indicate that mean monthly flow during April through June under Alternative 3 would be similar to or higher than flow under the No Action Alternative, with higher flow especially in May and June, which would potentially benefit conditions for eggs and larvae drifting downstream (Table O.3-34). The greatest reductions in flow resulting from Alternative 3 would occur in September and November of wet and above normal water years. Adult Striped Bass may reside throughout the Sacramento River in September (Tucker et al. 1998). However, although the Alternative 3 mean monthly flows are reduced from the No Action Alternative flows in wet and above normal years, they remain close to or well above 5,000 cfs (Table O.3-50 through O.3-52), which is likely adequate for foraging Striped Bass.

Optimal spawning temperature range for Striped Bass is 59 to 68°F and spawning ceases at about 70°F (Moyle 2002). The eggs can withstand temperatures of about 54 to 75°F, with the optimum being about 64°F (Emmett et al. 1991). Larvae tolerate temperatures of 50 to 77°F, but optimal temperatures for survival are 59 to 72°F (Emmett et al. 1991). Striped Bass adults and juveniles are tolerant of a wide range and rapid swings of water temperatures. The adults appear to prefer water temperatures ranging from about 68 to 75°F (Emmett et al., 1991) and juveniles prefer rearing temperatures of 61 to 66°F (Hasler 1988). Adults are under stress at temperatures over 77°F, and temperatures over 86°F are lethal (Moyle 2002).

HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River at Knights Landing during the April through June spawning period would be within the optimal range for spawning in April of all but wet years and in May of all but critically dry years, but would be above the optimal range in June during all water year types (Table O.3-49). The mean monthly temperatures would be below the optimal range for adults during April and May of all water year types except critically dry years in May, but would be within this range in all water year types in June. The temperatures would be acceptable for eggs and optimal for larvae throughout the spawning period (Table O.3-49). Juvenile striped bass generally do not occur in the Sacramento River upstream of the Delta. The adults, as noted earlier, may forage in the river upstream to and above RBDD from about May through early October. Mean monthly water temperatures at RBDD throughout this period would be well below the optimal range for adults (Table O.3-47).

The largest difference in water temperatures between the No Action Alternative and Alternative 3 at Knights Landing during the Striped Bass spawning season are moderate reductions in May of below normal and dry years and June of above normal, below normal and dry water years (Table O.3-31). With these reductions, water temperatures under Alternative 3 would be closer to the optimal range for spawning than those under the No Action Alternative, providing a minor benefit. The largest temperature differences at any time of year are substantial increases under Alternative 3 for September of wet and above normal water years. These increases would be potentially beneficial for foraging Striped Bass adults because the No Action Alternative water temperatures for these months and water year types would be well below the optimal range for adults throughout the river (Tables O.3-47 through O.3-49).

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 3, with regard to flow and water temperature, would have a less-than-significant impact on Striped Bass relative to the No Action Alternative.

O.3.7.2.14 American Shad

American shad migrate upstream in the Sacramento River starting in March, and typically spawn from April to June. Water temperature influences the timing of runs, with peak runs and spawning usually occurring at water temperatures of 62 to 75°F (Moyle 2002). Shad eggs drift downstream from spawning areas and hatch in 3 to 12 days, depending on water temperature (MacKenzie et al. 1985). However, more rapid development at higher temperatures appears to be associated with lower survival rates of embryos (Moyle 2002). Larval shad are planktonic for about 4 weeks, after which they metamorphose to actively swimming juveniles. Juveniles spend the next several months in freshwater, and seem to prefer temperatures of 63 to 77°F. In the Sacramento River, summer rearing habitat occurs in the main river from Colusa to the north Delta (Stevens et al. 1987). As the season progresses, juvenile shad move downstream and enter salt water primarily during September through November (Moyle 2002). In general, variations in river discharge and temperature during early larval development are considered important regulators of year-class strength and recruitment of American shad (Hinrichsen et al. 2013). Although the importance of various potential mechanisms is unknown, the abundance of juvenile American shad in the Sacramento-San Joaquin Delta has been shown to be positively correlated with freshwater inflow during the April through June spawning and nursery periods (Stevens et al. 1987, Kimmerer 2002, Kimmerer et al. 2009).

During the spawning and larval rearing period (April through June), CalSim II modeling results at Wilkins Slough indicates that average monthly flows in May and June under Alternative 3 would be higher than those under the No Action Alternative, which may have positive effects on spawning and early rearing success of American shad (Table O.3-52). In addition, with higher flows under Alternative 3, HEC-5Q modeling results indicate that mean monthly temperatures in the lower Sacramento River (Knights Landing) during May and June would be lower on average, which may improve water temperatures for developing embryos and larvae (Table O.3-49; Figures O.3-41 and O.3-91). The largest differences in flows and water temperatures in the Sacramento River under Alternative 3 and the No Action Alternative would occur in September and November of wet and above normal water years (Table O.3-49 and O.3-52). However, the importance of river inflows and river temperatures for juvenile shad in September and November is unknown. Correlations between Delta inflows and abundance of juvenile shad have been demonstrated for the months of April through August, with the highest correlations in April through June, suggesting that the principal factors influencing abundance occur during periods of larval dispersal and transport. Sacramento River flows and temperatures under Alternative 3 may have minor benefits to American Shad relative to the No Action Alternative, but because the potential effects are highly uncertain, Alternative 3 is considered to have a less-than-significant effect on American Shad.

O.3.7.2.15 Largemouth Bass

The Sacramento River above the Delta generally provides poor habitat conditions for Largemouth Bass because of large seasonal flow fluctuations, relatively cold water, and lack of suitable nesting and rearing habitat. Consequently, Largemouth Bass populations in the Sacramento River above the Delta are largely dependent on upstream sources, including reservoirs, floodplain ponds and sloughs, and irrigation canals that provide suitable conditions for spawning and rearing during the late spring and summer months.

Largemouth bass spawning activity typically starts in April when water temperatures reach 59 to 61°F, and continues through June (Moyle 2002). Nests are typically constructed at a depth of about 3 feet (Brown et al. 2009a). Optimal temperatures for successful spawning and incubation are 68 to 70°F, although spawning is generally observed over a range of 55°F to 79°F (Stuber et al. 1982). Eggs hatch in 2 to 7 days after spawning and the sac fry usually spend 5 to 8 days in the nest until they begin actively feeding (Moyle 2002). Optimal temperatures for growth of juvenile and adult bass range from 77 to 86°F, although growth will occur over a much wider range (50°F to 95°F) (Moyle 2002).

The CALSIM II and HEC-5Q modeling results for Alternative 3 indicate that Sacramento River flows would be higher and water temperatures would be lower in May and June relative to the No Action Alternative, potentially affecting largemouth bass spawning and incubation (Tables O.3-49 and O.3-52). However, based on modeled mean monthly water temperatures in the lower Sacramento River at Knights Landing, no substantial changes would be expected to occur in the frequency of suitable water temperatures for spawning and incubation (Figures O.3-41 and O.3-91). The relatively large changes in flows and water temperatures in September and November of wet and above normal years under Alternative 3 (Tables O.3-49 and O.3-52) could also affect habitat conditions for juvenile and adult bass, but water temperatures would remain below optimum levels for growth under both alternatives. Consequently, the generally poor habitat conditions for largemouth bass in the Sacramento River under the No Action Alternative would persist under Alternative 3. Therefore, changes in Sacramento River flows and water temperatures associated with Alternative 3 would have a less-than-significant effect on largemouth bass in the Sacramento River relative to the No Action Alternative.

O.3.7.2.16 Smallmouth Bass

The temperature optimal range for Smallmouth Bass spawning is 55 to 70°F (Brown et al. 2009b) and the optimal for adult growth is approximately 77 to 80°F, but rapid growth of has been seen in the wild at temperatures as high as 84°F, providing prey is abundant (Moyle 2002). Young-of-year Smallmouth Bass will select temperatures as high as 84 to 87°F. Populations are rarely established in water temperatures that do not exceed 66°F in summer for extended periods, and most smallmouth populations in California are present where summer temperatures are typically 69 to 71°F. In northern California reservoirs most spawning takes place in May and June, but spawning in streams may occur into July, depending on flows and temperatures. Males start making nest depressions when water temperatures reach 55°F to 61°F. The nests are typically built at depths of about 3 to 8 feet (Brown et al. 2009). In streams, nesting and reproduction can be disrupted by flow reductions that lead to nest dewatering, or elevated flows that wash embryos and fry out of nests or lower water temperatures excessively (Graham and Orth 1986; Lukas and Orth 1995).

CalSim II results for Wilkins Slough flow for Alternative 3 compared to No Action Alternative during the May through July spawning season indicate moderately increased flow during May and June of all of the water year types, except May of wet years, and slightly reduced flow in July, except in critically dry water years (Table O.3-52). Higher flows could adversely affect embryos and fry by dewatering nests or washing them out of the nests, but it is unknown what magnitude of flows would have these effects.

HEC-5Q monthly mean water temperatures at Hamilton City consistently fall within the 55°F to 70°F optimal spawning range during the spawning season of May through July under both Alternative 3 and the No Action Alternative (Table O.3-48). At Knights Landing, however, the temperatures fall within the optimal range during May of all water year types, but lie above the range during June and July of most water year types (Table O.3-49). The water temperatures under Alternative 3 are generally similar or moderately lower than those under the No Action Alternative. The monthly mean summer water temperatures at Hamilton City consistently fall below the 66°F threshold that has been found to be a minimum for Smallmouth Bass to establish populations in California (Moyle 2002), except for critically dry water years in August and September (Table O.3-48). At Knights Landing, however, the 66°F threshold is exceeded in all summer months and water year types except September of wet and above normal years under the No Action Alternative (Table O.3-49). Note that the large wet-and-above-normal-year September water temperature increases under Alternative 3 result in water temperatures exceeding the threshold, which may benefit Smallmouth Bass. The mean water temperatures are consistently well below the optimal range for adult growth, 77 to 80°F, at both locations.

The CalSim II flow and HEC-5Q water temperature results indicate that Alternative 3 would have a less-than-significant impact on Smallmouth Bass relative to the No Action Alternative with regard to flow and water temperature.

O.3.7.2.17 <u>Spotted Bass</u>

Spotted Bass inhabit streams and reservoirs and prefer moderate-size, clear, low-gradient sections of rivers and reservoirs (McKechnie 1966). They prefer pool habitat and slower, more turbid water than Smallmouth Bass but faster water than Largemouth Bass (Moyle 2002). Their summer water temperature preference is 75 to 87°F (Moyle 2002). In streams, nests are constructed in low-current areas on bottoms ranging from debris to gravel (Moyle 2002). Spawning depths are deeper than those of largemouth bass (Aasen and Henry 1981). They spawn in the spring when water temperatures rise to 59°F to 64°F (Aasen and Henry 1981; Howland 1931). Spawning continues through late May and early June, until temperatures reach 71 to 73°F.

During the spring (April through June) spawning season, CalSim II results for Wilkins Slough monthly mean flows under Alternative 3 are mostly higher than the No Action Alternative flows (Table O.3-52). Higher flows could adversely affect embryos and fry by dewatering nests or washing them out of the nests, but it is unknown what magnitude of flows would have these effects.

HEC-5Q monthly mean water temperatures at Knights Landing during the spawning season of April through June would largely be within the 59°F to 64°F spawning range in April under Alternative 3 and the No Action Alternative, but would exceed the range in May and June under both alternatives. The preferred summer water temperatures range of 75 to 87°F would be available only in critically dry years, especially in August, under both Alternative 3 and the No Action Alternative (Table O.3-49).

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 3, with regard to flow and water temperature, would have a less-than-significant impact on Spotted Bass relative to the No Action Alternative.

Potential changes to aquatic resources in the Sacramento River from Shasta cold water pool management

Shasta Cold Water Pool Management will not occur under either Alternative 3 or the No Action Alternative. Therefore, Alternative 3 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to some potential effects of this action. However, the No Action Alternative includes NMFS's 2009 BO RPAs to operate Shasta Reservoir for management of cold water in the reservoir and river for protection of anadromous salmonids, and includes requirements for Fall X2 flow releases, but Alternative 3 includes neither requirement. The effects of these differences in operations on water temperatures and flows in the Sacramento River and potential effects on water temperature and flow differences on the focal fish species in the river are discussed above in the assessments for the individual fish species in the section *Potential changes to aquatic resources in the Sacramento River from seasonal operations* under Alternative 3.

Potential changes to aquatic resources in the Sacramento River from spring pulse flows.

Spring Pulse Flows for fish will not occur under either Alternative 3 or the No Action Alternative. Therefore, Alternative 3 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

Potential changes to aquatic resources in the Sacramento River from fall and winter refill and redd maintenance.

Fall and winter refill and redd maintenance will not occur under either Alternative 3 or the No Action Alternative. Therefore, Alternative 3 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

Potential changes to aquatic resources in the Sacramento River from rice decomposition smoothing.

Rice decomposition smoothing will not occur under either Alternative 3 or the No Action Alternative. Therefore, Alternative 3 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

Potential changes to aquatic resources in the Sacramento River from spring management of spawning locations.

Rice decomposition smoothing will not occur under either Alternative 3 or the No Action Alternative. Therefore, Alternative 3 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

O.3.7.3 *Clear Creek*

O.3.7.3.1 Whiskeytown Reservoir Operations

Alternative 3 would incorporate the same flow and operations as described in Alternative 2 to meet requirements in D-1641 and other legal requirements and would incorporate habitat restoration and intervention measures. Under both the No Action Alternative and Alternative 3, flows from Whiskeytown Dam to Clear Creek would be managed for base flow of 50 cfs to 100 cfs based on downstream water rights and the 1963 Reclamation proposal to USFWS and NPS. Unlike the No Action Alternative, there would be no planned channel maintenance flows or pulse flows released from Whiskeytown Dam under Alternative 3.

Under current operations and the No Action Alternative, Whiskeytown Lake is annually drawn down 13 feet (approximately 35 TAF) between November and April for flood control purposes, although it can be lowered as much as 30 feet as needed for maintenance. Model output for Whiskeytown Lake predicts that compared to the No Action Alternative, minimum reservoir volumes would be lower under Alternative 3 during the months of May and June (1.3 TAF and 0.1 TAF lower, respectively) (Figure O.3-118, Table 0.3-53). During those two months, water surface elevations would also be lower under Alternative 3 compared to the No Action Alternative. In April, water surface elevations would be 1.6 TAF higher under Alternative 3 compared to the No Action Alternative. In all other months, Whiskeytown Lake storage volume under Alternative 3 would be either identical or 0.1 TAF to 0.2 TAF higher than under the No Action Alternative.

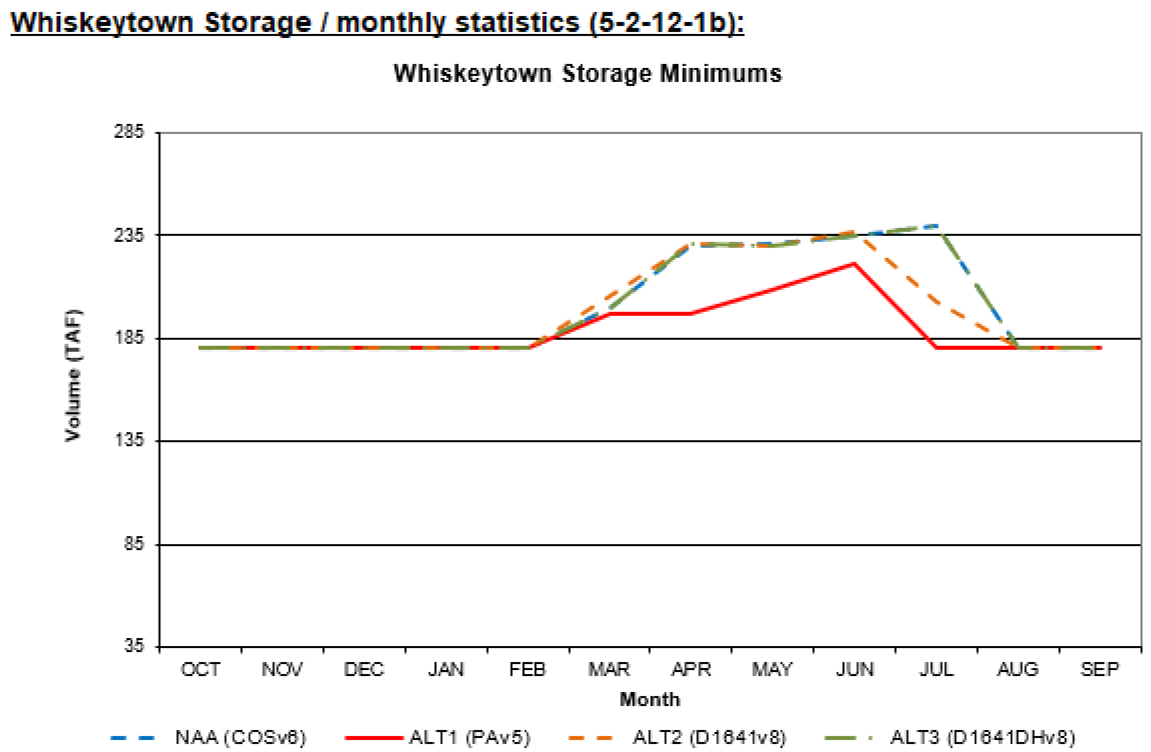

Figure O.3-118. Modeled Whiskeytown Lake Monthly Minimum Storage Volume under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 during all Water Year Types

Table 0.3-53. Modeled differences in Whiskeytown Lake monthly minimum storage volumes from March to July under Alternative 3 relative to the No Action Alternative.

Month	Change in Volume from No Action Alternative (TAF)
March	0.2
April	1.6
May	-1.3
June	-0.1
July	0.0

The proposed additional seasonal draw-downs in May and June under Alternative 3 could cause an increase in bank and bed erosion in newly exposed areas of tributary stream mouths where they are devoid of stabilizing riparian vegetation. This scour could cause channel incision (i.e., down-cutting) and result in increased lake water turbidity. Channel incision can create erosional nick points that propagate upstream until they encounter scour-resistant grade-controlling materials such as bedrock, at which point a cascade can form. However, annual minimum storage volume is not expected to change under this alternative. The additional draw-downs therefore represent a change in timing and duration of lower water surface elevation, not a new type or mechanism of disturbance, and channel incision may have already occurred and stabilized as a result of past operations.

Potential changes to aquatic resources in Clear Creek from seasonal variation in water surface elevation

Hardhead

Hardhead migrate from the reservoir into tributaries in April and May to spawn upstream of Whiskeytown Lake. The timing of proposed increased draw-downs from March through July under Alternative 3 could affect Hardhead if the lower water surface elevations in May expose any previously submerged cascades at tributary mouths or create new ones. No such cascades have been documented, but if they are present or created by tributary incision at low water, they could present barriers to migration that would prevent reservoir-dwelling adult Hardhead from spawning in tributary streams. Alternately, higher water surface elevation in April may benefit migrating Hardhead at the start of their upstream migration season.

Hardhead are not a cold-water species, so drawing additional cold water from the bottom layers of the reservoir would not be expected to affect them directly. Hardhead have shown sensitivity to high sediment loads (Gard 2002), so increased reservoir turbidity due to varial zone erosion during draw-down periods could reduce suitability of reservoir and downstream waters for Hardhead persistence.

The increased annual variations in reservoir water surface elevation under Alternative 3 could cause Hardhead to be affected by reducing habitat connectivity and increasing water turbidity. However, changes to storage volume and water surface elevation in Whiskeytown Lake are relatively small under Alternative 3 compared to the No Action Alternative, and higher water surface elevation in April could benefit migrating Hardhead at the start of their upstream migration season.

Other Fish Species

Central California Roach are not likely to be affected by changes in reservoir operations because, although they are found in upstream tributaries, they do not reside in Whiskeytown Lake, having likely been extirpated from the reach after the reservoir was originally filled in 1963. Future operations of Whiskeytown Dam under Alternative 3 are therefore unlikely to affect either individuals or populations.

Increased annual variations in reservoir water surface elevation under Alternative 3 compared to the No Action Alternative could cause varying effects to stocked and introduced nonnative game species in Whiskeytown Lake. Stocked species would not be expected to be affected by changes in reservoir operations. Rainbow Trout, Brown Trout, Kokanee Salmon, and Brook Trout typically spawn in tributary streams, but they are capable of spawning in lakes if they are unable to access moving water. Whiskeytown Lake Kokanee spawn in the fall, a period when no differences in water levels are expected under Alternative 3 compared to the No Action Alternative. Pond species such as Largemouth Bass, Smallmouth Bass, Spotted Bass, Bluegill, Black Crappie, Channel Catfish, and Brown Bullhead are able to tolerate a wide range of conditions, but the basses and panfish spawn in relatively shallow lake areas when water warms to at least 50°F in late spring or summer. Reducing reservoir volume in May and June could put some of their nests at risk of being dewatered in years when springtime conditions are warm. However, these species have rapid reproductive rates which can enable them to recover from episodic recruitment failures.

O.3.7.3.2 Clear Creek Flows

Potential changes to aquatic resources in Clear Creek from variation in flow

Under Alternative 3 Reclamation proposes minimum base flows in Clear Creek of 50 cfs to100 cfs in normal water years and 30 cfs to 70 cfs in critically dry water years, based on downstream water rights and the 1963 Reclamation proposal to USFWS and NPS, as described in the No Action Alternative (Table 3). Alternative 3 flows do not include predetermined CVPIA 3406(b)(2) flows and NMFS BO Action I.1.1, which are included in the No Action Alternative. Additionally, under Alternative 3 there are no channel maintenance flows or pulse flows, whereas under the No Action Alternative channel maintenance flows occur when flood operations occur and 2 pulse flows are released in May and June of at least 600 cfs for at least 3 days for each pulse per year.

Modeling results show that flows and temperatures in Clear Creek downstream of Whiskeytown Dam would be the same under Alternative 3 as those described under Alternative 2. Effects of flow and water temperature in Clear Creek downstream of Whiskeytown Dam to listed species would be the same under Alternative 3 and Alternative 2.

O.3.7.3.3 Spring Creek Debris Dam

Existing operations of the SCDD will continue under both Alternative 3 and the No Action Alternative. Therefore, Alternative 3 and the No Action Alternative are likely to have similar effects on aquatic resources.

O.3.7.3.4 Clear Creek Restoration Program

The Clear Creek Restoration Program is being implemented under both Alternative 3 and the No Action Alternative. Therefore, Alternative 3 and the No Action Alternative are likely to have similar effects on aquatic resources.

O.3.7.4 *Feather River*

O.3.7.4.1 <u>FERC Project #2100-134</u>

DWR, under Alternative 3, would operate Oroville Dam consistent with the NMFS, USFWS, and CDFW environmental requirements applicable for the current FERC License for the Oroville Complex (FERC Project #2100-134). Reclamation would operate Oroville Dam with minimum flows of 700 cfs to 800 cfs below the Thermalito Diversion Dam in the low flow channel (2006 Settlement Agreement), 750 cfs to 1,700 cfs below the Thermalito Afterbay outlet (1983 DWR-CDFG Agreement), and the DFG/DWR operation objective of 2,800 cfs at the mouth of the Feather River from April through September, with options to vary flow depending on year types. Under the No Action Alternative, DWR would operate Oroville Dam in accordance with ongoing management policies, criteria, and regulations, including water right permits and licenses issued by the SWRCB and operational requirements of the 2008 USFWS BO and the 2009 NMFS BO. Under the No Action Alternative, DWR typically releases water from Lake Oroville to meet the requirements of instream flows and D-1641.

Potential changes to aquatic resources in the Feather River due to seasonal variation in flow

CalSim II model output shows that Feather River flows under Alternative 3 and the No Action Alternative would comply with Feather River HFC minimum instream flow requirements during all months in wet, above normal, and below normal water years. In dry years where the preceding April to July unimpaired runoff is less than 55% of normal, Alternative 3 and the No Action Alternative would comply with minimum instream flow requirements in the HFC; however, where the preceding April to July unimpaired runoff is greater than 55% of normal, Alternative 3 would not comply with minimum instream flow requirements from October through March (Figure O.3-119). In critically dry years where the preceding April to July runoff is 55% or greater of normal, Alternative 3 and the No Action Alternative would not comply with minimum instream flows from October to March; however, where the preceding April to July runoff is less than 55% of normal, Alternative 3 and the No Action Alternative would not comply with minimum instream flow requirements in the HFC only in November (Figure O.3-119).

Overall, flows under Alternative 3 and the No Action Alternative are similar, but flows under the No Action Alternative are greater than flows under Alternative 3 from July through September of wet and above normal, and below normal years, and flows under Alternative 3 are greater than under the No Action Alternative from April through June of below normal, and dry water years (Figure O.3-121). Flows under Alternative 3 are also much greater than under the No Action Alternative in February of below normal years.

Overall, flows under Alternative 3 and the No Action Alternative are similar, but flows under the No Action Alternative are greater than flows under Alternative 3 from July through September of wet and above normal, and below normal years, and flows under Alternative 3 are greater than under the No Action Alternative from April through June of below normal, and dry water years (Figure O.3-121). Flows under Alternative 3 are also much greater than under the No Action Alternative in February of below normal years.

Figure O.3-119. CalSim II Estimates of Feather River Long-Term Average Flow below Thermalito, All Scenarios in Wet, Above Normal, Below Normal, Dry, and Critically Dry Water Years

Winter-Run Chinook Salmon

Winter-Run Chinook Salmon are not likely to be affected by changes in flow under Alternative 3 compared to the No Action Alternative due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Spring-Run Chinook Salmon would be exposed to the effects of Alternative 3 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Eggs and emerging fry of Spring-Run Chinook Salmon occur in the Feather River from September through February (NMFS 2016a); juvenile Spring-Run Chinook Salmon occur in the Feather River year-round, with peak abundance from November through May; and adult Spring-Run Chinook Salmon have a peak abundance in the Feather River from March through June. All life stages would thus be exposed to the effects of Alternative 3.

Spring-Run Chinook Salmon eggs and emerging fry would potentially benefit from increased Alternative 3 flows, leading to increased dissolved oxygenand decreased temperature in February of dry years when Alternative 3 flows are significantly higher than No Action Alternative flows (Figure O.3-119). Juvenile Spring-Run Chinook Salmon would benefit from increased Alternative 3 flows relative to No Action Alternative flows from November through March of wet years, January through April of above normal years, and February of below normal years when the increased flows could result in increased rearing and foraging habitat, higher dissolved oxygencontent, and reduced water temperatures (Figure O.3-119). Adult Spring-Run Chinook Salmon would benefit from increased Alternative 3 flows relative to No Action Alternative flows from April through June of below normal, dry, and critically dry years due to the resulting increased attraction flows and holding habitat (Figure O.3-119). Because Alternative 3 flows are higher than No Action Alternative flows during key months of all Spring-Run Chinook Salmon life stages, Alternative 3 may provide benefits for Spring-Run Chinook Salmon.

Fall-Run Chinook Salmon

Fall-Run Chinook Salmon would be exposed to the effects of Alternative 3 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Fall-Run Chinook Salmon occur in the Feather River year-round, with eggs and emerging fry occurring between January and April, juveniles out-migrating year-round with peaks from January to April and August to November, and holding and migrating adults occurring between April and July (NMFS 2016a). All life stages would thus be exposed to the effects of Alternative 3.

Fall-Run Chinook Salmon eggs and emerging fry would benefit from increased dissolved oxygenand decreased temperatures due to higher Alternative 3 flows from January to April of wet and above normal years and in February of below normal years (Figure O.3-119). Juvenile Fall-Run Chinook Salmon could benefit from increased Alternative 3 flows relative to No Action Alternative flows from January to April of wet and above normal years and in February of below normal years when increased flows result in increased rearing and foraging habitat, higher DO, and reduced water temperatures (Figure O.3-119). Migrating adult Fall-Run Chinook Salmon would benefit from increased Alternative 3 flows relative to No Action Alternative flows from April to July of below normal, dry, and critically dry years due to increased attraction flows and holding habitat (Figure O.3-119). Because Alternative 3 flows are higher than No Action Alternative flows during key months of all Fall-Run Chinook Salmon life stages, Alternative 3 may provide benefits for Fall-Run Chinook Salmon.

Central Valley Steelhead

Central Valley Steelhead would be exposed to the effects of Alternative 3 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Central Valley Steelhead eggs and fry occur in the Feather River from December to May; juveniles typically migrate to the ocean from January to May after spending 1 to 3 years in freshwater (CDFG 1996); peak adult migration occurs in September and October; and adult holding occurs December to March (NMFS 2016a).

Alternative 3 flows can affect Central Valley Steelhead by influencing water temperature, DO, sedimentation, substrate composition, habitat, food availability, predation, entrainment and stranding risk, habitat availability, and migration cues. Differences in flow under Alternative 3 and the No Action Alternative are minimal during the January to May period in which Central Valley Steelhead juveniles are out-migrating in all but below normal water years when Alternative 3 flows are considerably higher than No Action Alternative flows from mid-January through mid-March and can benefit juveniles via increased rearing and foraging habitat, higher dissolved oxygencontent, and reduced water temperatures (Figure O.3-119). The same is true for the December to May period in which Central Valley Steelhead eggs and fry are present in the Feather River. During the September and October adult peak migration period, No Action Alternative flows are considerably higher than Alternative 3 flows in September in wet and above normal water years, causing higher levels of flow attraction (Figure O.3-119); there are minimal differences in all other water years. During adult holding from December to March, differences between Alternative 3 and No Action Alternative flows are minimal except for in February of below normal water years when increased flows could increase available habitat. Because Alternative 3 flows are higher than No Action Alternative flows during key months of all Central Valley Steelhead life stages, Alternative 3 may provide benefits for Central Valley Steelhead.

North American Green Sturgeon

North American Green Sturgeon would be exposed to the effects of Alternative 3 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Green Sturgeon eggs and larvae occur in the Feather River from March to July; larvae and juveniles occur from April to August; subadults occur year-round; and adults occur from March to August (NMFS 2016a).

Differences in flow under Alternative 3 and the No Action Alternative are minimal during all water years in the March to August period in which Green Sturgeon eggs, larvae, juveniles, and adults occur in the Feather River; subadults occur year-round. Thus, only subadults would be exposed to the larger differences between Alternative 3 and the No Action Alternative in February of below normal water years when Alternative 3 flows are greater than they are under the No Action Alternative and in September of above normal and wet water years when No Action Alternative flows are greater than they are under Alternative 3. Because flow differences between Alternative 3 and the No Action Alternative during key periods of Green Sturgeon presence in the Feather River are minimal flow-related actions under Alternative 3 are not anticipated to substantially affect North American Green Sturgeon.

Potential changes to aquatic resources in the Feather River due to changes in water temperature from differences in flow

Water flow combines with other environmental drivers to affect aspects of water quality such as temperature. Water temperatures influence the condition and survival of fish species during all stages of their life cycle. Optimal water temperatures can facilitate physiological responses including faster growth rates, reduced stress, and heightened immunity to disease, leading to a higher likelihood of survival. In contrast, effects of elevated water temperatures include an inability to satisfy metabolic demand and acute to chronic physiological stress, possibly leading to mortality (Stillwater Sciences 2006; Martin et al. 2017).

Water temperatures in the Feather River HFC at Gridley Bridge follow a seasonal pattern with a high point around 72°F in July or August and a low point around 47°F in January (Figure O.3-120). Flow releases from Oroville facilities primarily influence Feather River water temperatures in summer and fall when these releases can help alleviate elevated water temperatures. Minimum water temperatures in the Feather River do not change substantially between water year type, but water temperatures can reach a maximum up to 4°F warmer (approximately 75°F) in critically dry years than in wet years (approximately 71°F; Figure O.3-121). Effects of water temperature on fish in the Feather River vary among species and life stages. Temperatures surpass suboptimal levels for all species and life stages at 68°F and stress-inducing levels at 75.2°F (Table O.3-54). There is, therefore, potential for adverse temperature-related effects on Feather River fish species.

Alternative 3 was designed to follow flow regulation procedures similar to procedures under the No Action Alternative as a way to minimize potential adverse temperature-related effects on various fish species in the Feather River. Certain water temperature objectives were developed to aid the development of Alternative 3 operations (Table O.3-55).

Table O.3-54. Water temperatures suitable for Spring- and Fall-Run Chinook, Central Valley Steelhead, and Green Sturgeon by life stage

Life Stage	Peak Occurrence	Optimal	Suboptimal	Stress-inducing
Spring-Run Chinook				
Eggs to fry	September to October	< 54°F	54°F to 58°F	> 58°F
Rearing to out-migrating	November to May	< 60°F	60°F to 65°F	> 65°F
Migrating adults	March to June	< 56°F	56°F to 65°F	> 65°F
Adult holding	May to August	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Fall-Run Chinook				
Eggs to fry	October to April	48.2°F to 55.4°F	55.4°F to 62.6°F	> 62.6°F
Rearing to out-migrating	April to June	55.4°F to 68°F	68°F to 75.2°F	> 75.2°F
Migrating adults	June to April	50°F to 68°F	68°F to 69.8°F	> 69.8°F
Central Valley Steelhead				
Eggs to fry	January	46°F to 52°F	52°F to 55°F	> 55°F
Rearing to out-migrating	January to May	< 65°F	65°F to 68°F	> 68°F
Migrating adults	September to October	< 52°F	52°F to 70°F	> 70°F
Adult holding	December to March	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Green Sturgeon				
Eggs to fry	May to July	53°F to 65°F	65°F to 66°F	> 66°F
Rearing to out-migrating	May to October	58°F to 66°F	66°F to 69°F	> 69°F
Migrating adults	March to May	53°F to 64°F	64°F to 66°F	> 66°F
Post-spawn adults	March to August	46°F to 68°F	68°F to 70°F	>70°F

Table 0.3-55. Maximum Daily Mean Water Temperature Objectives for the Feather River HFC

Period	Temperature (°F)
January 1 to March 31	56
April 1 to 30	61
May 1 to 15	64
May 16 to 31	64
June 1 to August 31	64
September 1 to 8	61
September 9 to 30	61
October 1 to 31	60
November 1 to December 31	56

Source: NMFS 2016a.

Modeled average water temperatures under both Alternative 3 and the No Action Alternative (Figure O.3-120) exceed the daily average water temperature objectives of 64°F from June 1 to August 31 and 61°F from September 1 to 30 (Table O.3-120). There is, therefore, potential for adverse temperature-related effects on Feather River anadromous fish species, although the presence and magnitude of these effects would vary between the different species and life stages. In particular, these modeled average temperatures would reach suboptimal or stress-inducing levels for Spring-Run Chinook eggs, fry, and adults, migrating Central Valley Steelhead, and Green Sturgeon eggs, fry, and post-spawn adults.

Modeling results indicate that water temperatures under Alternative 3 operations would be similar to temperatures under the No Action Alternative for much of the year (Figures O.3-120 and O.3-121). In August and September water temperatures in the Feather River at Gridley Bridge are projected to be, on average, up to 1°F warmer than under the No Action Alternative (Figure O.3-120). The most pronounced difference in August and September water temperatures between Alternative 3 and No Action Alternative scenarios would occur in wet years when this temperature difference could reach as much as 3°F and 1°F warmer in below normal years, whereas no difference is projected in dry or critically dry water years (Figure O.3-121). In below normal to dry water years, a notable difference in water temperature between Alternative 3 and No Action Alternative scenarios would occur instead in June, when Alternative 3 water temperatures would be lower than No Action Alternative temperatures by approximately 4°F (Figure O.3-121). In below normal to dry water years, a small difference in water temperature between Alternative 2 and No Action Alternative scenarios would also occur in July, when Alternative 2 water temperatures would surpass No Action Alternative temperatures by approximately 1°F (Figure O.3-121). These differences in water temperature between Alternative 3 and the No Action Alternative would therefore predominantly occur in summer months when water temperatures are higher (> 60°F) and more likely to lead to physiological stress and mortality.

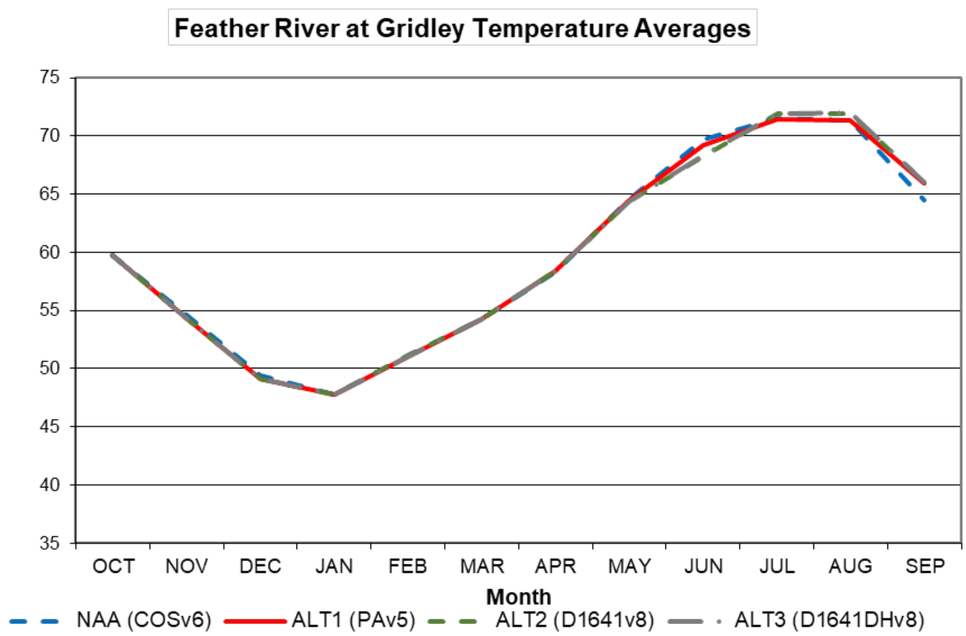

Figure O.3-120. RecTemp average Feather River water temperatures at Gridley Bridge under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 scenarios.

Figure O.3-121. RecTemp Average Estimated Feather River Water Temperatures at Gridley Bridge in Wet, Above Normal, Below Normal, Dry, and Critically Dry Water Year Types under the No Action Alternative, Alternative 1, Alternative 2, and Alternative 3 Scenarios

Winter-Run Chinook Salmon

Winter-Run Chinook are not likely to be affected by changes in flow under Alternative 3 compared to the No Action Alternative due to their limited distribution in the Feather River.

Spring-Run Chinook

Effects of water temperature on Spring-Run Chinook have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-54).

In the Feather River, Spring-Run Chinook eggs and emerging fry occur from September to February, peaking in abundance from September to October (NMFS 2016a). The only difference in water temperature between Alternative 3 and No Action Alternative scenarios during this period would occur in September of wet to dry water years when temperatures under Alternative 3 flows would be higher than temperatures under No Action Alternative flows (Figure O.3-121). This would result in potentially adverse effects from the slightly higher water temperatures under Alternative 3 than under the No Action Alternative, yet water temperatures under both scenarios would fall in the stress-inducing range for this life stage (Table O.3-54). The slightly higher water temperatures in September under Alternative 3 in wet and above normal water years, therefore, would result in a negligible adverse effect on Spring-Run Chinook eggs and emerging fry relative to the effect of the No Action Alternative.

The occurrence of rearing juvenile Spring-Run Chinook in the Feather River is possible year-round, but peak abundance is usually between November and May. During this period of peak abundance, there is little to no projected difference between water temperatures under Alternative 3 and the No Action Alternative (Figure O.3-120); therefore, the effect of water temperatures on juvenile Spring-Run Chinook would be negligible under Alternative 3 operations relative to operations under No Action Alternative.

Migrating adult (ocean to river) Spring-Run Chinook reach the Feather River between March and June at generally consistent levels across all four months. During the first three months of this time span, water temperatures would be nearly identical under Alternative 1 and the No Action Alternative (Figure O.3-120). In June of above normal and dry water years, however, water temperatures under Alternative 2 could be up to 4°F lower than under the No Action Alternative (Figure O.3-121), yet modeled water temperatures are above the threshold for stress-inducing temperatures for migrating adults under both Alternative 2 and the No Action Alternative (Table O.3-54). Effects of water temperature on this life stage, therefore, are anticipated to be slightly less severe under Alternative 3 than under the No Action Alternative.

Holding adult Spring-Run Chinook have the potential to occur in the Feather River from March to September with peak abundance between May and August. As indicated by the RecTemp model, Feather River water temperatures would be similar under Alternative 3 and the No Action Alternative during peak abundance and the majority of the possible time range (Figures O.3-120 and O.3-121) but would differ in June and September of wet to normal water years when temperatures under Alternative 3 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-121). Additionally, water temperatures in normal to dry water years would also differ when temperatures under Alternative 3 flows would be up to 4°F lower than temperatures under No Action Alternative flows (Figure O.3-121). Water temperatures in most water type years would then remain at stress-inducing levels for holding adults for an additional month under Alternative 3 than under the No Action Alternative when they would drop to the suboptimal range in September and June (Table O.3-54). Alternative 3 operations would therefore result in slightly adverse temperature-related effects on holding adult Spring-Run Chinook relative to the effects under the No Action Alternative in September and slightly lower adverse effects in June.

Alternative 3 has the potential for slightly adverse water temperature-related effects on eggs and fry, but very slightly beneficial effects on migrating adults and holding adults, so its overall effect on Spring-Run Chinook relative to the No Action Alternative is slightly adverse.

Fall-Run Chinook Salmon

Effects of water temperature on Fall-Run Chinook have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-54).

In the Feather River, Fall-Run Chinook eggs and emerging fry occur from October to April (CDFG 2012c). During this period there is no projected difference between water temperatures under Alternative 3 and the No Action Alternative (Figures O.3-120 and O.3-121); therefore, the effect of water temperatures on Fall-Run Chinook eggs and fry would be negligible under Alternative 2 operations relative to under No Action Alternative operations.

Juvenile Fall-Run Chinook typically occur in the Feather River from April to June. During the first two months of this time span, water temperatures would be essentially identical under Alternative 3 and the No Action Alternative (Figures O.3-120 and O.3-121). In June of below normal and dry water years, however, water temperatures under Alternative 3 could be up to 4°F lower than under the No Action Alternative (Figure O.3-121). The effect of this temperature difference would be slightly beneficial as temperature in these years would likely rise to suboptimal levels for juvenile Fall-Run Chinook under Alternative 3 and the No Action Alternative.

Migrating adult (ocean to river) Fall-Run Chinook reach the Feather River between June and April. This time span includes the slightly higher August and September water temperatures under Alternative 3 in wet and above normal years as well as the slightly lower June water temperatures in normal to dry years (Figure O.3-121). For migrating adult Fall-Run Chinook, water temperatures under Alternative 3 would then reach suboptimal and stress-inducing levels a couple of weeks more in summer of wet and above normal water than under the No Action Alternative but would drop to suboptimal and optimal levels approximately a couple of weeks more than under the No Action Alternative scenario in early summer of years below normal and dry water years (Figure O.3-121 and Table O.3-54). The net effect of Alternative 3 water temperatures on migrating adult Fall-Run Chinook relative to the No Action Alternative would be expected to be slightly adverse overall but would ultimately depend on rainfall levels experienced in the watershed.

Alternative 3 has the potential for slightly beneficial water temperature-related effects on juveniles and slightly adverse on migrating adults. Overall effect on Fall-Run Chinook relative to the No Action Alternative is slightly beneficial.

Central Valley Steelhead

Effects of water temperature on Central Valley Steelhead have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-54).

Central Valley Steelhead eggs and emerging fry occur in the Feather River from December to May, peaking in abundance in January (NMFS 2016a). Under Alternative 2 and the No Action Alternative, water temperature estimates for all water year types are essentially identical throughout this time period (Figure O.3-121), so no effect of Alternative 3 relative to the No Action Alternative is expected for Central Valley Steelhead eggs and fry.

Rearing juveniles typically migrate to the ocean from January to May after spending 1 to 3 years in freshwater (CDFG 1996). Under Alternative 3 and the No Action Alternative, water temperature estimates for all water year types are nearly identical throughout this time period (Figure O.3-121). Therefore, no effect of Alternative 3 relative to the No Action Alternative is expected for juvenile Central Valley Steelhead.

Migrating adult (ocean to river) Central Valley Steelhead reach the Feather River between September and October. Modeled water temperatures for Alternative 3 and the No Action Alternative differ in September of wet and above normal water years when temperatures under Alternative 3 could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-121), yet water temperatures would remain in the suboptimal range for migrating adults under Alternative 3 and the No Action Alternative (Table O.3-54). Adverse effects of water temperature on this life stage are therefore anticipated to be slightly less severe under the No Action Alternative than under Alternative 3.

Holding adult Central Valley Steelhead have the potential to occur in the Feather River from December to March. Under Alternative 3 and the No Action Alternative, water temperature estimates for all water year types are essentially identical throughout this time period (Figure O.3-121), and no effect of Alternative 3 relative to the No Action Alternative is expected for Central Valley Steelhead eggs and fry.

Alternative 3 has the potential for slightly adverse water temperature-related effects on migrating adults. Overall effects on Central Valley Steelhead under Alternative 3 relative to the No Action Alternative is slightly adverse.

North American Green Sturgeon

Effects of water temperature on North American Green Sturgeon have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-54).

Green Sturgeon eggs and emerging fry occur in the Feather River from May to July (NMFS 2016a). During May, water temperatures would be essentially identical under Alternative 3 and the No Action Alternative (Figures O.3-120 and O.3-121). In June of below normal and dry water years, however, water temperatures under Alternative 3 could be up to 4°F lower than under the No Action Alternative (Figure O.3-121), yet modeled water temperatures are above the threshold for stress-inducing temperatures for eggs and fry under both Alternative 3 and the No Action Alternative (Table O.3-54). However, in July of below normal and dry water years, water temperatures would be up to 1°F higher under Alternative 3 than under the No Action Alternative (Figure O.3-121), and similarly to June would have stress-inducing temperatures for eggs and fry under both Alternative 3 and the No Action Alternative (Table O.3-54). Effects of water temperature on this life stage of Green Sturgeon are therefore anticipated to be slightly less severe under Alternative 3 than under the No Action Alternative.

Rearing juvenile Green Sturgeon are present in the Feather River from May to October, with abundance peaking in September. During May and October, water temperatures would be essentially identical under Alternative 3 and the No Action Alternative (Figures O.3-120 and O.3-121). In June of below normal and dry water years, however, water temperatures under Alternative 3 could be up to 4°F lower than under the No Action Alternative (Figure O.3-121). This would result in water temperatures reaching suboptimal stress-inducing levels for juveniles later in June under Alternative 3 than under the No Action Alternative (Table O.3-54). However, in July of below normal and dry water years, water temperatures would be up to 1°F higher under Alternative 3 than under the No Action Alternative (Figure O.3-121), which would likely have stress-inducing temperatures for juveniles under both Alternative 3 and the No Action

Alternative (Table O.3-54). Water temperatures would differ in August and September of wet and above normal water years when temperatures under Alternative 3 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-121). Water temperatures in wet and above normal years would drop from stress-inducing levels for juveniles to suboptimal levels and again to optimal levels later in the month under Alternative 3 than under the No Action Alternative (Figure O.3-121, Table O.3-54). The effects of water temperature on juvenile Green Sturgeon under Alternative 3 would then be dependent on water year types with slightly beneficial effects in below normal and dry water years and slightly adverse effects in wet and above normal water years; therefore, the net effect would be slightly adverse under Alternative 3 than under the No Action Alternative.

Migrating adult (ocean to river) Green Sturgeon reach the Feather River between March and May and, upon spawning, can remain in the vicinity until August. From March to May, water temperatures would be essentially identical under Alternative 3 and the No Action Alternative (Figures O.3-120 and O.3-121). In June of below normal and dry water years, however, water temperatures under Alternative 3 could be up to 4°F lower than under the No Action Alternative (Figure O.3-121). Modeled June water temperatures are above the threshold for stress-inducing temperatures for migrating adults under both Alternative 3 and the No Action Alternative (Table O.3-54). However, water temperatures would reach the suboptimal threshold for post-spawn adults later in below normal and dry years under the No Action Alternative and optimal levels under Alternative 3. Water temperatures would differ in August of wet and above normal water years when temperatures under Alternative 3 flows could be up to 1°F higher than temperatures under No Action Alternative flows (Figure O.3-121), which would likely result in stress-inducing levels in migrating adults under both Alternative 3 and the No Action Alternative; yet these temperatures could reach stress inducing temperatures for post-spawn adults a couple of weeks more under Alternative 3 than under the No Action Alternative. Effects of water temperature on this life stage, therefore, are anticipated to be slightly less severe under Alternative 3 than under the No Action Alternative.

Alternative 3 has the potential for slightly adverse water temperature-related effects on juveniles in wet and above normal years but slightly beneficial effects on eggs, fry, and post-spawn adults in below normal and dry years. Overall, effect on North American Green Sturgeon under Alternative 3 relative to the No Action Alternative is minor and dependent on annual rainfall totals.

O.3.7.5 *American River*

Potential changes to aquatic resources in the American River from flood control

Flood Control for the American River at Folsom Dam would be the same under the Alternative 3 would be the same compared the No Action Alternative, since flood control follows the USACE Water Control Manual and flow management for Alternative 2 is according to the American River 2006 Flow Management Standard (Water Forum 2006), the same as the No Action Alternative. The Water Control Manual has been updated over time, and a new Water Control Manual was developed that utilizes forecasted inflow as the criteria for determining flood control releases. The new manual looks ahead five days and considers the forecasted inflow volume for the total of those five days. If that volume exceeds a threshold, a flood control release is specified. The concept is to pre-emptively draw the reservoir down in anticipation of high inflows, thus providing space to store the rain event when it arrives. This will allow Reclamation to pass higher precipitation events with lower peak releases which relieves stress on the downstream levees and provides a higher level of flood protection to downstream areas.

Potential changes to aquatic resources from Folsom Reservoir operations in the American River to meet Delta salinity requirements

Folsom Reservoir operations to address Delta water quality requirements under D-1641 would not change under Alternative 3, compared to the No Action Alternative. Folsom Reservoir flow requirements includes releases to meet Delta standards under D-1641, as needed. Since Folsom Reservoir is the closest reservoir to the Delta, releases from Folsom can more quickly address Delta water quality requirements. Releases to address Delta water quality objectives would be conducted, as needed, in coordination with the American River stakeholders. Releases to address Delta water quality objectives would improve water quality conditions, and thus habitat conditions for fish and other aquatic species in the Delta when hydrologic conditions are negatively affecting salinity levels.

Potential changes to aquatic resources from flows in the American River

Flows in the American River would be the same under Alternative 3, compared to the No Action Alternative, since flow management for Alternative 3 is according to the American River 2006 Flow Management Standard (Water Forum 2006), the same as the No Action Alternative. Under the Alternative 3, flow releases are managed according to the American River 2006 Water Forum Lower American Flow Management Standard, with the objective of providing suitable conditions for Fall-Run Chinook Salmon and Steelhead. Under the Flow Management Standard, flows are managed according to the Minimum Flow Requirements (MFR), which establishes minimum flows, as measured by the total release at Nimbus Dam, which vary throughout the year in response to the hydrology of the Sacramento and American River basins. The October 1 through December 31 MFR range between 800 and 2,000 cfs. The January 1 through Labor Day MFR range between 800 and 1,750 cfs. The post Labor Day through September MFR range between 800 and 1,500 cfs. As a general rule, the MFR must equal or exceed 800 cfs year round. Narrowly defined exceptions to this rule allow Nimbus releases to drop below 800 cfs to avoid depletion of water storage in Folsom Reservoir when dry or critically dry hydrologic conditions are forecasted to occur. These narrowly defined exceptions to the MFR are an important component of the Flow Management Standard. Since the No Action Alternative follows the existing condition implementation of the Alternative 2 would result in no change to flows in the lower American River.

Potential changes to aquatic resources in the American River due to changes in water temperature

Alternative 3 does not include water temperature objectives. However, water temperature modeling indicates that differences in water temperatures are more a function of hydrologic conditions than operations to meet objectives, water temperatures in the American River would be similar for Alternative 3, compared to the No Action Alternative (Figure 8). Since flow objectives are the same for Alternative 3 as for the No Action Alternative and follow the American River 2006 Flow Management Standard (Water Forum 2006), the flow conditions in the American River remain the same, and thus water temperatures no change in water temperatures are expected under Alternative 3. Temperature modeling indicates that there would be no change average water temperatures in the American River (Figure 8), or in wet years (Figure 9) and dry years (Figure 10).

Potential changes to aquatic resources in the American River from habitat restoration

Habitat for Chinook Salmon and Steelhead in the lower American River would be improved under Alternative 3, compared to the No Action Alternative. Alternative 3 includes implementation of spawning and rearing habitat projects in the American River and its tributaries. This action will likely result in long-term improvements to the habitat and conditions for Fall-Run Chinook Salmon, Steelhead, and other aquatic inhabitants. The spawning and rearing habitat projects would result in increased total spawning habitat area, increased and improved side channel habitat, improved intragravel incubation conditions, increased and improved total rearing habitat area, improved overall habitat complexity, and cover and refugia.

O.3.7.6 *Stanislaus River*

Potential changes to aquatic resources in the Stanislaus River due to changes in flows.

Similar to the previous discussion for Alternative 2 for flows below Goodwin Dam and at the mouth of the Stanislaus River, decreases in flow could affect various salmonid life stages, reduce suitable habitat for to varying degree by salmonid life stages, or have other undesirable results.

Like Alternative 1, Alternative 3 proposes spawning and rearing habitat restoration to offset effects related to changes in flow. As previously described under Alternative 1, the habitat restoration would result in increased survival of juvenile salmonids in the Stanislaus River.

The following effects would be expected to be similar under Alternative 3 to the potential effects as previously described for Alternative 2:

Potential changes to aquatic resources in the Stanislaus River due to changes in water temperature

The following effects would be expected to be similar under Alternative 3 to the potential effects as previously described for Alternative 1:

O.3.7.7 *San Joaquin River*

The following effects would be expected to be similar under Alternative 3 to the potential effects as previously described for the No Action Alternative:

Potential changes to aquatic resources in the San Joaquin River due to changes in flow

Potential changes to aquatic resources in the San Joaquin River due to changes in water temperature

O.3.7.8 *Bay-Delta*

O.3.7.8.1 Delta Smelt

Potential changes to Delta Smelt due to seasonal operations

Water operations criteria under Alternative 3 would be the same as under Alternative 2, i.e., largely governed by adherence to D-1641 criteria and other legal requirements, but the potential negative effects of these operations on Delta Smelt may differ between the alternatives. These differences may arise because of inclusion of a greater extent of programmatic intervention measures such as tidal habitat restoration and food subsidies to offset (or potentially more than offset) the negative effects of Alternative 3 on food availability and potentially habitat for Delta Smelt occupancy, as well as the *Delta Smelt Habitat Operations* conservation measure (which is the same as included in Alternative 1); such components would tend to make the difference between the No Action Alternative and Alternative 3 less than the difference between the No Action Alternative and Alternative 2. However, there could also be negative effects from tidal restoration such as changed hydrodynamics, as discussed below in *Potential changes to Delta Smelt from additional habitat restoration (25,000 acres within the Delta).*

Potential changes to Delta Smelt due to changes from Tracy and Skinner fish facilities improvements

Alternative 3 would include the carbon dioxide injection device previously described for Alternative 1 and therefore could have a positive effect on salvage efficiency relative to the No Action Alternative in this respect. However, given the potential increase in entrainment from seasonal operations (as discussed for Alternative 2) as a result of the No Action Alternative's OMR criteria from the USFWS (2008) BO not being included in Alternative 3, the negative effects from salvage at the Tracy and Skinner fish facilities could outweigh any increases in salvage efficiency at Tracy.

The following project-level effects would be expected to be similar under Alternative 3 to the potential effects as previously described for Alternative 1 because the operations are similar:

Potential changes to Delta Smelt from Clifton Court aquatic weed removal and algal bloom management

Potential changes to Delta Smelt from North Bay Aqueduct operations

The following project-level effects would be expected to be similar under Alternative 3 to the potential effects as previously described for Alternative 2 because of limited potential for effect or because the operations are similar:

Potential changes in Delta Smelt survival related to the Temporary Barriers Project

Potential changes to Delta Smelt from Contra Costa Water District operations

Potential changes to Delta Smelt from water transfers

Potential changes to Delta Smelt due to changes in Delta Cross Channel operations

Potential changes to Delta Smelt due to changes from Suisun Marsh facilities

O.3.7.8.2 Longfin Smelt

Potential changes to Longfin Smelt due to seasonal operations

Under Alternative 3, seasonal operations generally would be expected to have similar effects on Longfin Smelt as previously described for Alternative 2. However, Alternative 3 may have more potential to offset these effects given the larger extent of tidal habitat restoration that is included (see *Potential changes to Longfin Smelt from addtional habitat restoration (25,000 acres within the Delta)*).

Potential changes to Longfin Smelt due to changes from Tracy and Skinner fish facilities improvements

Alternative 3 would include the carbon dioxide injection device previously described for Alternative 1 and therefore could have a positive effect on Longfin Smelt salvage efficiency relative to the No Action Alternative in this respect. Given the potential increase in entrainment from seasonal operations (as discussed for Alternative 2), the negative effects from salvage at the Tracy and Skinner fish facilities could outweigh any increases in salvage efficiency at Tracy. However, as previously discussed for Alternative 2, the population-level effects may be limited given historically low entrainment loss during management under D-1641, as proposed under Alternative 3.

The following project-level effects would be expected to be similar under Alternative 3 to the potential effects as previously described for Alternative 1 because the operations are similar:

Potential changes to Longfin Smelt from Clifton Court aquatic weed and algal bloom management

Potential changes to Longfin Smelt from North Bay Aqueduct operations

The following project-level effects would be expected to be similar under Alternative 3 to the potential effects as previously described for Alternative 2 because of limited potential for effect or because the operations are similar:

Potential changes in Longfin Smelt survival due to the Temporary Barriers Project

Potential changes to Longfin Smelt from Contra Costa Water District operations

Potential changes to Longfin Smelt from water transfers

Potential changes to Longfin Smelt due to changes in Delta Cross Channel operations

Potential changes to Longfin Smelt due to changes from Suisun Marsh facilities

O.3.7.8.3 Sacramento Winter-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Rearing Winter-Run Chinook Salmon are present in the Delta between October and May. Key habitat attributes relevant to seasonal operations in the Delta include out-migration cues and entrainment risk.

Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to adversely affect juvenile Chinook Salmon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, and 2) “far-field” mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team’s (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver-linkage-outcome (DLO) framework for specifying how water project operations (the “driver”) can influence juvenile salmonid behavior (the “linkage”) and potentially cause changes in survival or routing (the “outcome”). The SST concluded altered “Channel Velocity” and altered “Flow Direction” were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O.3-122 provides a simplified conceptual model of the DLO defined by the CAMT SST.

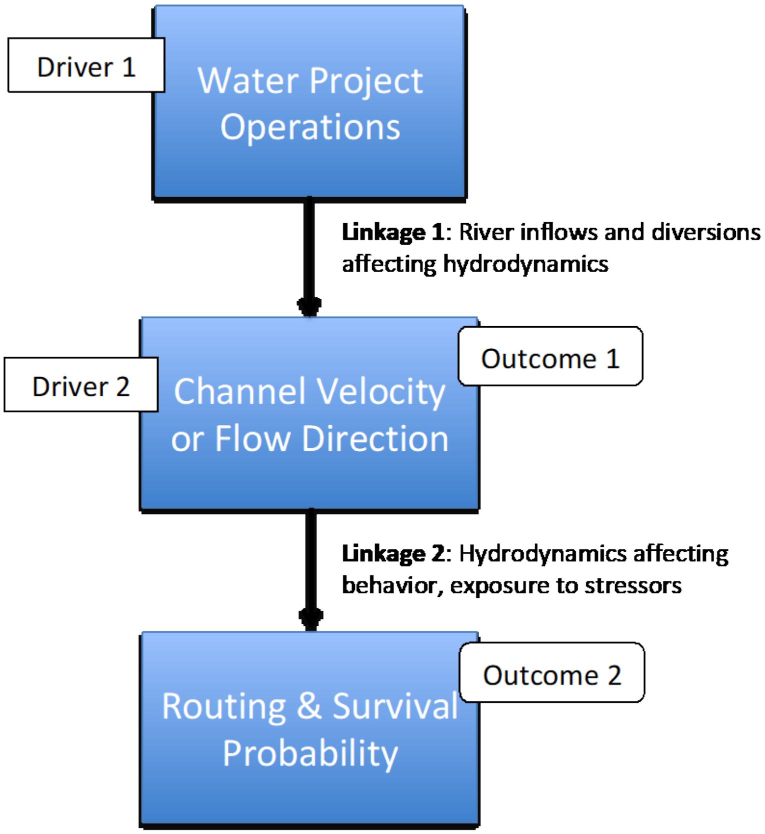

Figure O.3-122. Conceptual Model for Far-field Effects of Water Project Operations on Juvenile Salmonids in the Delta. This CM is a Simplified Version of the Information Provided by the CAMT SST.

To assess the potential for water project operations to influence survival and routing, Reclamation and DWR analyzed Delta hydrodynamic conditions by creating maps from DSM2 Hydro modeling. The maps are based on a comparative metric, proportion overlap (more below), to capture channel-level hydrodynamic details as a single number for color-scale mapping of Delta channels.

The objective of the comparative metric is to summarize the water velocity time series for each channel and scenario such the channel-level comparison is captured in a single number. For the proportion overlap metric, kernel density estimates are calculated on each time series. The kernel density estimates represent a non-parametric smoothing of the empirical distribution of time series values. The proportion overlap of two kernel density estimates is calculated with the following steps: 1) calculate the total area under the curve (AUC_t) as the sum of the AUC for each density estimate, 2) calculate the AUC of the overlapping portions (AUC_o) of the two density distributions being compared, and 3) calculate the overlapping proportion of the density distributions as AUC_o/AUC_t. Proportion overlap is naturally bound by zero and one; a value of zero indicates no overlap and a value of one indicates complete overlap. Lower values of proportion overlap identify channels demonstrating larger differences in a scenario comparison.

The proportion overlap metric is best applied over relatively short time periods because seasonal and annual variation in water velocity can overwhelm differences between scenarios. Thus, Reclamation calculated proportion overlap for every DSM2 channel for two seasons (Dec-Feb, Mar-May) in each water year (1922–2003). DSM2 output was excluded from water year 1921 to allow for an extensive burn-in period. The proportion overlap was calculated based on hourly DSM2 output. Because each season was roughly 90 days, each comparison involved roughly 4,300 DSM2 values (2 scenarios * 24 hours * 90 days) for each channel.

Because the proportion overlap was calculated for each channel in each water year, the proportion overlap values were summarized prior to mapping (i.e., not feasible to map proportion overlap for every comparison in every water year). To summarize, the minimum proportion overlap for each channel for each water year type for each comparison were found. The minimum values represent the maximum expected effect. Note that the year with the minimum proportion overlap for one channel might not be the same year as for another channel.

Entrainment

In the December through June period, the average total export rate, under Alternative 3, is higher than the export rate under No Action Alternative. Therefore, higher entrainment is expected compared to the No Action Alternative.

Zeug and Cavallo (2014) analyzed more than 1,000 release groups representing more than 28 million coded wire tagged juvenile fish including winter, late fall and Fall-Run Chinook Salmon. This data represents large release groups of tagged smolts where the number of fish representing each release group lost to entrainment at the export facilities has been estimated. Cavallo (2016) provided a supplemental assessment of Winter-Run Chinook Salmon entrainment risk (building upon Zeug and Cavallo 2014) that showed total CVP and SWP exports described entrainment risk better than OMR or other flow metrics. Entrainment loss results as reported below represents the proportion of coded wire tagged Winter-Run Chinook Salmon released upstream of the Delta which were entrained at South Delta export facilities. This proportion accounts for and includes expansion for sampling effort at the salvage facilities and also prescreen mortality. For December through February, Alternative 3 has an average total export rate greater than No Action Alternative (10,173 and 7,617 cfs respectively; Figure O1-1 in Appendix O, Attachment 1), and will therefore have greater entrainment risk. However, entrainment losses should average 0.8% and not exceed 2.2%. In the March through June period, total exports for Alternative 3 increase entrainment risk relative to No Action Alternative (6,782 vs. 4,164 cfs, respectively; Figure O1-2 in Appendix O, Attachment 1), but entrainment losses should average 0.4% and not exceed 1.5%.

Routing

Routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 3 were evaluated using DSM2. Juvenile Winter-Run Chinook Salmon are present in the Sacramento River at Sherwood Harbor upstream of the first distributary junctions between November and March with peak abundance in February and March (Reclamation 2019).

In the December to February period, velocity overlap between Alternative 3 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 83%, 79%, 68%, 70%, and 54% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-37 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 3 in below normal, above normal, and wet years and slightly lower in critically dry and dry years indicating routing into the interior Delta would be lower relative to No Action Alternative in normal and wet years and slightly higher relative to No Action Alternative in dry years (Perry et al. 2015; Figure O1-41 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 3 was more than

82%, 75%, 70%, 60%, and 79% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-38 in Appendix O, Attachment 1).

Abundance of juvenile Winter-Run Chinook Salmon at Chipps Island peaks in March and April but fish are collected between December and May (Reclamation 2019). During this time period, Winter-Run Chinook Salmon originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can potentially be exposed to hydrodynamic effects associated with the CVP and SWP that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 3 and the No Action Alternative (Figure O1-39 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 3 to the No Action Alternative in the March to May period (Figure O1-40 in Appendix O, Attachment 1).

Through-Delta Survival

Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases.

To examine potential effects of Alternative 3, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, there are higher velocities under Alternative 3 than the No Action Alternative in wet, above normal, and below normal years. Velocities were lower in critically dry and dry years but overlap was high (>84%; Figure O1-41 in Appendix O, Attachment 1). At Steamboat Slough in the December through February period, there are higher velocities under Alternative 3 than the No Action Alternative in wet and below normal years. Velocities were lower in critically dry, dry, and above normal years but overlap was high (>83%; Figure O1-42). In the March through May period at Walnut Grove, when Alternative 3 was compared to the No Action Alternative, velocity overlap ranged from 78.5-87.5% (Figure O1-43 in Appendix O, Attachment 1). Velocity overlap at Steamboat Slough in the March through May period ranged from 76.6% to 82.6% (Figure O1-44 in Appendix O, Attachment 1).

Overall, Alternative 3 results in similar or higher velocities in the Delta in the spring than under No Action Alternative, during the outmigrating juvenile time period. Survival probabilities are non-linear; however, the similar or higher discharge at Freeport in the spring under Alternative 3 results in similar or higher survival in the transition reaches. Higher flows also lead to lower probability of routing into the interior Delta, which has the lowest survival probability regardless of flow.

Potential changes to aquatic resources due to OMR management

See section on seasonal operations above which integrate OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

Under Alternative 3, the DCC may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Winter-Run Chinook Salmon in the Sacramento River at Sherwood Harbor, which is near the DCC, occurs from February through March (Reclamation 2019).

Therefore, the DCC is closed for the majority of the juvenile Winter-Run Chinook Salmon migration period in the Sacramento River and as such the proportion of juvenile Winter-Run Chinook Salmon exposed to an open DCC would be negligible. Juvenile Chinook Salmon entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010; Perry et al. 2018).

Potential changes to aquatic resources due to the Temporary Barriers Project

Juvenile Winter-Run Chinook Salmon are not expected to co-occur in space or time with the agricultural barriers indicating no potential impacts.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 3 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a) and remain unchanged from the No Action Alternative.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory route for Winter-Run Chinook Salmon (NMFS 2017c), approximately 18 miles from the Sacramento River via the shortest route. Designated critical habitat for Winter-Run Chinook Salmon does not occur within Rock Slough, but is present further to the north in the Delta (NMFS 2017c; NMFS 2014c). Salmonids are expected to avoid the area of the Rock Slough Intake during certain times of the year based on historical water temperatures.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Winter-Run Chinook Salmon presence near the Rock Slough Intake. Since 1994, fish monitoring has been conducted by CDFW and CCWD consistent with the separate biological opinions and permits that govern CCWD's operations. From 1994 through 1999, CDFW conducted fish monitoring at the Rock Slough Intake and in the Contra Costa Canal up to the first pumping plant. Over this 6-year period, CDFW captured a total of 13 juvenile Winter-Run Chinook Salmon from January through May (CDFG 2002c; NMFS 2017c). From 1999 to 2009, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected no juvenile or adult Winter-Run Chinook Salmon at the Rock Slough Headworks (Reclamation 2016; NMFS 2017c).

Since construction of the RSFS, operation of the hydraulic rake cleaning system has been shown to trap and kill adult Chinook Salmon and other non-listed fish (Reclamation 2016). From 2011-2018, 47 Salmon were recovered at the RSFS (Reclamation 2016, Appendix A; Tenera Environmental 2018a), but none of the captured fish were identified as Winter-Run Chinook Salmon (NMFS 2017c).

NMFS issued a biological opinion in 2017 (NMFS 2017c) that considered improvements to the RSFS facility including the hydraulic rake cleaning system, operations and maintenance (O&M) of the RSFS and associated appurtenances, and administrative actions such as the transfer of O&M activities from Reclamation to CCWD. NMFS determined that the O&M of RSFS may result in the incidental take of juvenile Winter-Run Chinook Salmon and provided an incidental take limit based upon the number of listed fish collected in the pre and post-construction RSFS monitoring (NMFS 2017c). The incidental take provided in NMFS 2017c is five juvenile Winter-Run Chinook Salmon per year.

CCWD's Fish Monitoring Program also samples behind the fish screens at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Winter-Run Chinook Salmon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD’s operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD’s operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD’s operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Winter-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Salmon can be “drawn” into the south Delta under reverse flows and high CVP and SWP pumping rates. One indicator of reverse flows is the net flow in Old and Middle Rivers (OMR). Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect OMR, and any effect that diversions at Rock Slough Intake would have in the Old and Middle River corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants.

However, diversions at the Rock Slough Intake could affect flows in the San Joaquin River at Jersey Point, which is approximately 14 river miles from the Rock Slough Intake (via the shortest route through Franks Tract). Mean velocity in a river channel can be calculated by dividing the flow rate by the cross-sectional area of the channel. The maximum effect of Rock Slough diversions on the channel velocity would be the maximum diversion rate (350 cfs) divided by the minimum cross-sectional area of the channel. This calculation assumes that all water diverted at Rock Slough comes from the San Joaquin River at Jersey Point, which is a conservative assumption (i.e., overestimates the effect on velocity). The cross-sectional area of the San Joaquin River at Jersey Point is approximately 60,500 square feet (sf), but varies depending on the tidal stage from approximately 56,000 sf (at low tide and low San Joaquin River flow) to 68,000 sf (at high tide and high San Joaquin River flow) as shown in Figure O.3-123.

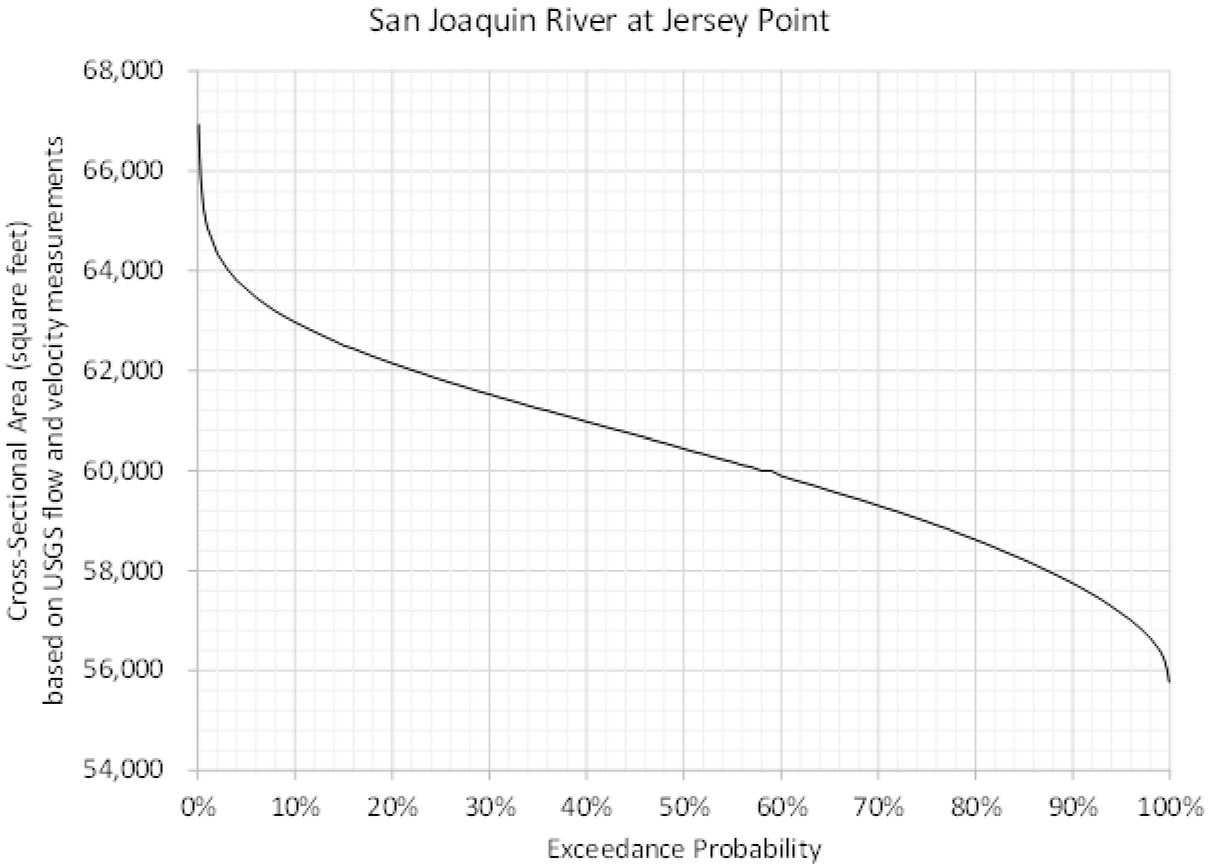

Figure O.3-23. Cross-sectional area of the San Joaquin River at Jersey Point (Station: 11337190) Calculated from USGS Measurements of Flow and Velocity every 15 Minutes for Water Years 2014 through 2018.

The maximum effect of water diversions at Rock Slough Intake on velocity in the San Joaquin River at Jersey Point is calculated as 350 cfs divided by 56,000 square feet; resulting in 0.00625 feet per second (ft/sec). For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from Rock Slough diversions. Furthermore, the actual effect is likely to be much lower than 0.00625 ft/sec because the water diverted at the Rock Slough Intake does not all come from the San Joaquin River west of Jersey Point.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, the combined effect of all three intakes is examined. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Winter-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant

particles such as phytoplankton. To examine the effect on neutrally buoyant particles, the distance that a particle would travel due to the maximum permitted Rock Slough diversions over the course of a day is calculated. A change in velocity of 0.00625 ft/sec could move a neutrally buoyant particle approximately 540 ft over the course of the day (0.00625 ft/sec * 86,400 sec/day). For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is not significant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 3 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Alternative 3 includes the North Bay Aqueduct (NBA) intake in the North Delta and operation of the Barker Slough Pumping Plant. Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant (monitoring data is available at https://www.wildlife.ca.gov/Regions/3). There should be no discernable effect to the Winter-Run Chinook Salmon due to the operations of the Barker Slough Pumping Facility. This is due to the infrequent presence of Winter-Run Chinook Salmon in the monitoring surveys indicating a low risk of entrainment. Further, Barker Slough Pumping Facility fish screens are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment while greatly minimizing any impingement of fish against the screen.

Alternative 1 also includes sediment removal with a suction dredge that could entrain Winter Run individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Winter Run occurring near the removal. The low occurrence of Chinook Salmon in monitoring efforts suggest that any potential imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

Under Alternative 3, Reclamation is extending the water transfer window until November, from the current July through September window. This extension could result in increased flows entering the Delta and increased pumping at Jones and Banks Pumping Plants.

Egg, alevin, and fry lifestages of Winter-Run Chinook Salmon do not occur in the Delta, and therefore would not be affected by this action. Winter-Run Chinook Salmon juveniles enter the Delta starting in December, and therefore would be unlikely to be exposed to increased pumping of water transfers through November. Adults returning from the ocean could possibly be in the Delta in July; however, they are strong swimmers, large fish that can avoid predators, and are unlikely to have impacts associated with direct entrainment of the pumping plants.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Winter-Run Chinook Salmon are present in the Delta between December and May with a peak in March and April (Reclamation 2019). The application of aquatic herbicide to the waters of CCF will occur between 28 June and 31 August. Treatment could occur prior to 28 June at tempertures ≥ 25˚C; however, Winter-Run Chinook Salmon would not be expected to occur at these temperatures. Treatment could also occur after 31 August if protective measures have not been triggered but few if any Winter-Run Chinook Salmon would be expected in the Delta during that time period. Thus, the probability of exposing Winter-Run Chinook Salmon to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the water temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facilities improvements

A small proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility. Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements based on lack of observed salvage during the August to October in-water work window (see Figures F.2.7, F.2.8, and F.2.9 in Appendix Fof the ROC LTO BA). However, a few early migrants could occur during the in-water work window based on occurrence in the north Delta (see Figures WR_Seines and WR_Sherwood in Appendix F of the ROC LTO BA).

To the extent that the construction affects the ability of juvenile Winter-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Figure 5.6-44), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Chinook Salmon entrained into CCF. It is important to note that only small proportions of Winter-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014).

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May to meet salinity standards set by the State Water Resources Control Board and Suisun Marsh Preservation Agreement provides water quality benefits to Winter-Run Chinook Salmon habitat. This beneficial operation coincides with downstream migration of juvenile Winter-Run Chinook Salmon (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Winter-Run Chinook Salmon in Montezuma Slough thus, the proportion of the total run utilizing this route is unknown. Winter-Run Chinook Salmon typically migrate through the estuary several months before spawning, but an extended delay in the estuary may affect their ability to access their natal spawning streams. Winter-Run generally utilize high stream flow conditions to assist their upstream migration. Rapid upstream movement may be needed to take advantage of a short duration high stream flow event, particular in dry years when high flow events may be uncommon. NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.7 ft/s, so that juvenile Winter-Run Chinook Salmon would be excluded from entrainment.

The Morrow Island Distribution System (MIDS) diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, its unlikely juvenile Winter-Run Chinook Salmon will be entrained into the water distribution system, since Winter-Run Chinook have not be caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor Winter-Run Chinook Salmon.

Goodyear Slough Outfall improves water circulation in the marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Winter-Run Chinook Salmon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits juvenile Winter-Run Chinook Salmon in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources due to changes from Delta Smelt summer-fall habitat operations

No Winter-Run Chinook Salmon are detected in the Delta between June and September. Therefore, no effects would occur as a result of the Suisun Marsh Salinity Control Gate operation.

Potential changes to aquatic resources due to changes from Clifton Court predator management

Clifton Court predator management efforts could reduce predation on listed fishes following entrainment into CCF, reducing pre-screen loss.

Potential changes to aquatic resources due to the San Joaquin Basin Steelhead Telemetry Study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

Potential changes to aquatic resources from monitoring

A number of monitoring activities described in Appendix C - Real Time Water Operations Charter, in section Routine Operations and Maintenance on CVP Activities would have the potential to capture Winter-Run Chinook Salmon. Not all the existing IEP monitoring programs that target pelagic fish identify Chinook Salmon race. Of the programs that target and identify Winter-Run Chinook Salmon, collective catches are less than 1% of the Winter-Run JPE (Reclamation 2019). Because such a small percentage of the total JPE is captured in the monitoring programs, the effects of the monitoring programs are not likely to have effects to the Winter-Run Chinook Salmon population. These monitoring programs are important for understanding entry and residence time of Winter-Run Chinook Salmon into the Delta and San Francisco Estuary.

O.3.7.8.4 Central Valley Spring-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Reclamation and DWR propose to operate the C.W. Bill Jones Pumping Plant and the Harvey O. Banks Pumping Plant. These pumping plants affect the hydrodynamics of the south and central Delta resulting in effects to Spring-Run Chinook Salmon entrainment, routing and through Delta survival. Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to negatively impact juvenile Chinook Salmon in two distinct ways: 1) "near-field" mortality associated with entrainment to the export facilities, 2) "far-field" mortality resulting from altered hydrodynamics. See Winter-Run Chinook Salmon effects section for more detail concerning "far-field" and "near-field."

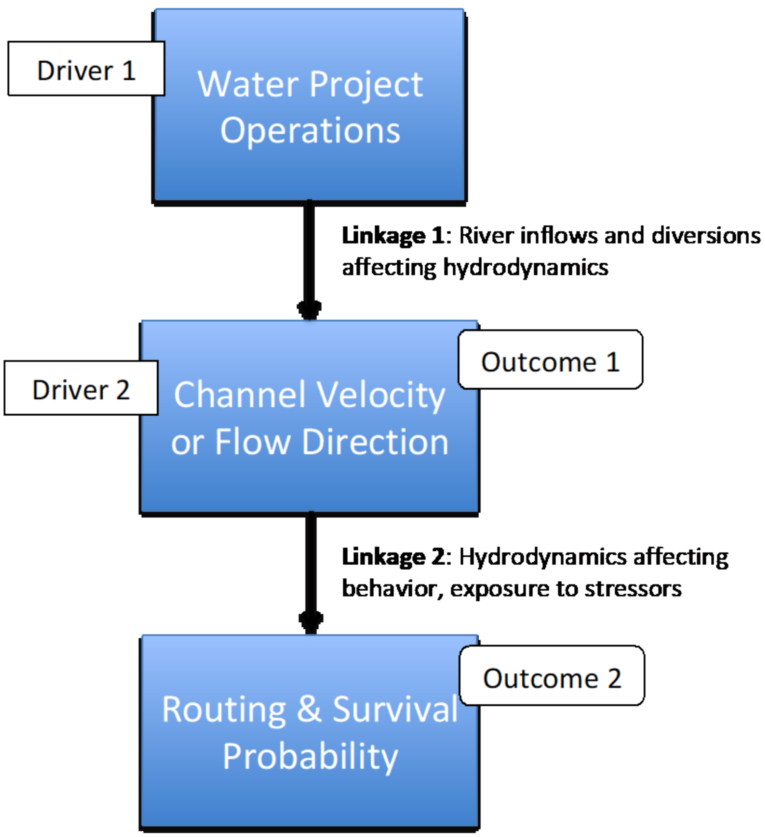

Figure O.3-124. Conceptual model for far-field effects of water project operations on juvenile salmonids in the Delta. This CM is a simplified version of the information provided by the CAMT SST.

Entrainment

Among 6.8 million tagged natural origin and 2.8 million tagged hatchery origin Spring-Run Chinook Salmon juveniles, entrainment loss averaged less than 0.0005% (Zeug and Cavallo 2014). Although data for juvenile Spring-Run Chinook Salmon originating from the San Joaquin River are limited, Zeug and Cavallo (2014) analyzed salvage of San Joaquin River-origin Fall-Run juvenile Chinook Salmon that are found in the Delta at a similar time as Spring-Run Chinook Salmon. Salvage of Fall-Run Chinook Salmon originating from the San Joaquin River averaged 1.4% and increased with export rate at the CVP and SWP (Zeug and Cavallo 2014). However, there were few observations at export rates greater than 3,000 cfs. Average mortality at the facilities represents < 5% total juvenile mortality for San Joaquin River-origin populations but can range as high as 17.5% (Zeug and Cavallo 2014).

In the December through February period, Alternative 3 proposes an average total export rate higher than No Action Alternative (2,556 cfs; Figure O1-1 in Appendix O, Attachment 1) and will, therefore, have a higher entrainment risk. Total exports proposed for Alternative 3 in March-June (2,618 cfs higher than No Action Alternative; Appendix O, Attachment 1, Figure O1-2), when juvenile Spring-Run Chinook Salmon are most abundant in the Delta, will increase entrainment risk relative to No Action Alternative. Recent acoustic studies of juvenile Fall-Run Chinook Salmon in the San Joaquin River revealed that when the Head of Old River Barrier is out, >60% of fish detected at Chipps Island came through CVP, indicating that salvage is a higher survival route than volitional migration.

Routing

As stated in the Sacramento Winter-Run Chinook effects section, routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Juvenile Spring-Run Chinook Salmon are present in the Delta between November and early June with a peak in April (Reclamation 2019). In the December to February period, velocity overlap between Alternative 3 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 83%, 79%, 68%, 70%, and 54% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-37 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 3 in below normal, above normal, and wet years and slightly lower in critically dry and dry years indicating routing into the interior Delta would be lower relative to No Action Alternative in normal and wet years and slightly higher relative to No Action Alternative in dry years (Perry et al. 2015; Figure O1-41 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 3 was more than 82%, 75%, 70%, 60%, and 79% in critical, dry, below normal, above normal, and wet years, respectively (Figure O1-38 in Appendix O, Attachment 1).

Spring-Run Chinook Salmon originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can be exposed to hydrodynamic project effects that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 1 and both the No Action Alternative scenarios (Figure O1-5 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 1 to No Action Alternative in the March to May period (Figure O1-6 in Appendix O, Attachment 1).

Juvenile Spring-Run Chinook Salmon are present in the Delta between November and early June with a peak in April (Reclamation 2019). Early studies using coded wire tags indicated that survival of San Joaquin River-origin juvenile Chinook Salmon was lower in the Old River Route relative to the San Joaquin main stem (Newman 2008). This finding led to strategies designed to keep larger proportions of fish in the San Joaquin River main stem including the Head of Old River rock barrier and non-physical barriers. Recent studies using acoustic technology have indicated that differences in survival among the two routes are not significant (Buchanan et al. 2013; Buchanan et al. 2018). Thus, fish that enter Old River are unlikely to experience reduced survival.

Spring–run Chinook Salmon originating from the San Joaquin River that remain in the San Joaquin River main stem at the Head of Old River are exposed to additional junctions that lead into the interior Delta including; Turner Cut, Columbia Cut, Middle River, Old River, Fisherman's Cut and False River. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junctions with San Joaquin Rivers between Alternative 1 and No Action Alternative scenarios (Figure O1-5 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 1 to No Action Alternative in the March to May period (Figure O1-6 in Appendix O, Attachment 1).

In the December through February period, velocity overlap between Alternative 2 and No Action Alternative in the channel upstream of the Head of Old River was 92.8%, 84.8%, 55.1%, 65.6%, and 53.8% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-23 in Appendix O, Attachment 1). In the March to May period, velocity overlap was 83.1%, 62.9%, 61.8%, 64.3%, and 43.1% in critical, dry, below normal, above normal, and wet years, respectively (Figures O1-24 in Appendix O, Attachment 1).

Through-Delta Survival

To examine potential effects of Alternative 3, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this "transitional" region. During the December to February period at Walnut Grove, velocity distributions for Alternative 3 relative to No Action Alternative were most different in wet years (72.5%) with higher velocities in Alternative 3. Velocities were also greater for Alternative 3 relative to No Action Alternative in below normal and above normal years although overlap was greater (>78%; Figure O1-41 in Appendix O, Attachment 1). In critically dry and dry years, velocity distributions were more similar (>84%; Figure O1-41 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, velocities under Alternative 3 were higher than No Action Alternative in wet and below normal years and similar in above normal, dry, and critically dry years (Figure O1-42 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 3 and No Action Alternative was >78% across all water year types with similar velocities under Alternative 3 (Figure O1-43 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 3 and No Action Alternative scenarios was >76% with similar velocities under Alternative 3 (Figure O1-44 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 3, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the "transitional" region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 3 relative to No Action Alternative exhibited high overlap in all water year types (≥81.3%; Figure O1-45 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 3 and No Action Alternative in critically dry and dry water years (≥77%) and moderate in wet, above normal, and below normal years (65%; Figure O1-46 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 3 and No Action Alternative (≥80%; Figure O1-47 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-47). At the Head of Middle River in the March –May period, overlap between Alternative 3 and No Action Alternative was moderate in all water year types (41-65%) and higher in critically dry years >78% (Figure O1-48 in Appendix O, Attachment 1). Velocities were generally lower under Alternative 3 than No Action Alternative (Figure O1-48 in Appendix O, Attachment 1).

Potential changes to aquatic resources due to OMR management

See section on seasonal operation above which integrates OMR management

Potential changes to aquatic resources due to Delta Cross Channel operations

The Delta Cross Channel may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. Significant amounts of flow and many juvenile Spring-Run Chinook Salmon enter the DCC (when the gates are open) and Georgiana Slough, especially during increased Delta pumping. Mortality of juvenile Salmon entering the central Delta is higher than for those continuing downstream in the Sacramento River. Juvenile Chinook Salmon that are entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010) The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Spring-Run Chinook Salmon in the Sacramento River past Knights Landing, which is upstream of the DCC, occurs from March-April (Reclamation 2019). Therefore, the DCC is closed to protect the majority of the juvenile Spring-Run Chinook Salmon migration period in the Sacramento River and reduce the proportion of fish exposed to an open DCC.

Potential changes to aquatic resources due to the Temporary Barriers Project

The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30.

The proportion of juvenile Spring-Run Chinook Salmon exposed to the agricultural barriers (Temporary Barrier Program, TBP) depends on their annual timing of installation and removal. Due to their location, primarily migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Spring-Run Chinook Salmon in the Delta is March and April (Reclamation 2019). If the agricultural barriers are operating as early as April 15 then they have the potential to expose a large proportion of the juvenile Spring-Run Chinook Salmon migrating down the San Joaquin River. When the Head of Old River barrier is not in place, acoustically tagged juvenile Chinook Salmon have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). Flap gates tied up on agricultural barriers from May 16 to May 31 would help to reduce the negative effect of the barriers during this period. However, juveniles migrating before or after this period could be exposed to the agricultural barriers with flaps down which apparently decreases passage success and survival (DWR 2018).

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 3 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD's operation, including operation of the Rock Slough Intake, for Alternative 3 remain unchanged from the current operations.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory route for Central Valley Spring-Run Chinook Salmon (NMFS 2017c), approximately 18 miles from the Sacramento River and 10 miles from the San Joaquin River via the shortest routes. Designated critical habitat for Spring-Run Chinook Salmon does not occur within Rock Slough, but is present further to the north in the Delta (NMFS 2017c; NMFS 2014c). Salmonids are expected to avoid the area of the Rock Slough Intake during certain times of the year based on historical water temperatures, which range from lows of about 45°F in winter (December and January) to over 70°F beginning in May and continuing to October (Reclamation 2016).

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Central Valley Spring-Run Chinook Salmon presence near the Rock Slough Intake. Since 1994, fish monitoring has been conducted by CDFW and CCWD consistent with the separate biological opinions and permits that govern CCWD's operations. From 1994 through 1999, CDFW conducted fish monitoring at the Rock Slough Intake and in the Contra Costa Canal up to the first pumping plant. Over this 6-year period, CDFW captured a total of 108 juvenile Central Valley Spring-Run Chinook Salmon from March through May (CDFG 2002c; NMFS 2017c). From 1999 to 2009, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected a total of 11 juvenile Central Valley Spring-Run Chinook Salmon from March through May at the Rock Slough Headworks (Reclamation 2016; NMFS 2017c) and 4 juvenile Central Valley Spring-Run at Pumping Plant #1 (CCWD 2019). No adult Spring-Run Chinook Salmon were collected in the vicinity of the Rock Slough Intake from 1994 through 2009 (CDFG 2002c; Reclamation 2016; NMFS 2017c). No juvenile or adult Central Valley Spring-Run Chinook Salmon have been collected in CCWD's Fish Monitoring Program at the Rock Slough Intake since 2008.

Since construction of the RSFS, operation of the hydraulic rake cleaning system has been shown to trap and kill adult Chinook Salmon and other non-listed fish (Reclamation 2016). From 2011-2018, 47 Salmon were recovered at the RSFS (Reclamation 2016, Appendix A; Tenera Environmental 2018a), but none of the captured fish were identified as Spring-Run Chinook Salmon (NMFS 2017c).

CCWD's Fish Monitoring Program also samples behind the fish screens at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Spring-Run Chinook Salmon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD's operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at

maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes (i.e., 10 miles from the San Joaquin River and 18 miles from the Sacramento River), juvenile Spring-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Spring-Run can be “drawn” into the south Delta under reverse flows and high CVP and SWP pumping rates.

One indicator of reverse flows is the net flow in OMR. Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect net reverse flow in OMR, and any effect that diversions at Rock Slough Intake would have in the OMR corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the OMR corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstem of the Sacramento River or the San Joaquin River and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run Chinook Salmon. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, we examine the combined effect of all three intakes. CCWD’s Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD’s combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD’s Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Spring-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is insignificant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 3 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Alternative 3 includes the North Bay Aqueduct (NBA) intake in the North Delta and operation of the Barker Slough Pumping Plant. Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant (monitoring data is available at https://www.wildlife.ca.gov/Regions/3). The NBA is located within designated critical habitat for Spring-Run Chinook Salmon. There should be no discernable effect to the Spring-Run Chinook Salmon due to the operations of the Barker Slough Pumping Facility. This is due to the infrequent presence of Spring-Run Chinook Salmon in the monitoring surveys indicating a low risk of entrainment. Further, Barker Slough Pumping Facility fish screens are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment while greatly minimizing any impingement of fish against the screen.

Alternative 1 also includes sediment removal with a suction dredge that could entrain Spring Run individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Spring Run occurring near the removal. The low occurrence of Chinook Salmon in monitoring efforts suggest that any potential imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

Under Alternative 3, Reclamation is expanding the transfer window to November from the current July to September. Expanding the transfer window could lead to increased pumping at Jones and Banks Pumping Plants, when capacity is available. The Figures below show when capacity is available under Alternative 1 and the No Action Alternative, in terms of exceedances, years in the model period of record, and average by water year types. These values are total available, and are not filtered for the pattern on which water might be acquired for transfer. The pattern of acquisition could decrease these values, as well as reoperation of storage that might be required, or the water cost of meeting D-1641. Prior estimates indicate that approximately 50% of the capacity in the figures below would be useful for water transfers given these timing and upstream considerations. In addition, a 20-30% surcharge on acquisition might be necessary to accommodate the salinity related inefficiencies that arise in operations. Based on the figures below and these additional estimates, expanding the water transfer window could result in an additional approximately 50 TAF of pumping in most yeartypes. As more stored water is available from CVP and SWP reservoirs to pump in wetter yeartypes, most of the available capacity for transfers is in drier yeartypes (Figures O.3-125 through O.3-127).

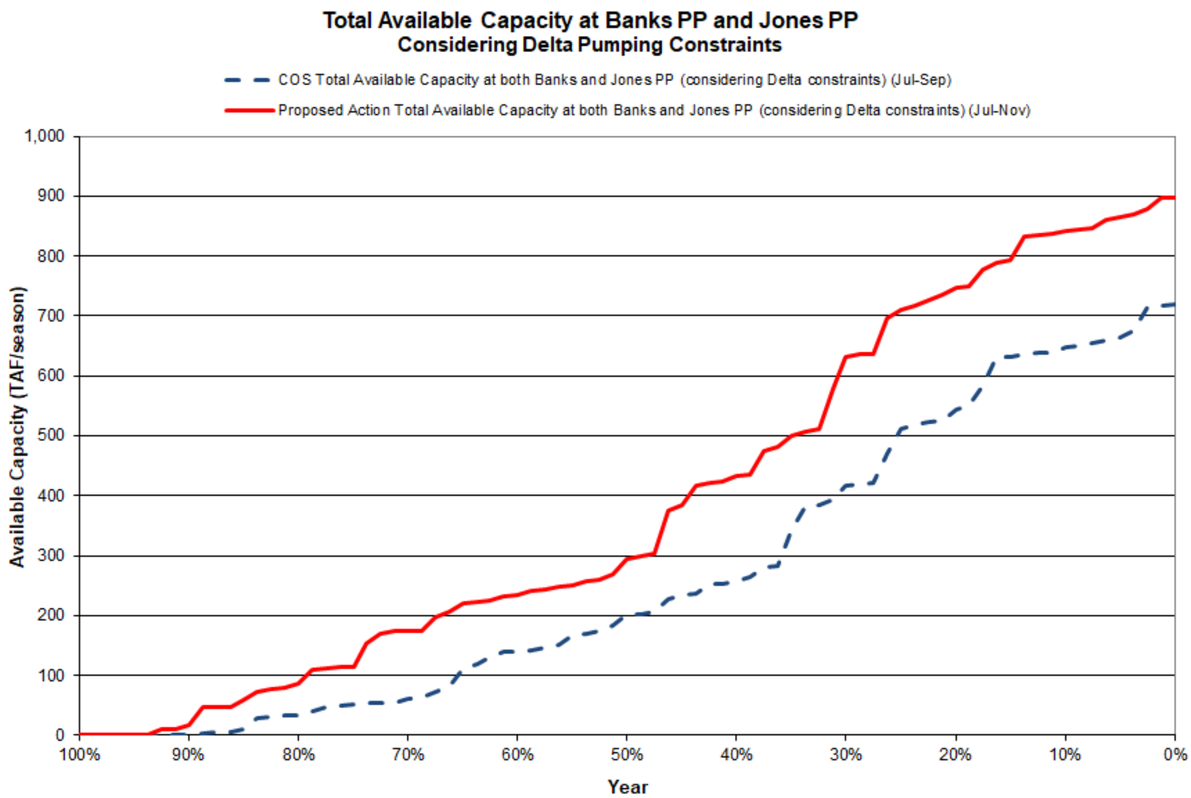

Figure O.3-125. Exceedance of Available Capacity for Transfers at Jones and Banks under the Alternative 1 and No Action Alternative

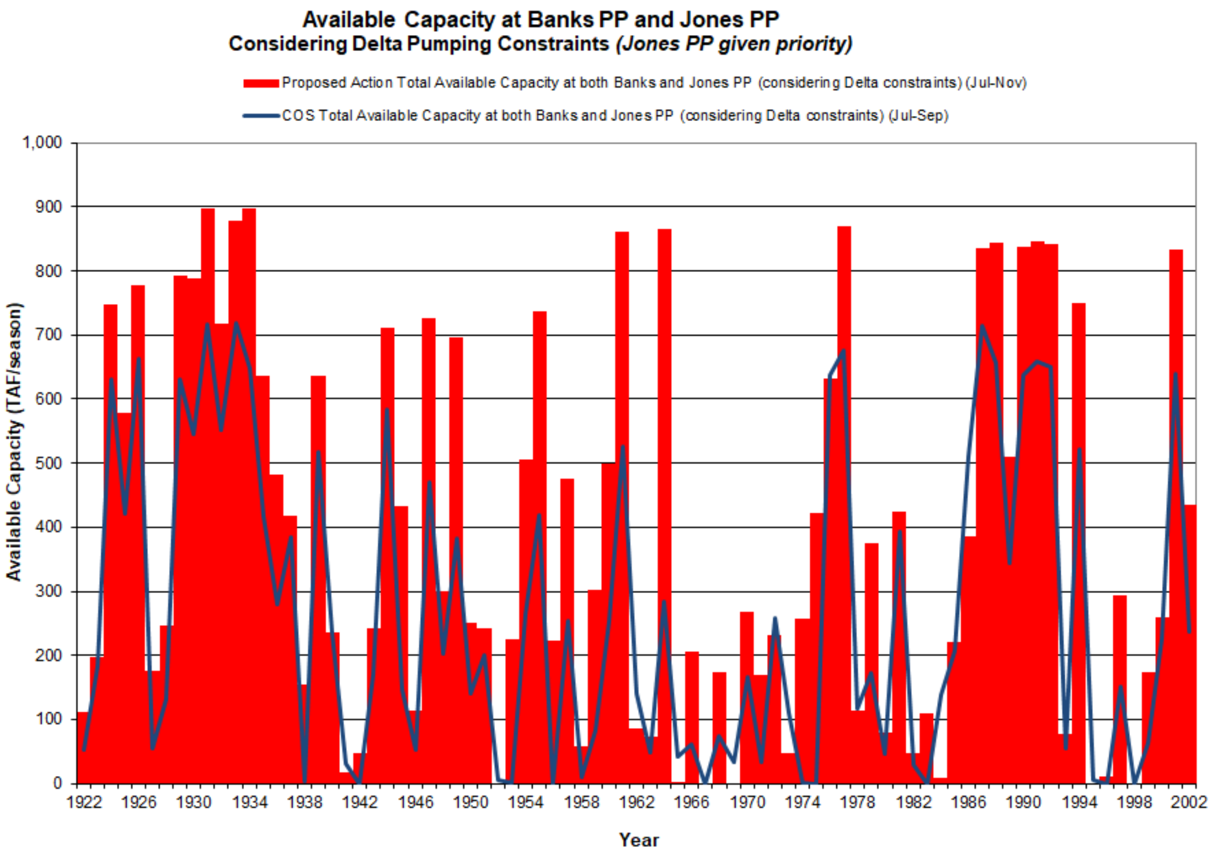

Figure O.3-126. Modeled Annual Maximum Available Capacity for Transfers under Alternative 1 and No Action Alternative, CalSim Period of Record (1922–2003)

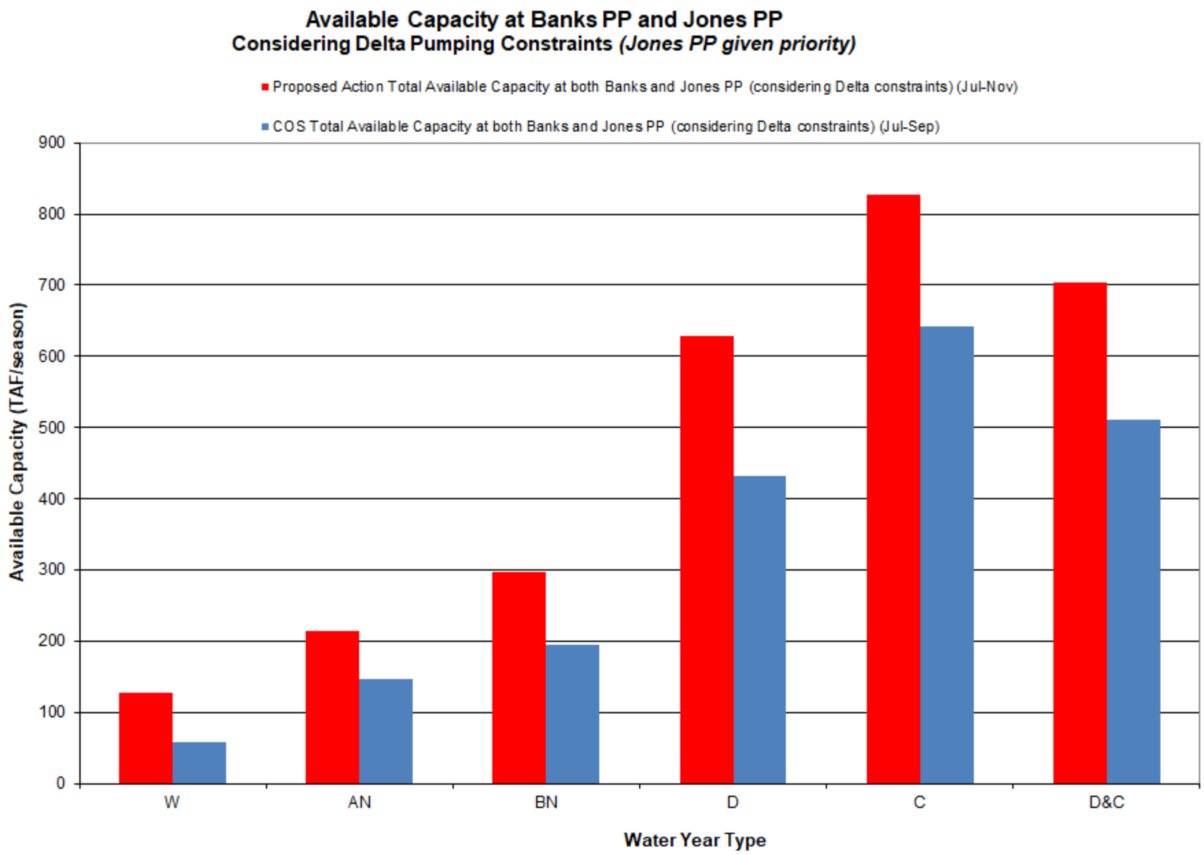

Figure O.3-127. Water Year Type average available capacity at Jones and Banks Pumping Plants

Egg, aelvin, fry, and adult lifestages of Spring-Run Chinook Salmon would not be exposed to the effects of increased water transfers as they do not occur in the Delta during July through November. Juvenile Central Valley Steelhead are detected at Chipps Island between December and July with the highest abundance in March to May (Reclamation 2019). Thus, only the very early or late migrants could potential be exposed to water transfers that occur during this time. These early or late migrant uvenile Spring-Run Chinook Salmon could be exposed to increased effects of entrainment, routing, and decreased Delta survival (see OMR management section) as a result of the expanded water transfer window. Increased flows during conveyance in the Sacramento River could provide small survival benefits to migrating juveniles (Perry et al. 2018).

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Spring-Run Chinook Salmon are present in the Delta between mid-November and early June with a peak in April (Table5.6-1). The application of aquatic herbicide to the waters of Clifton Court Forebay will occurbetween 28 June and 31 August. Treatment could occur prior to 28 June at tempertures ≥ 25˚C; however, Spring-Run Chinook Salmon would not be expected to occur at these temperatures. Treatment could also occur after 31 August if protective measures have not been triggered but few if any Spring-Run Chinook Salmon would be expected in the Delta during that time period.

Thus, the probability of exposing Spring-Run Chinook Salmon to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facilities improvements

A number of programmatic actions are proposed to improve salvage efficiency of TFCF, including installing a carbon dioxide injection device to allow remote controlled anesthetization of predators in the secondary channels of the Tracy Fish Facility. These actions could potentially benefit juvenile Spring-Run Chinook Salmon through greater salvage efficiency.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see figures in Appendix F of the ROC LTO BA: WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race). Risks to these few individuals would be minimized through appropriate mitigation measures (Appendix E, *Mitigation Measures*), the selected in-water work window, and the small scale of the in-water construction. For juvenile Spring-Run Chinook Salmon that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Predator control efforts at Skinner Fish Facility under Alternative 3 to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May to meet salinity standards set by the State Water Resources Control Board and Suisun Marsh Preservation Agreement provides water quality benefits to Spring-Run Chinook Salmon habitat. This beneficial operation coincides with downstream migration of juvenile Spring-Run Chinook Salmon (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Spring-Run Chinook Salmon in Montezuma Slough thus, the proportion of the total run utilizing this route is unknown. Spring-Run Chinook Salmon typically migrate through the estuary several months before spawning, but an extended delay in the estuary may affect their ability to access their natal spawning streams. Spring-Run generally utilize high stream flow conditions during the spring snowmelt to assist their upstream migration. Rapid upstream movement may be needed to take advantage of a short duration high stream flow event, particular in dry years when high flow events may be uncommon. If the destination of a pre-spawning adult Salmon is among the smaller tributaries of the Central Valley, it may be important for migration to be unimpeded, since access to a spawning area could diminish with receding flows. However NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.7 ft/s, so that juvenile Spring-Run Chinook Salmon would be excluded from entrainment.

The Morrow Island Distribution System (MIDS) diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, its unlikely juvenile Central Valley Spring-Run Chinook Salmon will be entrained into the water distribution system, since Spring-Run Chinook have not be caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor Spring-Run Chinook Salmon.

Goodyear Slough Outfall improves water circulation in the marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Spring-Run Chinook Salmon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits juvenile Spring-Run Chinook Salmon in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat

No Spring-Run Chinook Salmon are detected in the Delta between June and September. Therefore, no effects would occur as a result of the Suisun Marsh Salinity Control Gate operation.

Potential changes to aquatic resources due to changes from Clifton Court predator management

Predator control efforts at Clifton Court Forebay under Alternative 3 could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts during the summer in-water work window.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

Potential changes to aquatic resources from monitoring

Less than 2% of the estimated Spring-Run Chinook Salmon population, as indexed by the Red Bluff Rotary Screw Trap data, is collectively captured by the salmonid monitoring programs that support CVP operations (Reclamation 2019). Because such a small percentage of the estimated Spring-Run Chinook Salmon juvenile production is captured in the monitoring programs, the effects of the monitoring programs are not likely to have effects to the Spring-Run population.

O.3.7.8.5 Central Valley Fall-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Hydrodynamic changes associated with river inflows and South Delta exports have been hypothesized to adversely affect juvenile Chinook Salmon in two distinct ways: 1) "near-field" mortality associated with entrainment to the export facilities, 2) “far-field” mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be most appropriately assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team’s (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver- linkage-outcome (DLO) framework for specifying how water project operations (the “driver”) can influence juvenile salmonid behavior (the “linkage”) and potentially cause changes in survival or routing (the “outcome”). The SST concluded altered “Channel Velocity” and altered “Flow Direction” were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O.3-128 provides a simplified conceptual model of the DLO defined by the CAMT SST.

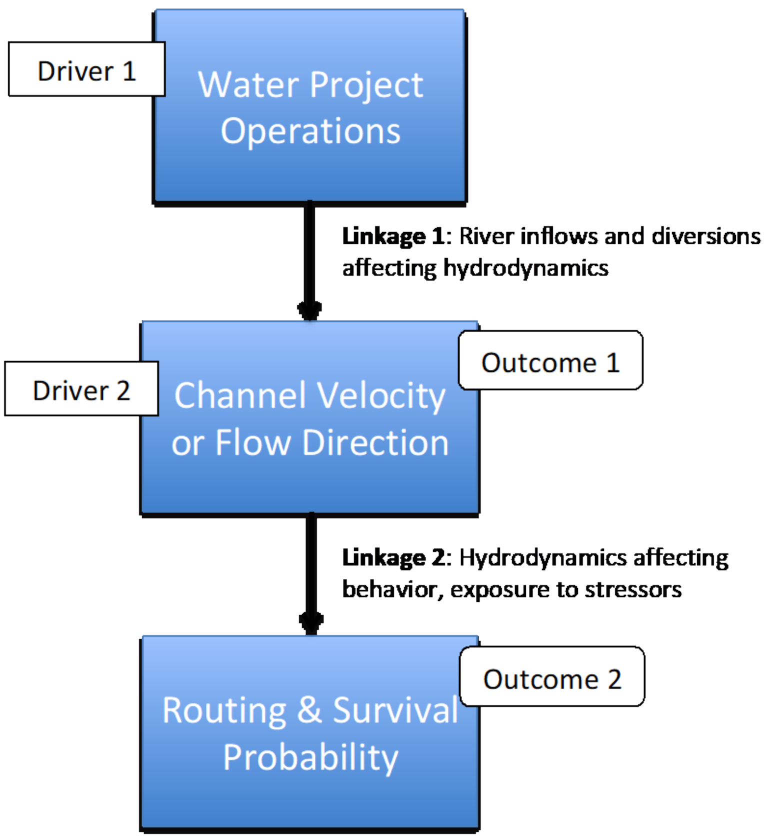

Figure O.3-128. Conceptual model for far-field effects of water project operations on juvenile salmonids in the Delta. This CM is a simplified version of the information provided by the CAMT SST.

Though many juvenile salmonid tagging studies have been conducted in the Delta, the focus has primarily been on estimating reach survival and routing- not assessing export-related hydrodynamic mechanisms defined by the SST’s DLO. In fact, most tagging studies have targeted areas of the Delta where “Channel Velocity” and “Flow Direction” may not be appreciably affected by exports (e.g., Newman and Brandes 2010; Perry et al. 2010; Perry et al. 2012; Perry et al. 2015; Michel et al. 2013).

In order to assess the potential for water project operations to influence survival and routing, we analyzed Delta hydrodynamic conditions by utilizing outputs from DSM2 Hydro modeling. Our analysis of DSM2 output is based on our previous work creating map-based visualizations of spatial hydrodynamic patterns at the scale of the Delta. The map-based approach allows us to identify a 'footprint' of the hydrodynamic differences between scenarios. The maps are based on a comparative metric, proportion overlap (more below), to capture channel-level hydrodynamic details as a single number for color-scaled mapping of Delta channels. Our previous work made clear that spatial patterns were more easily discerned by mapping comparative metrics than by mapping descriptive metrics in multiple panels.

The objective of the comparative metric is to summarize the water velocity time series for each channel and scenario such the channel-level comparison is captured in a single number. For the proportion overlap metric, kernel density estimates are calculated on each time series. The kernel density estimates represent a non-parametric smoothing of the empirical distribution of time series values. The proportion overlap of two kernel density estimates is calculated with the following steps: 1) calculate the total area under the curve (AUC_t) as the sum of the AUC for each density estimate, 2) calculate the AUC of the overlapping portions (AUC_o) of the two density distributions being compared, and 3) calculate the overlapping proportion of the density distributions as AUC_o/AUC_t. Proportion overlap is naturally bound by zero and one; a value of zero indicates no overlap and a value of one indicates complete overlap. Lower values of proportion overlap identify channels demonstrating larger differences in a scenario comparison.

The proportion overlap metric is best applied over relatively short time periods because seasonal and annual variation in water velocity can overwhelm differences between scenarios. Thus, we calculated proportion overlap for every DSM2 channel for two seasons (Dec-Feb, May-Mar) in each water year (1922–2003). We excluded DSM2 output from water year 1921 to allow for an extensive burn-in period. We calculated proportion overlap based on hourly DSM2 output. Because each season was roughly 90 days, each comparison involved roughly 4,300 DSM2 values (2 scenarios * 24 hours * 90 days) for each channel.

Because we calculated proportion overlap for each channel in each water year, we summarized the proportion overlap values prior to mapping (i.e., not feasible to map proportion overlap for every comparison in every water year). To summarize, we found the minimum proportion overlap for each channel for each water year type for each comparison. The minimum values represent the maximum expected effect. Note that the year with the minimum proportion overlap for one channel might not be the same year as for another channel.

Entrainment

Zeug and Cavallo (2014) analyzed > 1000 release groups representing, more than 28 million coded wire tagged juvenile fish including winter, late fall and Fall-Run Chinook Salmon. This data is extremely useful because it represents large release groups of tagged smolts where the number of fish representing each release group lost to entrainment at the export facilities has been estimated. Estimating loss from "raw" salvage is problematic because the actual stock or basin of origin is often unknown (e.g., poor performance of length-at-date curves). Furthermore, with "raw" salvage, the number of smolts produced and potentially exposed to entrainment is unknown. The CWT salvage data analyzed by Zeug and Cavallo (2014) overcomes these deficiencies and provides the most appropriate basis for defining stock-specific categories of entrainment risk.

The average proportion Sacramento River-origin Fall-Run Chinook salvaged over a 15-year period was 0.0001 and the proportion of mortality accounted for by entrainment averaged 0.0003 (Zeug and Cavallo 2014). Salvage increased with increasing exports but loss never exceeded 1% regardless of export rate.

Late Fall-Run juveniles were salvaged at a higher rate than any other race (0.02% of each release group) and entrainment related mortality accounted for almost 1% of total mortality on average (Zeug and Cavallo 2014). Proportional loss of Late-Fall remained low until exports exceeded ~9,000 cfs when proportional loss could approach 8% (Zeug and Cavallo 2014). In the December through February period when Late Fall-Run are most abundant, Alternative 2 proposes an average total export rate higher than No Action Alternative (2,556 cfs; Figure O1-1) and will therefore have a higher entrainment risk. Total exports proposed for Alternative 2 in March-June (2,618 cfs higher than No Action Alternative; Figure O1-2) when juvenile Fall-Run are most abundant in the Delta, will increase entrainment risk relative to No Action Alternative, but entrainment losses for Fall-Run Chinook Salmon will be extremely low. Entrainment risk will also increase for Late Fall-Run and losses will likely be higher relative to Fall-Run.

Routing

Routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 1 were evaluated using DSM2 as described above. Juvenile Fall-Run Chinook Salmon abundance in the Delta is greatest between February and May and Late Fall-Run are present in the Delta between November and July with peaks in January through February and April through May (Table FR_1, LFR_1). In the December through February period, velocity overlap between Alternative 1 and No Action Alternative in the Sacramento River main stem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 83%, 79%, 68%, 70%, and 54% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-37 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 3 in below normal, above normal, and wet years and slightly lower in critically dry and dry years indicating routing into the interior Delta would be lower relative to No Action Alternative in normal and wet years and slightly higher relative to No Action Alternative in dry years (Perry et al. 2015; Figure O1-41 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 3 was more than 82%, 75%, 70%, 60%, and 79% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-38).

Fall-Run and Late Fall-Run Chinook Salmon juveniles originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can be exposed to hydrodynamic project effects that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 3 and the No Action Alternative (Figure O1-39 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 3 to the No Action Alternative in the March to May period (Figure O1-40).

Through-Delta Survival

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of the proposed project, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, velocity distributions for Alternative 3 relative to No Action Alternative were most different in wet years (72.5%) with higher velocities in Alternative 3. Velocities were also greater for Alternative 3 relative to No Action Alternative in below normal and above normal years although overlap was greater (>78%; Figure O1-41 in Appendix O, Attachment 1). In critically dry and dry years, velocity distributions were more similar (>84%; Figure O1-41 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, velocities under Alternative 3 were higher than No Action Alternative in wet and below normal years and similar in above normal, dry, and critically dry years (Figure O1-42 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 3 and No Action Alternative was >78% across all water year types with similar velocities under Alternative 3 (Figure O1-43 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 3 and No Action Alternative scenarios was >76% with similar velocities under Alternative 3 (Figure O1-44 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 3, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the “transitional” region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 3 relative to No Action Alternative exhibited high overlap in all water year types (≥81.3%; Figure O1-45 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 3 and No Action Alternative in critically dry and dry water years (≥77%) and moderate in wet, above normal, and below normal years (65%; Figure O1-46 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 3 and No Action Alternative (≥80%; Figure O1-47 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-47). At the Head of Middle River in the March –May period, overlap between Alternative 3 and No Action Alternative was moderate in all water year types (41-65%) and higher in critically dry years >78% (Figure O1-48 in Appendix O, Attachment 1). Velocities were generally lower under Alternative 3 than No Action Alternative (Figure O1-48).

Potential changes to aquatic resources due to OMR management

See section on seasonal operations which includes OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

The Delta Cross Channel may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Fall-Run Chinook Salmon in the Sacramento River past West Sacramento, which is near the DCC, occurs from February through May (Table FR_1). Therefore, the DCC is closed for the majority of the juvenile Fall-Run Chinook Salmon migration period in the Sacramento River and as such the proportion of fish exposed to an open DCC would be low. Juvenile Fall-Run Chinook Salmon that are entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010).

Potential changes to aquatic resources due to the Temporary Barriers Project

The Temporary Barriers Project (TBP) consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions and one rock barrier to improve San Joaquin River salmonid migration in the south Delta. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, Grant Line Canal near Tracy Boulevard Bridge, and the head of Old River. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30. The head of Old River Barrier is only installed from September 16 to November 30 to improve flow and dissolved oxygenconditions in the San Joaquin River for the immigration of adult Fall-Run Chinook Salmon.

The proportion of juvenile Fall-Run Chinook Salmon exposed to the TBP depends on their annual timing of installation and removal. Due to their location, primarily migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Fall-Run Chinook Salmon in the Delta at Mossdale is February through May (Table FR_1). The Head of Old River Barrier would have no effect on juvenile Fall-Run Chinook Salmon if installed from September 16 to November 30 as juvenile Fall-Run are largely absent from this section of the San Joaquin River during this time period (FR_1). If the agricultural barriers are operating as early as April 15 then they have the potential to expose a large proportion of the juvenile Fall-Run Chinook Salmon migrating down the San Joaquin River. When the Head of Old River barrier is not in place, acoustically tagged juvenile Chinook Salmon have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). Flap gates tied up on agricultural barriers from May 16 to May 31 would help to reduce the negative effect of the barriers during this period. However, juveniles migrating before or after this period could be exposed to the agricultural barriers with flaps down which apparently decreases passage success and survival (DWR 2018). Therefore, the potential negative effects of the agricultural barriers depends on when they are installed and whether the flap gates are down or tied up but overall would be medium to high.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 3 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD's operations, including operation of the Rock Slough Intake, under Alternative 3 would remain unchanged from the current operations.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Fall-Run/Late Fall-Run Chinook Salmon presence near the Rock Slough Intake. From 1999 to 2011, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected 23 juvenile Fall-Run/Late Fall-Run Chinook Salmon at the Rock Slough Headworks and Contra Costa Pumping Plant #1. Since construction of the Rock Slough Fish Screen in 2012, no Fall-Run/Late Fall-Run Chinook Salmon have been collected behind the fish screen. CCWD's Fish Monitoring Program also samples at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Fall-Run/Late Fall-Run Chinook Salmon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD’s operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD’s operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD’s operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Central Valley Fall-Run/Late Fall-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Salmon can be “drawn” into the south Delta under reverse flows and high CVP and SWP pumping rates.

One indicator of reverse flows is the net flow in Old and Middle Rivers (OMR). Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect net reverse flow in Old and Middle Rivers (OMR), and any effect that diversions at Rock Slough Intake would have in the Old and Middle River corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the Old and Middle River corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstems of the Sacramento River or the San Joaquin River and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, we examine the combined effect of all three intakes. CCWD’s Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD’s combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD’s Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Central Valley Fall-Run/Late Fall-Run Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is not significant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD’s operations under Alternative 3 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD’s operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant, however several years of monitoring have failed to consistently capture any salmonids during the winter Delta Smelt surveys (1996 to 2004) in Lindsey Slough or Barker Slough. Captures of Chinook Salmon have usually occurred in the months of February and March and typically are only a single fish per net haul (http://www.delta.dfg.ca.goc/data/nba). Most Chinook Salmon captured have come from Miner Slough, which is a direct distributary from the Sacramento River via Steamboat and Sutter Sloughs. Few if any San Joaquin River-origin Fall-Run Chinook Salmon are expected to be exposed to the North Bay aqueduct because it is not on the migration route of this species.

Alternative 3 also includes sediment removal with a suction dredge that could entrain Fall Run individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Fall Run occurring near the removal. The low occurrence of Chinook Salmon in monitoring efforts suggest that any potential imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few if any juvenile Fall-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Fall-Run are present in the Delta between mid-November and early June with a peak in April (Table_WR1). The application of aquatic herbicide to the waters of Clifton Court Forebay will occur during the summer months of July and August. Thus, the probability of exposing Spring-Run Chinook Salmon to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June. Mechanical harvesting would occur on an as-needed basis and therefore listed salmonids could be exposed to this action, if entrained into the Forebay. The overall effect of this action is low.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facilities improvements

Although actions at the Tracy facility could positively affect juvenile Fall-Run Chinook Salmon through greater salvage efficiency, only small proportions of Fall-Run Chinook Salmon are lost at the CVP (Zeug and Cavallo 2014).

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Chinook Salmon entrined into Clifton Cout Forebay. However, given that only small proportions of Fall-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014), the population-level positive effect of this action would be low. Larger proportions of Late Fall-Run Chinook Salmon are lost at the facilities and this action would have a larger effect for this run.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May coincides with downstream migration of juvenile Fall-Run Chinook Salmon (Table FR_1). NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.2 ft/s (for Delta Smelt protection), so that juvenile Fall-Run Chinook Salmon would be excluded from entrainment.

NMFS (2009: 438) considered it unlikely that juvenile Winter-Run Chinook Salmon, would be entrained by the three unscreened 48-inch culverts that form the Morrow Island Distribution System (MIDS) water intake, as a result of their larger size and better swimming ability relative to the size of Fall-Run Chinook Salmon observed to have been entrained (<45 mm), and also because the location of the MIDS intake on Goodyear Slough is not on a migratory corridor for listed juvenile salmonids. Although Fall-Run have been entrained at this facility, only a small proportion of total migrants are likely to encounter it.

NMFS (2009: 438) concluded that it would be unlikely that Chinook Salmon would encounter or be negatively affected by the Goodyear Slough outfall given its location and design, which is intended to improve water circulation in Suisun Marsh and therefore was felt by NMFS (2009: 438) to likely be of benefit to juvenile salmonids by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat Juvenile Fall-Run Chinook Salmon are abundant in the Delta in December and January and April and May (Table FR_1). Late Fall-Run are most abundant from January through April. Small fractions of each run could be exposed to Fall Delta Smelt habitat actions. For fish that are exposed, increased turbidity may reduce susceptibility to predation and increase through-Delta survival.

Potential changes to aquatic resources due to changes from Clifton Court predator management

Pre-screen survival of juvenile Chinook Salmon has been shown to be low (Gingras 1997) and predation is thought to be a major source of mortality. Analyses by Zeug and Cavallo (2014) indicate that only small proportions of Sacramento River-origin Fall-Run Chinook Salmon arrive at the facilities. However, moderte proportions of San Joaquin River-origin Fall-Run Chinook Salmon arrive at the facilities. For fish that are entrained into Clifton Cout Forebay, predator control may increase pre-screen survival. The overall effect of the action is low for Sacramento River-Origin fish and moderte for San Joaquin River and Mokelumne River-origin fish

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

O.3.7.8.6 Central Valley Steelhead

Potential changes to aquatic resources due to seasonal operations

Entrainment

ICF (2018) analyzed salvage of Central Valley Steelhead at the CVP and SWP between 2003 and 2017 and found that salvage increased with export rate and decreased with San Joaquin River flow. Salvage also decreased with OMR flow. However, OMR is a metric comprised of both exports and San Joaquin River flow which complicates attempts to understand individual effects.

In the December through February period, Alternative 3 proposes an average total export rate slightly higher than the No Action Alternative (2,556 cfs; Figure O1-1 in Appendix O, Attachment 1) and will therefore have higher entrainment risk. Total exports proposed for Alternative 3 in March-June (2,618 cfs higher than No Action Alternative; Figure O1-2 in Appendix O, Attachment 1) when juvenile Central Valley Steelhead are most abundant in the Delta at Chipps Island (Reclamation 2019), will increase entrainment risk relative to No Action Alternative.

Routing

Routing of juvenile Central Valley Steelhead into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 3 were evaluated using DSM2. Juvenile Central Valley Steelhead are present in the Sacramento River at Hood upstream of the first distributary junctions between November and early June with peak abundance from February to early June (Reclamation 2019). In the December to February period, velocity overlap between Alternative 3 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 83%, 79%, 68%, 70%, and 54% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-37 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 3 in below normal, above normal, and wet years and slightly lower in critically dry and dry years indicating routing into the interior Delta would be lower relative to No Action Alternative in normal and wet years and slightly higher relative to No Action Alternative in dry years (Perry et al. 2015; Figure O1-41 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 3 was more than 82%, 75%, 70%, 60%, and 79% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-38 in Appendix O, Attachment 1).

Through-Delta Survival

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 3, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, velocity distributions for Alternative 3 relative to No Action Alternative were most different in wet years (72.5%) with higher velocities in Alternative 3. Velocities were also greater for Alternative 3 relative to No Action Alternative in below normal and above normal years although overlap was greater (>78%; Figure O1-41 in Appendix O, Attachment 1). In critically dry and dry years, velocity distributions were more similar (>84%; Figure O1-41 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, velocities under Alternative 3 were higher than

No Action Alternative in wet and below normal years and similar in above normal, dry, and critically dry years (Figure O1-42 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 3 and No Action Alternative was >78% across all water year types with similar velocities under Alternative 3 (Figure O1-43 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 3 and No Action Alternative scenarios was >76% with similar velocities under Alternative 3 (Figure O1-44 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 1, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the "transitional" region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 3 relative to No Action Alternative exhibited high overlap in all water year types (≥81.3%; Figure O1-45 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 3 and No Action Alternative in critically dry and dry water years (≥77%) and moderate in wet, above normal, and below normal years (65%; Figure O1-46 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 3 and No Action Alternative (≥80%; Figure O1-47 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-47). At the Head of Middle River in the March –May period, overlap between Alternative 3 and No Action Alternative was moderate in all water year types (41-65%) and higher in critically dry years >78% (Figure O1-48 in Appendix O, Attachment 1). Velocities were generally lower under Alternative 3 than No Action Alternative (Figure O1-48).

Potential changes to aquatic resources due to OMR management

See section on Seasonal Operations which includes OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

Significant flow and many juvenile Central Valley Steelhead enter the central Delta when the DCC gates are open. Mortality of juvenile Central Valley Steelhead entering the central Delta is higher than for those continuing downstream in the Sacramento River. The peak migration of juvenile Central ValleyV Steelhead in the Sacramento River past Knights Landing, which is upstream of the DCC, occurs from January through February (Table 5.10-1). Therefore under Alternative 2, the continued operation of the DCC to protect the majority of the juvenile Central Valley Steelhead during their migration period in the Sacramento River would reduce the proportion of fish exposed to an open DCC and result in beneficial impacts to this life stage when compared to the No Action Alternative.

Potential changes to aquatic resources due to the Temporary Barriers Project

The Temporary Barriers Project (TBP) consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions and one rock barrier to improve San Joaquin River salmonid migration in the south Delta. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, Grant Line Canal near Tracy Boulevard Bridge, and the head of Old River. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30. The Head of Old River Barrier is only installed from September 16 to November 30 to improve flow and dissolved oxygenconditions in the San Joaquin River for the immigration of adult Fall-Run Chinook Salmon.

The proportion of juvenile Central Valley Steelhead exposed to the TBP depends on their annual timing of installation and removal. Due to their location, primarily juvenile Central Valley Steelhead migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Central Valley Steelhead in the San Joaquin River in the vicinity of the TBP (Mossdale) occurs in April and May (Reclamation 2019). If the agricultural barriers are operating as early as April 15, there is potential exposure to a large proportion of the juvenile Central Valley Steelhead migrating down the San Joaquin River.

When the Head of Old River barrier is not in place, acoustically tagged juvenile Central Valley Steelhead have demonstrated a high probability of selecting the Old River route (Buchanan 2018[PC1]), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Central Valley Steelhead migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Central Valley Steelhead passage past the agricultural barrier was improved (DWR 2018). Therefore, although Alternative 3 does not include HORB, which could result in negative impacts to Central Valley Steelhead juvenile migration, the improvements to the agricultural barriers (including flap gates tied up from May 16 to May 31) would help to reduce the negative effect of the barriers on migrating juvenile Central Valley Steelhead during this period relative to No Action Alternative. However, juvenile Central Valley Steelhead migrating before or after this period could be exposed to the agricultural barriers with flaps down, which apparently decreases passage success and survival (DWR 2018). Therefore, the potential negative effects of the agricultural barriers under Alternative 1 on juvenile Central Valley Steelhead depends on when they are installed and whether or not the flap gates are down.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD’s operations in Alternative 3 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD’s operations, including operation of the Rock Slough Intake, under Alternative 3 would remain unchanged from the current operations.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Central Valley Steelhead presence near the Rock Slough Intake. From 1999 to 2011, the 11 years prior to construction of the RSFS, CCWD’s Fish Monitoring Program collected 15 juvenile Central Valley Steelhead at the Rock Slough Headworks and Pumping Plant #1. Since construction of the Rock Slough Fish Screen, no Central Valley Steelhead have been collected behind the fish screen. CCWD’s Fish Monitoring Program also samples at CCWD’s other south Delta intakes. Since the intakes have been in operation, CCWD’s Fish Monitoring Program has never collected Central Valley Steelhead at CCWD’s Old River Intake or Middle River Intake (CCWD 2019).

CCWD’s operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD’s operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Central Valley Steelhead are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile salmonids can be "drawn" into the south Delta under reverse flows and high CVP and SWP pumping rates. One indicator of reverse flows is the net flow in OMR. Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect OMR, and any effect that diversions at Rock Slough Intake under Alternative 3 would have in the OMR corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the Old and Middle River corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstems of the Sacramento or San Joaquin Rivers and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, the combined effect of all three intakes was examined. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Central ValleySteelhead.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is insignificant in comparison to the tidal excursion and mixing at this location. Although the diversions at Rock Slough Intake are not likely to impact juvenile Central Valley Steelhead, the aggregate effect of all water diversions in the Delta, including exports at Jones and Banks Pumping Plants can affect channel velocity.

In summary, CCWD's operations under Alternative 3 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Under Alternative 3, there would be no changes to operational criteria at the NBA's BSPP relative to current op. Juvenile Central Valley Steelhead could occur in the vicinity of the BSPP; however, the fish screens used at the facility are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment and greatly minimize impingement of fish against the screen itself (NMFS 2009). In addition, the location of the facility is well off the typical migration corridor of juvenile Central Valley Steelhead (NMFS 2009: 417). No juvenile Central Valley Steelhead have been captured during CDFW monitoring surveys from 1996 to 2004 (http://www.delta.dfg.ca.goc/data/nba).

Alternative 3 also includes sediment removal with a suction dredge that could entrain Fall Run individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Fall Run occurring near the removal. The low occurrence of Chinook Salmon in monitoring efforts suggest that any potential imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

Central Valley Steelhead juveniles could be exposed to increased entrainment, predation, and decreased through-Delta survival as a result of the expanded transfer window under Alternative 3, but as the peak of the juvenile out-migration is in the spring, effects are anticipated to be minimal. No other lifestages of Central Valley Steelhead would co-occur in time and space with water transfers from the Delta.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Under Alternative 3, the application of aquatic herbicide to the waters of CCF will occur between 28 June and 31 August. Treatment could occur prior to 28 June at tempertures ≥ 25˚C; however, steelhead would not be expected to occur at these temperatures. Treatment could also occur after 31 August if protective measures have not been triggered but few if any steelhead would be expected in the Delta during that time period. Juvenile Central Valley Steelhead abundance in the Delta peaks between March and May (Reclamation 2019). Based on typical water temperatures in the vicinity of the salvage facilities during this period, the water temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June. As such, it is unlikely that juvenile Central Valley Steelhead would be rearing near this location after mid-June and the potential application of aquatic herbicide would only occur well after the peak out-migration period (Reclamation 2019) and therefore Central Valley Steelhead are not expected to be exposed to herbicide application activities.

Mechanical harvesting would occur on an as-needed basis and therefore listed salmonids could be exposed to this action, if entrained into the CCF. Potential direct and indirect effects to listed fish species from mechanical weed harvesters include mortality or injury from harvester strikes, entanglement in weeds lifted from the water, reduction of aquatic prey species, and temporary disturbances. Increased boat noise and disturbance of the water during harvesting, the slow speed of the harvester (approximately 2 miles per hour), and beginning harvesting closest to the edge should allow fish to escape the area proposed for mowing. However, Central Valley Steelhead are unlikely to be present and exposed to the adverse effects due to extreme temperatures.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facilities improvements

Small proportions of Sacramento River-origin Central Valley Steelhead and moderate proportions of Mokelumne River and San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the Tracy Fish Facility. However, for fish that arrive at the facility, the proposed improvements resulting in greater salvage efficiency under Alternative 3 are likely to increase survival of juvenile Central Valley Steelhead.

As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, none to a few late migrants or early migrants have the potential to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements. Risks of decrease Central Valley Steelhead juvenile salvage during construction would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, Mitigation Measures).

Skinner Fish Facility improvements under Alternative 3 to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May under Alternative 3 coincides with downstream migration of juvenile Central Valley Steelhead (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Central Valley Steelhead thus, the proportion of the total run utilizing this route is unknown. However NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

Under Alternative 3, the Roaring River Distribution System water diversion intake is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.2 ft/s (for Delta Smelt protection), excluding juvenile Central Valley Steelhead from entrainment (NMFS 2009: 437).

The MIDS diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, it is unlikely juvenile Central Valley Steelhead will be entrained into the water distribution system because Central Valley Steelhead have not been caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor for Central Valley Steelhead. The operation of the MIDS under Alternative 3 would not impact Central Valley Steelhead.

Goodyear Slough Outfall improves water circulation in the Suisun Marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Central Valley Steelhead are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits Central Valley Steelhead in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat Central Valley Steelhead juveniles are in the Delta in the spring. Reclamation proposes to conduct actions for Fall Delta Smelt Habitat in the fall, as adult Central Valley Steelhead are migrating upstream. Fall Delta Smelt Habitat actions are unlikely to affect adult Central Valley Steelhead.

Potential changes to aquatic resources due to changes from Clifton Court predator management

Clifton Court predator management under Alternative 3 could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

Potential changes to aquatic resources from monitoring

Population estimates for wild Steelhead remain outstanding in the Central Valley, therefore it is difficult to quantify the effects of the monitoring on Steelhead populations. However, most existing monitoring programs in the Central Valley and Delta/SF Estuary are not designed to capture Steelhead, which are much larger than Chinook Salmon upon river and Delta entry. Existing programs likely have poor capture efficiency for collecting and retaining Steelhead. Therefore, it is unlikely the monitoring programs have any effects to the population.

O.3.7.8.7 North American Green Sturgeon Southern DPS

Potential changes to aquatic resources due to seasonal operations

Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to negatively impact southern DPS Green Sturgeon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, 2) “far-field” mortality resulting from altered hydrodynamics. The SST completed a thorough review of this subject and defined a driver- linkage-outcome (DLO) framework for specifying how water project operations (the “driver”) can influence juvenile salmonid behavior (the “linkage”) and potentially cause changes in survival or routing (the “outcome”). A similar analysis is not available for southern DPS Green Sturgeon.

Entrainment

As described by NMFS (2009: 386), impacts to the migratory corridor function of juvenile and subadult Green Sturgeon critical habitat from south Delta exports are less clear than for juvenile salmonids because Green Sturgeon spend 1 to 3 years rearing in the Delta environment before transitioning to their marine life history stage. During this Delta rearing phase, Green Sturgeon are free to migrate throughout the Delta. In the conceptual model, it is hypothesized that higher rates of exports may result in higher rates of entrainment. However, estimating entrainment risk from raw salvage data is not possible due to a lack of information on the number of juvenile Green Sturgeon potentially exposed to salvage.

Juvenile southern DPS Green Sturgeon (> 5 mo) are present in the Delta all year and subadults are most abundant from June through November. In the June through September period under Alternative 3 Reclamation proposes an average total export rate slightly higher than No Action Alternative (440 cfs; Figure O1-15 in Appendix O, Attachment 1) and are unlikely to measurably increase entrainment risk.

Total exports proposed for Alternative 3 in September-November (904 cfs higher than No Action Alternative; Figure O1-16 in Appendix O, Attachment 1) are unlikely to measurably increase entrainment risk relative to No Action Alternative.

Juvenile White and Green Sturgeon are infrequent at the TFCF, but may occur in the facility salvage year-round. Salvage is expected to be similar and slightly higher than No Action Alternative under Alternative 3.

Routing

Juvenile Green Sturgeon (>5 mo) are present in the Delta all year and subadults are most abundant from June to November (Reclamation 2019). Juvenile Green Sturgeon swim and behave quite differently and have distinct body morphologies and habitat associations in the Delta compared to outmigrating salmonids, so it is hypothesized that juvenile Green Sturgeon have different routing-hydrology survival relationships. Per NMFS (2009: 338), Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways. It is highly uncertain how Green Sturgeon routing would change with Alternative 3.

Through-Delta Survival

Little is known about the relationship between survival of juvenile Green Sturgeon and Delta hydrology. Green Sturgeon reside in the Delta for 1 to 3 years suggesting they encounter a variety of daily, seasonal, and annual hydrological conditions. The majority of Green Sturgeon in the Delta are likely not surviving through the Delta per se, but using these habitats for rearing and foraging. Per NMFS (2009: 338), Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways. For juvenile outmigrating Green Sturgeon present in these regions, increasing negative velocities under Alternative 3 may result in lower survival. However, as described above, there is a lower probability of juvenile Green Sturgeon residing in this area.

Potential changes to aquatic resources due to OMR management

See section above on Seasonal operations which includes OMR management

Potential changes to aquatic resources due to Delta Cross Channel operations

Delta Cross Channel operations under Alternative 3 are changed to allow Reclamation to predict water quality exceedances and open the DCC if D-1641 criteria are predicted to be exceeded. This results in greater opening times of the DCC.

Little is known about the migratory behavior of juvenile Green Sturgeon in the Sacramento River basin. It is likely that juvenile Green Sturgeon (larger than the 75 mm) will not enter the Delta prior to their first winter and thus would not be exposed to the open DCC gates. If juvenile Green Sturgeon are exposed to the open DCC gates, they could be entrained into the central / south Delta and exposed to biological and physical conditions in this area, including potentially greater predation. It is likely that these fish will enter the Delta sometime in the winter or spring following their hatching upriver and encounter both types of gate configurations as they enter the Delta.

Potential changes to aquatic resources due to the Temporary Barriers Project

Agricultural Barriers (Temporary Barriers Project, or TBP) are included in Alternative 3 and consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, and Grant Line Canal near Tracy Boulevard Bridge. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30.

Juvenile Green Sturgeon are present in the Delta in all months of the year. However, little is known about their spatial distribution. When the south Delta agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up (May 16 to May 31), outmigrating Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). It could be inferred that passage of outmigrating juvenile Green Sturgeon may also be improved when flap gates are tied up. Therefore, the potential negative effects of the agricultural barriers under Alternative 3 depends on when they are installed and whether the flap gates are down or tied up.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD’s operations in Alternative 3 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD’s operations, including operation of the Rock Slough Intake, for Alternative 3 remain unchanged from current conditions and the No Action Alternative.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory routes for southern DPS Green Sturgeon (NMFS 2017c), approximately 18 miles from the Sacramento River and 10 miles from the San Joaquin River via the shortest routes. Water temperatures in Rock Slough range from lows of about 40 degrees F in winter (December and January) to over 70 degrees F beginning in May and continuing through October (NMFS 2017c).

A review of the 24 years of fish monitoring data (1994–2018) near the Rock Slough Intake both pre- and post-construction of the Rock Slough Fish Screen (RSFS) showed that southern DPS Green Sturgeon have never been observed in Rock Slough (CDFG 2002c; Reclamation 2016; NMFS 2017c; Tenera Environmental 2018b, ICF 2018). CCWD’s Fish Monitoring Program also samples at CCWD’s other south Delta intakes. Since the intakes have been in operation, CCWD’s Fish Monitoring Program has never observed southern DPS Green Sturgeon at CCWD’s Old River Intake or Middle River Intake (CCWD 2019).

It is unlikely that juvenile, subadult, or adult Green Sturgeon would be present in Rock Slough due to the shallow depth, warm water temperatures, and low dissolved oxygenwhich make the area unsuitable habitat during most of the year. Therefore, it is unlikely that Green Sturgeon will be entrained at Rock Slough Intake and unlikely that Green Sturgeon would be impacted by CCWD operations.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Overall, the modeled exports in Alternative 3 represent a significant increase in export levels and, thus, a greater risk to Green Sturgeon in the waters adjacent to the pumping facility compared to their historical vulnerability (NOAA 2009). However, Green Sturgeon are expected to be fully screened out of the facilities by the positive barrier fish screen in place at the pumping facility.

Alternative 3 also includes sediment removal with a suction dredge that could entrain Green Sturgeon individuals occurring near the suction dredging. In addition, aquatic weed removal with a grappling system could disturb Green Sturgeon occurring near the removal. The low occurrence of Green Sturgeon in monitoring efforts suggest that any potential imacts from sediment and aquatic weed removal would be limited.

Potential changes to aquatic resources due to water transfers

As discussed under the Spring-Run Chinook Salmon water transfer section, under Alternative 3 Reclamation proposes to expand the transfer window to November. This extended transfer window could result in approximately 50 TAF of additional pumping per year in most years, with associated entrainment, routing, and through-Delta survival impacts. Please see the OMR management section for a discussion of the effects of pumping.

Juveniles older than 5 months, subadults, and adult Green Sturgeon could be exposed to the effects of increased pumping due to water transfers. Although southern DPS Green Sturgeon are present in the Delta in all months of the year, Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways (NMFS 2009:338). Therefore, there are no negative impacts of increased pumping at Jones and Banks Pumping Plants due to water transfers under Alternative 3.

Juvenile southern DPS Green Sturgeon are present in the Delta in every month of the year (Reclamation 2019). Thus, some portion of the population would be exposed to this action. Increases in Delta inflow during water transfers may have benefits for juvenile Green Sturgeon. However, there is no information on relationships between flow and juvenile Green Sturgeon ecology.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few southern DPS juvenile Green Sturgeon Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program as part of Alternative 3. Although southern DPS juvenile Green Sturgeon are present in the Delta in all months of the year, Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways (NMFS 2009:338). The application of aquatic herbicide to the waters of Clifton Court Forebay will occur between 28 June and 31 August. Treatment could occur prior to 28 June at tempertures ≥ 25˚C; however, Green Sturgeon would not be expected to occur at these temperatures. Treatment could also occur after 31 August if protective measures have not been triggered but few Green Sturgeon are collected at the facility indicating the impact would be minimal. Thus, the likelihood of exposing juvenile Green Sturgeon to the herbicide is very low. Mechanical harvesting would occur on an as-needed basis and, therefore, juvenile Green Sturgeon could be exposed to this action, if entrained into the Forebay.

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facilities improvements

Upgrades to the TFCF under Alternative 3 will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish, and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

Upgrades to the TFCF will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

As previously described, juvenile Green Sturgeon can occur in the Delta year-round (Reclamation 2019) and, therefore, have the potential to be exposed to the effects of construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements. If construction affects the efficiency of Green Sturgeon salvage (which is an element of entrainment risk. (Reclamation 2019)), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures (Appendix E, *Mitigation Measures*).

Skinner Fish Facility improvements under Alternative 3, which involve predator control efforts, can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently. Thus, Alternative 3 is not likely to negatively impact juvenile Green Sturgeon.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from June through September under Alternative 3 coincides with a portion of the downstream migration of juvenile southern DPS Green Sturgeon, as well as adult southern DPS Green Sturgeon. Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. During full gate operation, the flashboards are installed and the radial gates open and close twice each tidal day. Green Sturgeon are thought to successfully pass through either the boat lock or through the gates during periods when the gates are open. NMFS (2009) determined that operation of the SWSCG is unlikely to produce conditions that support unusually high numbers of predators, change habitat suitability or availability for rearing or migration of juvenile and adult Green Sturgeon. Green Sturgeon are strong swimmers and therefore the operation of the Suisun Marsh Salinity Control Gate will have no impact on adults or juvenile Green Sturgeon.

The low screen velocity at the intake culverts combined with a small screen mesh size are expected to successfully prevent Green Sturgeon from being entrained into the RRDS under Alternative 3. (NOAA 2009).

The MIDS intakes under Alternative 3 do not currently have fish screens, and juvenile Green Sturgeon are more prone to entrainment than other species such as White Sturgeon (Poletto et al. 2014). However, fisheries monitoring performed in 2004-05 and 2005-06 identified entrainment of 20 fish species, none of which were Green Sturgeon (NOAA 2009). Presence of Green Sturgeon in the area of the MIDS intake is not well studied or documented, but it if Green Sturgeon are present they may potentially avoid entrainment as they do not typically swim along the surface where the diversion is located.

Due to its location and design, Green Sturgeon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall under Alternative 3 likely benefits juvenile Green Sturgeon in Suisun Marsh by improving water quality and increasing foraging opportunities (NOAA 2009).

Potential changes to aquatic resources due to changes from Clifton Court predator management

Predator control efforts under Alternative 3 can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

None of the Green Sturgeon life stages would benefit from the Delta Fish Species Conservation Hatchery under Alternative 3. As with the other proposed construction activities in the Delta, the year-round occurrence of juvenile Green Sturgeon in the Delta (Reclamation 2019) means that this life stage, as well as the timing of the adult Green Sturgeon occurring in the Delta during May to October, could be exposed to Delta Fish Species Conservation Hatchery construction under *Alternative 3*. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risks from these potential effects would be minimized with through the application of mitigation measures (Appendix E, *Mitigation Measures*).

Potential changes to aquatic resources from monitoring

Population estimates for Green Sturgeon also remain outstanding in the Central Valley. Similar to Steelhead, the existing monitoring programs very rarely catch Green Sturgeon because most monitoring programs are not designed to capture them. Similar to Steelhead, it is unlikely the monitoring programs have an effect to the population.

O.3.7.9 *Nearshore Pacific Ocean on the California Coast*

O.3.7.9.1 Southern Resident Killer Whale

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

As with Alternative 2, Alternative 3 water operations would not include many of the criteria currently in place as a result of the NMFS (2009a) SWP/CVP BO’s RPA. Based on the same reasoning applied to Alternative 2, Alternative 3 therefore could result in potential negative effects to Central Valley Chinook Salmon stocks and Southern Resident Killer Whale. As with Alternative 2, there is some uncertainty in this conclusion given that effects are potentially limited by the medium importance of Central Valley Chinook Salmon stocks to Southern Resident Killer Whale diet and the relatively high representation of hatchery-origin juvenile Chinook Salmon, many of which are released downstream of the Delta (Reclamation 2019).

O.3.8 Alternative 3 – Program-Level Effects

O.3.8.1 *Sacramento River*

Potential changes to aquatic resources from Battle Creek restoration

Acceleration of the Battle Creek restoration program will be implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

Potential changes to aquatic resources from lower intakes near Wilkins Slough

Lowering intakes of diversions near Wilkins Slough will be implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

Potential changes to aquatic resources due to Shasta TCD Improvements

Improvement of the Shasta TCD will be implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

Potential changes to aquatic resources from operation of the Livingston-Stone National Fish Hatchery (Winter-Run Chinook Salmon)

Increased production of Winter-Run Chinook Salmon at the Livingston-Stone National Fish Hatchery is being implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

Potential changes to aquatic resources from small screen program installation

The construction and operation of fish screens on water diversions is being implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

Potential changes to aquatic resources from spawning habitat restoration

Spawning habitat restoration is being implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

Potential changes to aquatic resources from rearing habitat restoration

Rearing habitat restoration is being implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

Potential changes to aquatic resources due to adult rescue activities

Adult rescue is being implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

Potential changes to aquatic resources due to trap and haul activities

The juvenile trap and haul strategy is being implemented under both Alternative 3 and Alternative 1. Therefore, Alternative 3 and Alternative 1 are likely to have similar effects on aquatic resources compared to the No Action Alternative with respect to this measure.

O.3.8.2 *Bay-Delta*

O.3.8.2.1 Delta Smelt

The following potential program-level effects would be similar under Alternative 3 as under Alternative 1:

Potential changes to Delta Smelt from food subsidies (Sacramento Deepwater Ship Channel food study; North Delta food subsidies/Colusa Basin Drain study; Suisun Marsh Roaring River Distribution System food subsidies study)

Potential changes to Delta Smelt from tidal habitat restoration (complete 8,000 acres from 2008 BO)

Potential changes to Delta Smelt from predator hot spot removal

Potential changes to Delta Smelt from Delta Cross Channel gate improvement

Potential changes to Delta Smelt due to changes from Tracy and Skinner Fish Facility improvements

Potential changes to Delta Smelt from Delta fish species conservation hatchery

In addition to these potential effects that would be expected to be similar to the effects under Alternative 1, Alternative 3 would include the following:

Potential changes to Delta Smelt from additional habitat restoration (25,000 acres within the Delta)

Restoration of an additional 25,000 acres of Delta habitat under Alternative 3 would have the potential to provide a greater extent of positive effects to Delta Smelt as previously described for the completion of 8,000 acres of habitat required under the USFWS (2008) BO, i.e., increased food availability and habitat for Delta Smelt to occupy depending on provision of suitable habitat features. The additional 25,000 acres of habitat restoration has the potential to more than offset the negative effects of seasonal operations on food availability, which is intended to be offset by the 8,000 acres of tidal habitat restoration required by the USFWS (2008) BO. However, 25,000 acres of tidal habitat restoration in the north Delta would change hydrodynamics such that there would be a lower tidal range at the DCC and therefore potentially reduced magnitude of Sacramento River flow entering the DCC, which in turn could reduce lower San Joaquin River net flow and negatively affect the subsidy of *P. forbesi* to the low salinity zone (Figures SJR_jul, SJR_aug, SJR_sep; see also discussion by RMA 2010). As with the completion of 8,000 acres of habitat restoration, potential negative effects from contaminants would be managed with minimization measures, as described in the ROC LTO BA).

O.3.8.2.2 Longfin Smelt

The following potential program-level effects would be similar under Alternative 3 as under Alternative 1:

Potential changes to Longfin Smelt from food subsidies (Sacramento Deepwater Ship Channel food study; North Delta food subsidies/Colusa Basin Drain study; Suisun Marsh Roaring River Distribution System food subsidies study)

Potential changes to Longfin Smelt from tidal habitat restoration

Potential changes to Longfin Smelt from predator hot spot removal

Potential changes to Longfin Smelt from Delta Cross Channel gate improvement

Potential changes to Longfin Smelt due to changes from Tracy and Skinner Fish Facility improvements

Potential changes to Longfin Smelt from the small screen program

Potential changes to Longfin Smelt from Delta fish species conservation hatchery

In addition to these potential effects that would be expected to be similar to the effects under Alternative 1, Alternative 3:

Potential changes to Longfin Smelt from additional habitat restoration (25,000 acres within the Delta)

Restoration of an additional 25,000 acres of Delta habitat under Alternative 3 would have the potential to provide a greater extent of positive effects to Longfin Smelt as previously described for the completion of 8,000 acres of habitat required under the USFWS (2008) BO, i.e., increased food availability and habitat for occupancy by Longfin Smelt, albeit with perhaps limited effects given that most Longfin Smelt would tend to be downstream of restored areas. Potential negative effects from contaminants would be limited through application of appropriate mitigation measures for aquatic resources, as previously outlined for the 8,000 acres of tidal habitat restoration.

O.3.8.2.3 Sacramento Winter-Run Chinook Salmon

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

This action would hydrologically connect the Sacramento River with the Sacramento Deepwater Ship Channel (SDWSC) via the Stone Lock facility from mid-spring to late fall. Juvenile Winter-Run Chinook Salmon may be exposed to the Sacramento Deepwater Ship Channel (SDWSC) component of Alternative 3. This action would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018) to provide food web benefits to Delta Smelt. Juvenile Winter-Run Chinook Salmon abundance downstream of Stone Lock at Sherwood Harbor is highest in February and March, declines in April, and is moderate in November (Reclamation 2019). Juvenile Winter-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be routed into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, if survival rates are similar, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit associated with Alternative 3. A hydrologically connected SDWSC could potentially attract adult Winter-Run Chinook Salmon. If the connection is maintained there would likely not be impacts to adults. However, if the connection is not maintained there could be migratory delays and stranding.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and therefore would have limited effects on Winter-Run Chinook Salmon, who are in the Delta between December and May for juveniles, and December to July for adults.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 3, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Winter-Run Chinook Salmon, who are in the Delta between December and May for juveniles, and December to July for adults.

Potential changes to aquatic resources due to tidal habitat restoration

Although migration through the Delta represents a short period, a large proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to 8,000 acres of tidal habitat restoration in the Delta. Tidal habitat restoration is expected to benefit juvenile Winter-Run Chinook Salmon in several aspects represented by the Winter-Run Chinook Salmon conceptual model, (see Figure 5.6-4 of the ROC LTO BA) including increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta. Reclamation and DWR will consult on future tidal habitat restoration with USFWS and NMFS on potential effects to fish from construction-related effects.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Winter-Run Chinook Salmon. Although Alternative 3 would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Winter-Run Chinook Salmon. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016). Winter-Run Chinook Salmon juveniles in the Bay-Delta are unlikely to be exposed to the effects of construction at predator hot spot removal locations in the Sacramento River, as the in-water work window is in the summer / fall when Winter-Run Chinook Salmon juveniles are generally in the upper river.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Winter-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. Few Winter-Run Chinook Salmon are expected to be exposed to improvements to the Delta Cross Channel. Seasonal closure periods would still be in place to protect migrating salmonids. Potential diurnal operation during closure periods could increase exposure of Winter-Run Chinook Salmon juveniles to entrainment into the interior Delta. Improved biological and physical monitoring associated with improvements would likely minimize potentially increased routing into the interior Delta and subsequent entrainment. Greater operational flexibility and increased gate reliability resulting from improvements would reduce the risk of gate failure that could result in higher rates of entrainment.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

A small proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility. Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements based on lack of observed salvage during the August to October in-water work window (see Figures F.2.7, F.2.8, and F.2.9 in Appendix F of the ROC LTO BA). However, a few early migrants could occur during the in-water work window based on occurrence in the north Delta (see Figures WR_Seines and WR_Sherwood in Appendix F of the ROC LTO BA).

To the extent that the construction affects the ability of juvenile Winter-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Reclamation 2019), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures, including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12 (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Chinook Salmon entrained into CCF. It is important to note that only small proportions of Winter-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014).

Potential changes to aquatic resources from the small screen program

There may be some overlap Winter-Run Chinook Salmon with the main late spring-fall irrigation period for small diversions. Diversion screening could reduce entrainment of late migrating individuals. It is important to note that only a small proportion of the population would be exposed.

Few if any juvenile Winter-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Winter-Run Chinook Salmon primarily migrate from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

The operation of the Delta Fish Species Conservation Hatchery would not provide benefits to any life stage of Winter-Run Chinook Salmon. Potential negative effects of the Delta Fish Species Conservation Hatchery include inadvertent propagation and spread of invasive or nuisance species, which could affect juvenile Winter-Run Chinook Salmon through changes in food web structure, for example, in the case of invasive quagga and zebra mussels (Fera et al. 2017). Additional impacts could include reduced water quality resulting from hatchery discharge. Potential negative effects from discharged water are expected to be minimal due to the water treatment and the very small size of the discharge compared to flows in the

Sacramento River near the hatchery location. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Winter-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Bay-Delta, few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of early migrants to in-water and shoreline construction of the hatchery intake and outfall, as illustrated by timing of occurrence in Sacramento seines and trawls (see Figures F.2.4 and F.2.5 in Appendix F of the ROC LTO BA). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of construction of the Delta Fish Species Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

O.3.8.2.4 Central Valley Spring-Run Chinook Salmon

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

This action would hydrologically connect the Sacramento River with the Sacramento Deepwater Ship Channel (SDWSC) via the Stone Lock facility from mid-spring to late fall. Juvenile Spring-Run Chinook Salmon abundance in the Delta is moderate in March and peaks in April (Reclamation 2019). Juvenile Spring-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be enter into the SDWSC. There are potential benefits to Spring-Run Chinook Salmon from this action. Fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar. However, estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. Also, there is potential for decreased migration time to the ocean and exposure to larger food sources of Liberty Island, but this is currently uncertain.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and therefore would have limited effects on Spring-Run Chinook Salmon, who are in the Delta January through February for adults, and November through June for juveniles, with a peak of juvenile migration from March to April.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 3, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Spring-Run Chinook Salmon, who are in the Delta January through February for adults, and November through June for juveniles, with a peak of juvenile migration from March to April.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Spring-Run Chinook Salmon are expected to benefit from continuing to construct the 8,000 acres of tidal habitat restoration in the Delta under Alternative 3. Benefits include increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of yearling migrants that enter the Delta in the fall. Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes the following: temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance, indirect impairment of aquatic ecosystem productivity, loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. Many of these are elements highlighted in the SAIL conceptual model (Figure 5.6-4). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14 (Appendix E, *Mitigation Measures*).

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 3 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Spring-Run Chinook Salmon. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Spring-Run Chinook Salmon. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016).

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Greater operational flexibility and increased gate reliability resulting from improvements to the Delta Cross Channel under Alternative 3 would reduce the risk of gate failure that could result in higher rates of entrainment of Spring-Run Chinook Salmon, if left open. Few Spring-Run Chinook Salmon are expected to be exposed to in-water construction related improvements to the Delta Cross Channel due to observance of species protective work windows. Seasonal closure periods would still be in place to protect Spring-Run Chinook Salmon. The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Spring-Run

Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. However, improved biological and physical monitoring associated with improvements would likely minimize potentially increased entrainment.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

A number of programmatic actions are proposed to improve salvage efficiency of TFCF, including installing a carbon dioxide injection device to allow remote controlled anesthetization of predators in the secondary channels of the Tracy Fish Facility. These actions could potentially benefit juvenile Spring-Run Chinook Salmon through greater salvage efficiency.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see figures in Appendix Fof the ROC LTO BA*:* WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race). Risks to these few individuals would be minimized through appropriate mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12 (Appendix E, *Mitigation Measures*), the selected in-water work window, and the small scale of the in-water construction. For juvenile Spring-Run Chinook Salmon that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Predator control efforts at Skinner Fish Facility under Alternative 3 to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts.

Potential changes to aquatic resources from the small screen program

Few if any juvenile Spring-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Sacramento River Spring-Run Chinook Salmon primarily from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

The operation of the Delta Fish Species Conservation Hatchery would not provide benefits to any life stage of Winter-Run Chinook Salmon. Potential negative effects of the Delta Fish Species Conservation Hatchery include inadvertent propagation and spread of invasive or nuisance species, which could affect juvenile Winter-Run Chinook Salmon through changes in food web structure, for example, in the case of invasive quagga and zebra mussels (Fera et al. 2017). Additional impacts could include reduced water quality resulting from hatchery discharge. Potential negative effects from discharged water are expected to be minimal due to the water treatment and the very small size of the discharge compared to flows in the Sacramento River near the hatchery location. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Winter-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Bay-Delta, few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes

Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of early migrants to in-water and shoreline construction of the hatchery intake and outfall, as illustrated by timing of occurrence in Sacramento seines and trawls (see Figures F.2.4 and F.2.5 in Appendix F of the ROC LTO BA). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-14. (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of construction of the Delta Fish Species Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

O.3.8.2.5 Central Valley Fall-Run Chinook Salmon

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

Moderate to high proportions of juvenile Fall-Run Chinook Salmon are expected to be exposed to the Sacramento Deepwater Ship Channel (SDWSC) action. This action would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018). Juvenile Fall-Run Chinook Salmon abundance in the Delta is moderate in peaks in April and May (Table FR_1). Juvenile Fall-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be entrained into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar. The effect of this action on juvenile Fall-Run Chinook Salmon is moderate.

No San Joaquin River-origin Fall-Run are expected to be exposed to the Sacramento Deepwater Ship Channel.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

This action is proposed to occur in July or September which is largely outside of the migration period for juvenile Fall-Run and Late Fall-Run Chinook Salmon in the Delta (Table _FR1, Table LFR1). For fish that are exposed, increased food production could potentially enhance growth. The effect of this action is expected to be low.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

This action is proposed to occur in July or September which is largely outside of the migration period for juvenile Fall-Run and Late Fall-Run Chinook Salmon in the Delta (Table _FR1, Table LFR1). For fish that are exposed, increased food production could potentially enhance growth. The effect of this action is expected to be low.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Fall-Run and Late Fall-Run Chinook Salmon are expected to be exposed to 8,000 acres of tidal habitat restoration in the Delta. Tidal habitat restoration is expected to benefit juvenile Chinook Salmon in several aspects represented by the Winter-Run conceptual model (Figure WR_CM4) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta. Migration through the Delta represents a short period in the migration of juvenile Fall-Run and Late Fall-Run Chinook Salmon. Thus the total effect of this action is moderate.

Few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance (e.g., gill damage and reduced ability to take in oxygen, increasing metabolic cost), indirect impairment of aquatic ecosystem productivity (e.g., reduction in benthic macroinvertebrate production and availability), loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. Many of these are elements highlighted in the SAIL conceptual model (Reclamation 2019). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14 (Appendix E Miigation Measures).

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Fall-Run and Late Fall-Run Chinook Salmon. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Spring-Run Chinook. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016).

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Greater operational flexibility and increased gate reliability resulting from improvements to the Delta Cross Channel under Alternative 3 would reduce the risk of gate failure that could result in higher rates of entrainment of Fall-Run and Late Fall-Run Chinook Salmon, if left open. Few Fall-Run or Late fall-Run Chinook Salmon are expected to be exposed to in-water construction related improvements to the Delta Cross Channel due to observance of species protective work windows. Seasonal closure periods would still be in place to protect Chinook Salmon. The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Fall-Run and Late Fall-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. However, improved biological and physical monitoring associated with improvements would likely minimize potentially increased entrainment.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

A small proportion of juvenile Fall-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see Figures WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race in Appendix F of the ROC LTO BA). To the extent that the construction affects the ability of juvenile Fall-Run, and Late Fall-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Figure WR_CM4), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12 (Appendix E, *Mitigation Measures*). Given the low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction, it is concluded that the negative population-level effects of Tracy Fish Facility Improvements construction would be low on this life stage.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Chinook Salmon entrined into Clifton Cout Forebay. However, given that only small proportions of Fall-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014), the population-level positive effect of this action would be low. Larger proportions of Late Fall-Run Chinook Salmon are lost at the facilities and this action would have a larger effect for this run.

Potential changes to aquatic resources from the small screen program

Although there may be moderate overlap Fall-Late Fall-Run Chinook Salmon with the main late spring-fall irrigation period for small diversions, and small diversion screening could reduce entrainment of late migraing individuals, the potential population-level positive effect would be low because only a small proportion of the population would be exposed.

Few if any juvenile Fall- /Late Fall-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Sacramento River Fall- /Late Fall-Run Chinook Salmon primarily migrate from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

Potential effects of the Delta Fishes Conservation Hatchery include inadvertent propagation and release of nuisance species and reduced water quality resulting from hatchery discharge. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Fall-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route. The overall impact of the operation of this facility is low.

As with the other proposed construction activities in the Bay-Delta, few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Table FR_1, LFR_1). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2 and MM-AQUA-4 through MM-AQUA-14. (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures will reduce effects, and the in-water construction is of a small scale.

O.3.8.2.6 <u>Central Valley Steelhead</u>

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

Moderate to high proportions of Central Valley Steelhead are expected to be exposed to the Sacramento Deepwater Ship Channel (SDWSC) conservation measure under Alternative 3. This conservation measure would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018), allowing food to enter the Delta and an alternate migration pathway. Juvenile Central Valley Steelhead abundance in the Delta peaks in February through May (Reclamation 2019). Juvenile Central Valley Steelhead passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be entrained into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar.

No Central Valley Steelhead are expected to be exposed to the Sacramento Deepwater Ship Channel construction, as the in-water work window does not overlap with their occurrence in the Delta.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall, and does not overlap in time or space with juvenile Central Valley Steelhead occurrence in the Delta. There would not be any effect to Central Valley Steelhead adults.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 3, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Central Valley Steelhead juveniles, who are in the Delta between December and July. The action is not expected to have any effect on Central Valley Steelhead adults.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Central Valley Steelhead are expected to benefit from 8,000 acres of tidal habitat restoration in the Delta under Alternative 3. Tidal habitat restoration is expected to benefit juvenile

Central Valley Steelhead in several aspects represented by the Winter-Run Chinook Salmon conceptual model (Figure 5.6-4) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta; however, the Delta only represents a small fraction of the total migration route.

Few if any juvenile Central Valley Steelhead would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be exposure of a few late migrants, as illustrated by timing of occurrence in Chipps mid-water trawls (Reclamation 2019). Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance (e.g., gill damage and reduced ability to take in oxygen, increasing metabolic cost), indirect impairment of aquatic ecosystem productivity (e.g., reduction in benthic macroinvertebrate production and availability), loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. The risk from these potential effects would be minimized through application of MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 – through MM-AQUA-12, and MM-AQUA-14.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 3 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids, including Central Valley Steelhead. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of Central Valley Steelhead. All hotspots are limited in scale relative to overall available habitat, and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016). However, implementation of this action would likely improve conditions for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Completion of DCC gate improvements would benefit Central Valley Steelhead of all life stages within the CVP watershed systems. The peak migration of juvenile Central Valley Steelhead in the Sacramento River past Hood, which is near the DCC, occurs from February through mid-June (Reclamation 2019). No San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the DCC. As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, few late migrants or early migrants have the potential to be exposed to potential construction from improvements to the DCC under Alternative 3.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

Small proportions of Sacramento River-origin Central Valley Steelhead and moderate proportions of Mokelumne River and San Joaquin River-origin Central ValleyV Steelhead are expected to be exposed to the Tracy Fish Facility. However, for fish that arrive at the facility, the proposed improvements resulting in greater salvage efficiency under Alternative 3 are likely to increase survival of juvenile Central Valley Steelhead.

As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, none to a few late migrants or early migrants have the potential to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements. Risks of decrease Central Valley Steelhead juvenile salvage during construction would be minimized through appropriate mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12.

Skinner Fish Facility improvements under Alternative 3 to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources from the small screen program

Fish screens under Alternative 3 would also benefit this lifestage in the same ways described above. Juvenile Central Valley Steelhead outmigrating in the Bay-Delta may be exposed to the effects of construction of screens since they migrate downstream during most months of the year, with a peak emigration period in the spring and a smaller peak in the fall (Hallock et al. 1961). Juvenile Central Valley Steelhead may be found in the work area of these projects; however, MM-AQUA-7 would minimize impacts.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

Potential effects of the Delta Fishes Conservation Hatchery include inadvertent propagation and release of nuisance species and reduced water quality resulting from hatchery discharge. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Central Valley Steelhead would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Delta under Alternative 3, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) which means that none to a few late or early migrants of this life stage could be exposed to Delta Fishes Conservation Hatchery construction. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risk from these potential effects would be minimized through application of MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-14 (Appendix E, *Mitigation Measures*).

O.3.8.2.7 North American Green Sturgeon Southern DPS

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

As described above, juvenile Green Sturgeon may potentially be entrained into the DWSC. Fish entering the SDWSC would not, however, be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar between the SDWSC and the Sacramento main stem

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta or Suisun Marsh food subsidies by routing drain water would occur in summer/fall and therefore could provide food benefits to Green Sturgeon juveniles, who are in the Delta in the fall.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Provision of north Delta or Suisun Marsh food subsidies by routing drain water would occur in summer/fall and therefore could provide food benefits to Green Sturgeon juveniles, who are in the Delta in the fall.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile southern DPS Green Sturgeon are expected to be exposed to continuing to implement the 8,000 acres of tidal habitat restoration in the Delta under Alternative 3. Tidal habitat restoration is expected to benefit juvenile Green Sturgeon in several aspects represented by the Green Sturgeon juvenile conceptual model (Figure 5.12-3 of the ROC LTO BA) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 3 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids. It is currently unknown if predation on juvenile Green Sturgeon in the Delta is limiting their productivity. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the rearing and migratory corridors of juvenile Green Sturgeon.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Little is known about the migratory behavior of juvenile Green Sturgeon in the Sacramento River basin. It is likely that juvenile Green Sturgeon (larger than the 75 mm) will not enter the Delta prior to their first winter and thus would not be exposed to the open DCC gates. It is likely that these fish will enter the Delta sometime in the winter or spring following their hatching upriver and encounter both types of gate configurations as they enter the Delta. More information is required to accurately assess the migratory movements of juvenile Green Sturgeon in the river system, as well as their movements within the Delta during their rearing phase in estuarine/Delta waters. Greater operational flexibility and increased gate reliability resulting from improvements would reduce the risk of gate failure that could result in higher rates of entrainment.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

Upgrades to the TFCF will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

As previously described, juvenile Green Sturgeon can occur in the Delta year-round (Reclamation 2019) and, therefore, have the potential to be exposed to the effects of construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements. If construction affects the efficiency of Green Sturgeon salvage (which is an element of entrainment risk; Figure 5.12-3), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures including MM-AQUA-1, MM-AQUA-2, MM-AQUA-7, MM-AQUA-8, MM-AQUA-10 and MM-AQUA-12 (Appendix E, *Mitigation Measures*).

Skinner Fish Facility improvements under Alternative 3, which involve predator control efforts, can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently. Thus, Alternative 3 is not likely to negatively impact juvenile Green Sturgeon.

Potential changes to aquatic resources from the small screen program

Southern DPS Green Sturgeon are expected to be present in the Delta during the main irrigation period for small diversions (late spring-fall). Diversion screening under Alternative 3 could reduce entrainment of individual Green Sturgeon. However, there is currently no information on the proportion of juvenile Green Sturgeon that are entrained into small unscreened diversions. North American Green Sturgeon in the juvenile to subadult/adult life stage may be exposed to the effects of construction of screens since they are present in the Sacramento River year-round (Reclamation 2019). Effects are the same as described above for juveniles. MM-AQUA-7 would minimize risk.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

None of the Green Sturgeon life stages would benefit from the Delta Fish Species Conservation Hatchery under Alternative 3. As with the other proposed construction activities in the Delta, the year-round occurrence of juvenile Green Sturgeon in the Delta (Reclamation 2019) means that this life stage, as well as the timing of the adult Green Sturgeon occurring in the Delta during May to October, could be exposed to Delta Fish Species Conservation Hatchery construction under Alternative 3. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risks from these potential effects would be minimized with through the application of MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-14 (Appendix E, *Mitigation Measures*).

O.3.8.3 *Nearshore Pacific Ocean on the California Coast*

O.3.8.3.1 <u>Southern Resident Killer Whale</u>

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

Building on the analyses provided in Alternatives 1 and 2, given the medium priority of Central Valley Chinook Salmon stocks and the contribution of hatchery-origin Chinook Salmon released downstream of the potential proposed action influence, there may be limited effects of Alternative 3 programmatic activities on Southern Resident Killer Whale through changes in Chinook Salmon prey abundance. There is some uncertainty in this conclusion given the considerably greater extent of tidal habitat restoration (25,000 acres) compared to the other alternatives (i.e., the remainder of the 8,000 acres required under the

USFWS 2008 BO), which could lead to positive effects relative to the other alternatives, including the No Action Alternative.

O.3.9 Alternative 4 – Project-Level Effects

O.3.9.1 *Trinity River*

O.3.9.1.1 Seasonal Operations

Under Alternative 4, the Trinity River system would be operated according to the Trinity River ROD with lower Klamath River augmentation flows and unimpaired flow objectives in the Trinity River.

Potential changes to aquatic resources due to changes in reservoir storage

Model results predict that under Alternative 4, storage volume in Trinity Lake would increase throughout the entire year in most water year types compared to the No Action Alternative (Figure O.3-129). On average, storage is expected to increase by 47 TAF under Alternative 4 compared to the No Action Alternative.

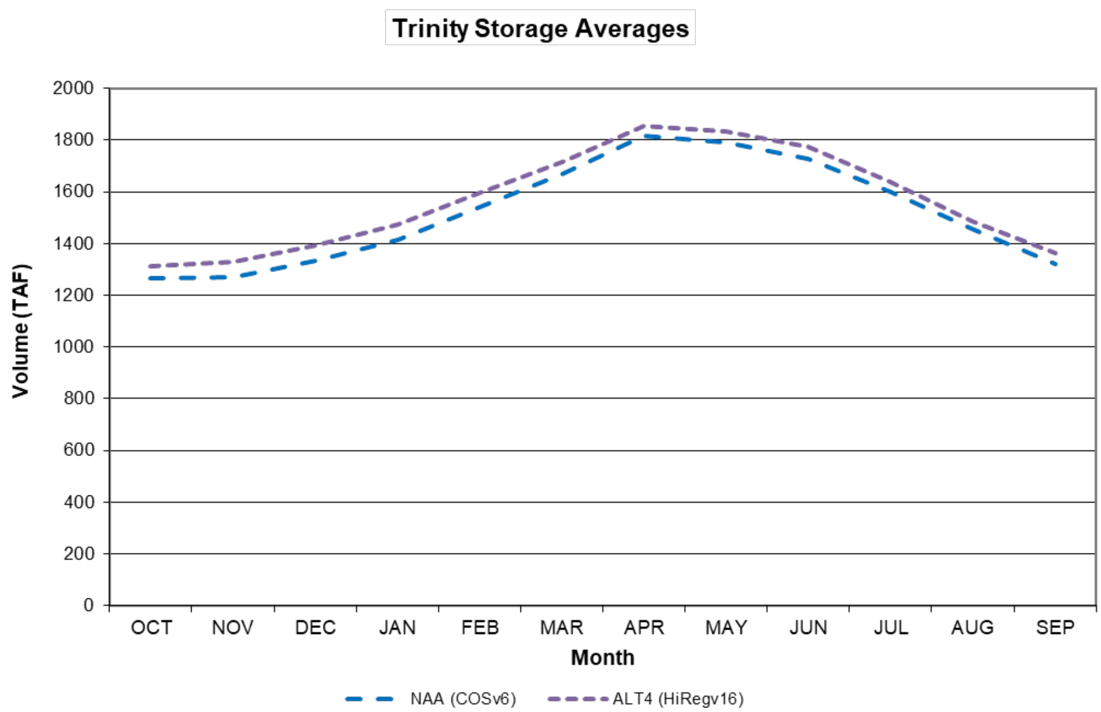

Figure O.3-129. Average Monthly Storage in Trinity Lake for the No Action Alternative and Alternative 4

The effects of changes in reservoir storage conditions as they relate to water temperature can be assessed by looking at temperatures in the Trinity River downstream of Trinity Dam. Average monthly water temperatures in the Trinity River downstream of Trinity Dam would remain similar under Alternative 4 compared to the No Action Alternative (Figure O.3-130). Maximum modeled water temperatures in the Trinity River downstream of Trinity Dam are generally similar under Alternative 4 compared to the No Action Alternative except in September when temperatures are approximately 8°F lower under

Alternative 4 and in October when temperatures are approximately 2°F lower under Alternative 4 compared to the No Action Alternative (Figure O.3-131).

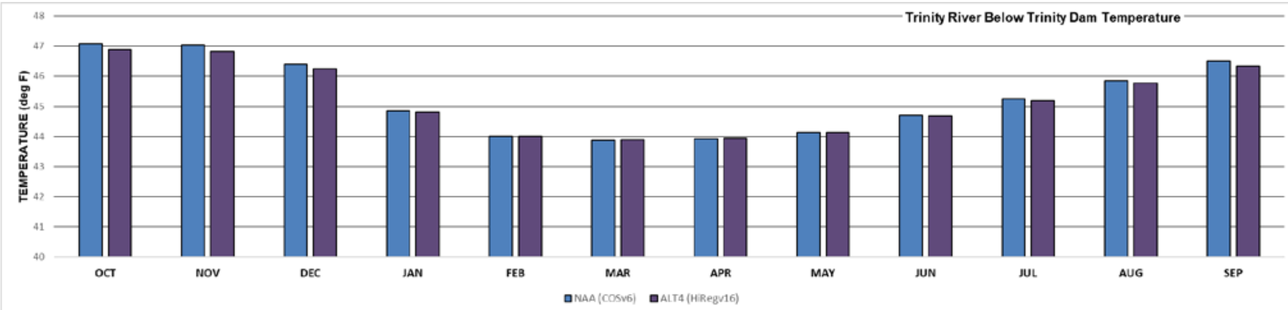

Figure O.3-130. Average Trinity River Water Temperatures below Trinity Dam for the period October to September, Average of All Water Year Types

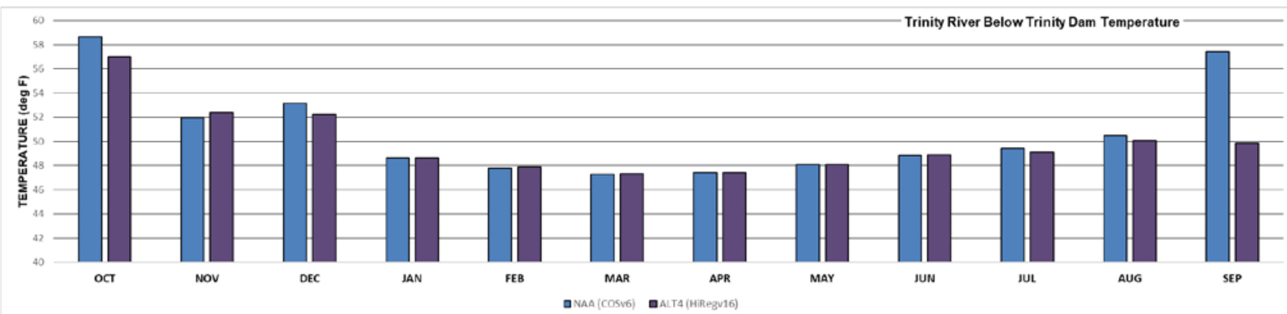

Figure O.3-131. Maximum Trinity River Water Temperatures below Trinity Dam for the Period October to September, Average of All Water Year Types

No focal fish species occur in Trinity Lake or in the Trinity River downstream of Trinity Dam. Effects of Trinity Reservoir storage on fish in the Trinity River downstream of Lewiston Dam are described below.

Potential changes to aquatic resources from variation in flow

Under Alternative 4 modeled average flows in the Trinity River downstream of Lewiston Dam are expected to be similar to flows under the No Action Alternative for the period of April through September with higher flows during October and December through March and either higher or lower flows in November and based on water year type. In wet years, flows would increase by between 7% and 11% during December through March under Alternative 4 compared to flows under the No Action Alternative (Figure O.3-132). In above normal water years, flows would decrease by 11% in November (603 cfs versus 678 cfs) and increase by 69% in February (894 cfs versus 528 cfs) under Alternative 4 compared to flows under the No Action Alternative. In critically dry years, flows would increase by 9% in October (342 cfs to 373 cfs) and November (275 cfs to 300 cfs) under Alternative 4 compared to flows under the No Action Alternative.

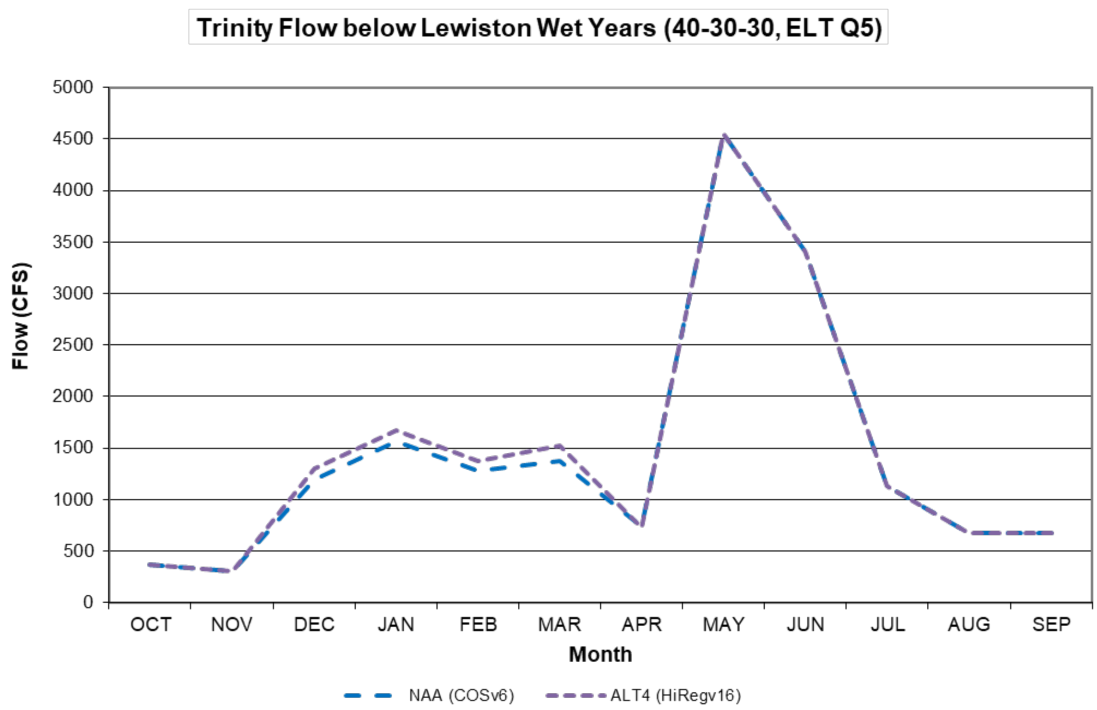

Figure O.3-132. Average Monthly Flow in the Trinity River downstream of Lewiston Dam for the No Action Alternative and Alternative 4 during Wet Years.

Coho Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 4 compared to the No Action Alternative. Minor differences (≤11%) from October through March of some water year types may affect spawning and juvenile rearing habitat for Coho Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these changes in flow are not expected to result in a detectable effect on Coho Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in February of above normal water years would increase by approximately 69% under Alternative 4 (894 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Coho Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Spring-Run Chinook Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 4 compared to the No Action Alternative. Minor differences (≤11%) from October through March of some water year types may affect spawning and juvenile rearing habitat for Spring-Run Chinook Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these changes in flow are not expected to result in a detectable effect on Spring-Run Chinook Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in February of above normal water years would increase by approximately 69% under Alternative 4 (894 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Spring-Run Chinook Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Fall-Run Chinook Salmon

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 compared to the No Action Alternative. Minor differences (≤11%) from October through March of some water year types may affect spawning and juvenile rearing habitat for Fall-Run Chinook Salmon. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these changes in flow are not expected to result in a detectable effect on Fall-Run Chinook Salmon spawning or juvenile rearing habitat (USFWS 1999). Flows in February of above normal water years would increase by approximately 69% under Alternative 4 (894 cfs) compared to the No Action Alternative (528 cfs). This increase in flow could increase the likelihood of Fall-Run Chinook Salmon egg mortality due to redd scour, potentially resulting in reduced incubation success in areas where local conditions contribute to substantial mobilization of gravel in the redds.

Steelhead (Winter- and Summer-Run)

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 3 compared to the No Action Alternative. Minor differences (≤11%) from November through March of some water year types may affect juvenile rearing habitat for Steelhead. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999), these changes in flow are not expected to result in a detectable effect on Steelhead juvenile rearing habitat (USFWS 1999). Flows in February of above normal water years would increase by approximately 69% under Alternative 4 (894 cfs) compared to the No Action Alternative (528 cfs). This increase in flow may increase the amount of spawning habitat for Steelhead. Based on previous flow habitat relationship studies in the Trinity River (USFWS 1999: 123), increasing flows from 500 cfs to 800 cfs showed little change in the amount of spawning habitat for Steelhead in the Trinity River from downstream of Lewiston Dam to the confluence with Dutch Creek.

Green Sturgeon

Green Sturgeon occur within the lower 43 miles of the Trinity River, approximately 70 miles downstream of Lewiston Dam. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in flow under Alternative 4 are not likely to affect Green Sturgeon.

White Sturgeon

White Sturgeon are not likely to be affected by changes in reservoir operations under Alternative 4 compared to the No Action Alternative due to their limited distribution in the lower Klamath River, primarily in the estuary.

Pacific Lamprey

Flows in the Trinity River downstream of Lewiston Dam would generally be similar under Alternative 4 compared to the No Action Alternative. However, minor differences (≤11%) in November and December of some water year types and a larger difference in February (69%) of above normal water years are expected. Increased flows in February overlap with the Pacific Lamprey adult migration period but are not expected to affect migration because Pacific Lamprey migration spans multiple seasons and associated flows. Although previous flow habitat relationship studies in the Trinity River (USFWS 1999) did not focus on Pacific Lamprey, results for salmonids suggest that changes in flow under Alternative 4 would not result in a detectable effect on juvenile rearing or adult holding habitat for Pacific Lamprey compared to the No Action Alternative.

American Shad

American Shad are primarily found in the lower Klamath River but may occur in the lower sections of the Trinity River up to approximately RM 24 at the town of Willow Creek. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Therefore, changes in flow under Alternative 4 would not affect American Shad.

Potential changes to aquatic resources due to variation in temperature

Modeling results indicate that changes in monthly average water temperature in the Trinity River downstream of Lewiston Dam would be similar between Alternative 4 and the No Action Alternative. Differences in monthly average temperature between Alternative 4 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-133). Modeled maximum temperatures in the Trinity River would be lower under Alternative 4 compared to the No Action Alternative in July, September, and October when the maximum temperature would be 1.5°F to 4.4°F lower. Maximum temperatures would be similar in the remaining months (Figure O.3-134 and Table O.3-56).

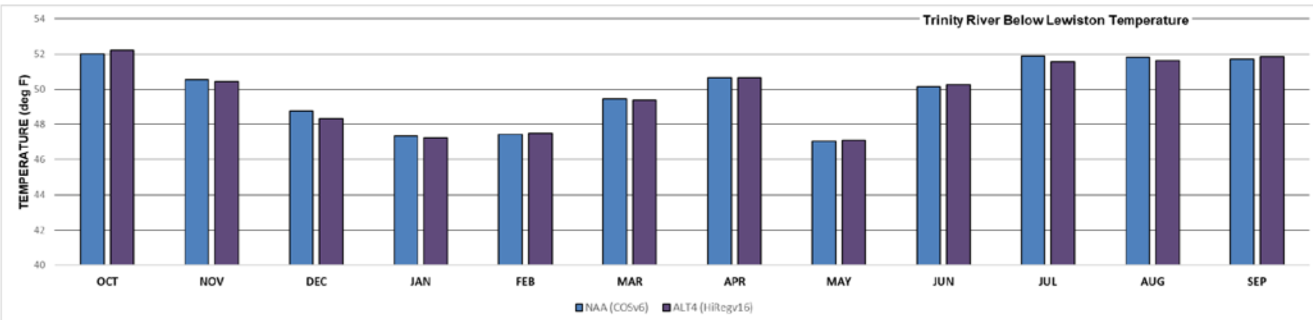

Figure O.3-133. Average Trinity River Water Temperatures below Lewiston Dam for the Period October to September, Average of All Water Year Types

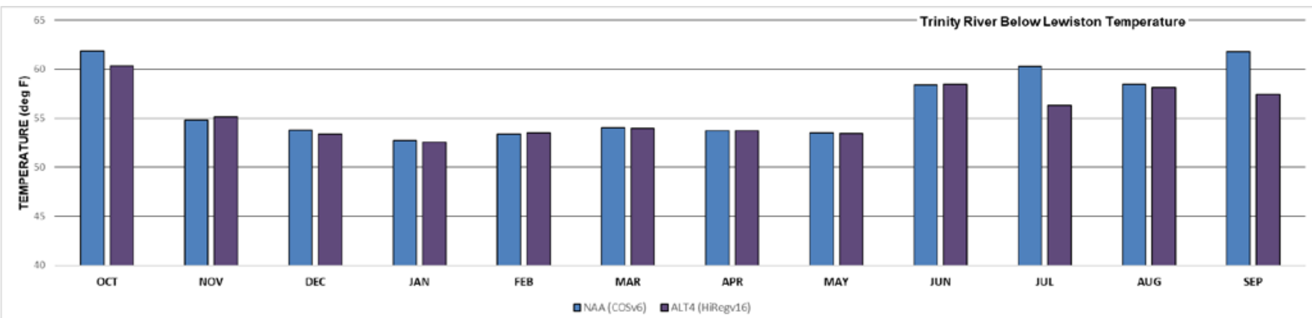

Figure O.3-134. Maximum Trinity River Water Temperatures below Lewiston Dam for the Period October to September, Average of All Water Year Types

Table O.3-56. Maximum Trinity River Water Temperatures below Trinity Dam for the Period October to September, Average of all Water Year Types (Differences >1°F Are Highlighted)

Alt	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
No Action Alternative	61.8	54.8	53.8	52.7	53.4	54.1	53.7	53.5	58.4	60.3	58.4	61.8
ALT 4	60.3	55.1	53.4	52.6	53.5	54.0	53.7	53.4	58.5	56.3	58.1	57.4

In a previous study that looked at flow and water temperatures in the Trinity River (USFWS 1999), results indicated that flow does not have a significant influence on water temperatures from mid-October through early April when cooler air temperatures help maintain cold water temperatures even when flow releases drop below 150 cfs. Once tributary influence begins to decrease and meteorological conditions warm from May to mid-July, flow releases become more influential on downstream temperatures, particularly during hot-dry conditions. Maintaining a flow of 450 cfs during the summer and early fall was found to meet the water temperature objectives for the Trinity River when water released from Lewiston Dam was 53°F or less (USFWS 1999: 203). Water temperatures are most influenced by flow releases from May through mid-October. Flow from May to October would be similar under Alternative 4 compared to the No Action Alternative in most water year types except in critically dry water years. In critically dry years, flow in October would increase by approximately 9% under Alternative 4 compared to the No Action Alternative, from 342 cfs to 373 cfs. Based on modeling results, changes in operations under Alternative 4 are expected to result in lower maximum water temperatures by 1.5°F during October in the Trinity River downstream of Lewiston Dam. Although flow would be similar under Alternative 4 compared to the No Action Alternative during July and September, maximum water temperatures are expected to decrease by 4.0°F and 4.4°F under Alternative 4 compared to the No Action Alternative during these months (Figure O.3-134 and Table O.3-56).

Coho Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 4 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 4 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-133). Modeled maximum temperatures in the Trinity River in July, September, and October would be approximately 1.5°F to 4.4°F lower under Alternative 4 compared to the No Action Alternative with similar maximum temperatures during the remaining months (Figure O.3-134 and Table O.3-56). Although maximum water temperatures under Alternative 4 during September and October exceed the NCRWQCB (2018) objectives for the Trinity River, maximum temperatures are expected to be lower under Alternative 4 compared to the No Action Alternative during these months. Lower water temperatures during September and October under Alternative 4 may increase juvenile Coho Salmon rearing success compared to conditions under the No Action Alternative.

Spring-Run Chinook Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 4 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 4 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-133). Modeled maximum temperatures in the Trinity River in July, September, and October would be approximately 1.5°F to 4.4°F lower under Alternative 4 compared to the No Action Alternative with similar maximum temperatures during the remaining months (Figure O.3-134 and Table O.3-56). Spring-Run Chinook Salmon spawning usually peaks in October but typically ranges from the third week of September through November. Although maximum water temperatures under Alternative 4 during September and October exceed the NCRWQCB (2018) objectives for the Trinity River, maximum temperatures are expected to be lower under Alternative 4 compared to the No Action Alternative during these months. Lower water temperatures during September and October under Alternative 4 may increase the success of adult migration, spawning, and juvenile rearing of Spring-Run Chinook Salmon compared to conditions under the No Action Alternative.

Fall-Run Chinook Salmon

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 4 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 4 and the No Action Alternative would be less than 0.5°F different for all months of the year (Figure O.3-133). Modeled maximum temperatures in the Trinity River in July, September, and October would be approximately 1.5°F to 4.4°F lower under Alternative 4 compared to the No Action Alternative with similar maximum temperatures during the remaining months (Figure O.3-134 and Table O.3-56). Fall-Run Chinook Salmon spawning usually occurs between October and December with peak spawning activity occurring in November Although maximum water temperatures under Alternative 4 during September and October exceed the NCRWQCB (2018) objectives for the Trinity River, maximum temperatures are expected to be lower under Alternative 4 compared to the No Action Alternative during these months. Lower water temperatures during September and October under Alternative 4 may increase the success of adult migration and spawning of Fall-Run Chinook Salmon compared to conditions under the No Action Alternative.

Steelhead (Winter- and Summer-Run)

Water temperatures in the Trinity River below Lewiston Dam are generally expected to be similar under Alternative 4 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 4 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-133). Modeled maximum temperatures in the Trinity River in July, September, and October are approximately 1.5°F to 4.4°F lower under Alternative 4 compared to the No Action Alternative with similar maximum temperatures during the remaining months. Although maximum water temperatures under Alternative 4 during September and October exceed the NCRWQCB (2018) objectives for the Trinity River, maximum temperatures are expected to be lower under Alternative 4 compared to the No Action Alternative during these months. Lower water temperatures during September and October under Alternative 4 may increase the success of juvenile rearing Steelhead compared to conditions under the No Action Alternative.

Green Sturgeon

Green Sturgeon occur within the lower 43 miles of the Trinity River, approximately 70 miles downstream of Lewiston Dam. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Results of previous water temperature modeling for the Trinity River (USFWS 1999) predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 43 with smaller temperature differences expected downstream of RM 43 to the confluence of the Trinity and Klamath Rivers. Therefore, changes in water temperature under Alternative 4 are not likely to affect Green Sturgeon.

White Sturgeon

White Sturgeon are not likely to be affected by changes in reservoir operations under Alternative 4 compared to the No Action Alternative due to their limited distribution in the lower Klamath River, primarily in the estuary.

Pacific Lamprey

Model results predict that water temperatures in the Trinity River below Lewiston Dam would be similar under Alternative 4 compared to the No Action Alternative. Differences in monthly average temperature between Alternative 4 and the No Action Alternative would be less than 0.5°F for all months of the year (Figure O.3-133). Modeled maximum temperatures in the Trinity River in July, September, and October would be approximately 1.5°F to 4.4°F lower under Alternative 4 compared to the No Action Alternative with similar maximum temperatures in the remaining months. Although maximum water temperatures under Alternative 4 during September and October exceed the NCRWQCB (2018) objectives for the Trinity River, maximum temperatures are expected to be lower under Alternative 4 compared to the No Action Alternative during these months. Lower water temperatures during September and October under Alternative 4 may increase Pacific Lamprey juvenile rearing success compared to the No Action Alternative.

American Shad

American Shad are primarily found in the lower Klamath River but may occur in the lower sections of the Trinity River up to approximately RM 24 at the town of Willow Creek. Water temperature and habitat conditions within this section of the Trinity River are heavily influenced by several large tributaries that enter the Trinity River (e.g., the North Fork Trinity River, New River, and the South Fork Trinity River). As a result, minor changes in reservoir operations are likely to be undetectable this far downstream. Results of previous water temperature modeling for the Trinity River (USFWS 1999) predicted a difference of approximately 1°F in water temperature for flows of 300 cfs and 450 cfs near RM 24 with smaller temperature differences expected downstream to the confluence of the Trinity and Klamath Rivers. Therefore, changes in water temperature under Alternative 4 would not affect American Shad.

O.3.9.1.2 Trinity River Record of Decision

The Trinity River ROD is being implemented under both Alternative 4 and the No Action Alternative. Therefore, implementation of the variable annual flow regime, restoration actions, and monitoring and adaptive management, per the Trinity River ROD under Alternative 4 would have similar effects as the No Action Alternative on Coho Salmon, Chinook Salmon (Spring- and Fall-Run), Steelhead (Winter- and Summer-Run), Green Sturgeon, White Sturgeon, Pacific Lamprey, and American Shad.

O.3.9.1.3 Grass Valley Creek Flows from Buckhorn Dam

A combination of a history of poor logging practices in the upper GVC basin and bedrock geology composed mainly of weathered quartz diorite (decomposed granite) resulted in increased deposition of fine sediments at critical spawning grounds in the Trinity River (Reclamation 2012a). In an effort to trap and, in turn, reduce fine sediment input into the Trinity River, Buckhorn Dam was constructed in 1991. Water from Buckhorn Reservoir is released from two sources: (1) the spillway, at an elevation of 2,803.13 ft; and (2) the outlet channel, which receives a constant flow of 6 cfs to 10 cfs that travels approximately 2,300 ft to its confluence with the spillway outlet.

GVC is an important spawning tributary for Coho Salmon, Steelhead, and Pacific Lamprey in the upper Trinity River basin. Restoration of the upstream 800 ft of outlet channel was performed in 2012 to enhance spawning and rearing within the outlet reach of GVC. Reclamation proposes flow releases of up to 100 cfs, lasting anywhere from a few hours to one week, from Buckhorn Dam down the outlet channel when the reservoir elevation exceeds 2,803.13 ft between March 1 and April 15. The primary objects of the proposed spring releases are: (1) to cue out-migration of juvenile salmonids residing in the outlet channel; and (2) to maintain habitat conditions through physical geomorphic processes (scour and deposition). Additional fall releases to the outlet channel during October and November are proposed to provide adult Coho Salmon sufficient flow for upstream migration and spawning. Proposed fall flows would provide ≥0.6 ft depth at riffle crests in the outlet channel for 600 ft downstream from the outlet works and a ≥10 cfs flow increase at USGS gage 11525630, located near the mouth of GVC.

Storage volume in Buckhorn Reservoir would likely remain the same or minimally decrease under Alternative 4 compared with the No Action Alternative during most water year types. Spring releases under both Alternative 4 and the No Action Alternative are only triggered when Buckhorn Dam is at capacity. Historically, flows from March 1 through April 15 at the GVC USGS gage have reached or exceeded 100 cfs (Table O.3-57 and Figure O.3-135). The main difference between Alternative 4 and the No Action Alternative is the location of flow releases; under Alternative 4 the outlet channel is the primary release point, and under the No Action Alternative the spillway is the primary release point. Since spring releases are dependent on the reservoir being at capacity, no effect on reservoir level is anticipated. However, fall releases during dry and critically dry years may have a minimal effect on reservoir levels if inflow to the reservoir is less than flow released from the reservoir.

Table O.3-57. Mean minimum and maximum discharges (cfs) in Grass Valley Creek at USGS gage 11525630 from March 1 through April 15, 2005 to 2018

Year	Mean (cfs)	Minimum (cfs)	Maximum (cfs)	Water Year Type
2005	106	66	263	Wet
2006	176	99	841	Extremely Wet
2007	36.2	27	49	Dry
2008	63.6	40.8	104	Dry
2009	91.5	47.1	961	Dry
2010	104	68.2	548	Wet
2011	159	42.4	581	Wet
2012	73.9	19	533	Normal
2013	37.1	29.3	74.5	Dry
2014	25.5	9.76	138	Critically Dry
2015	29.5	22	40.6	Dry
2016	130	36.5	585	Wet
2017	117	94.3	206	Extremely Wet
2018	27.1	14	202	Critically Dry
Average:	84	44	366.2	NA

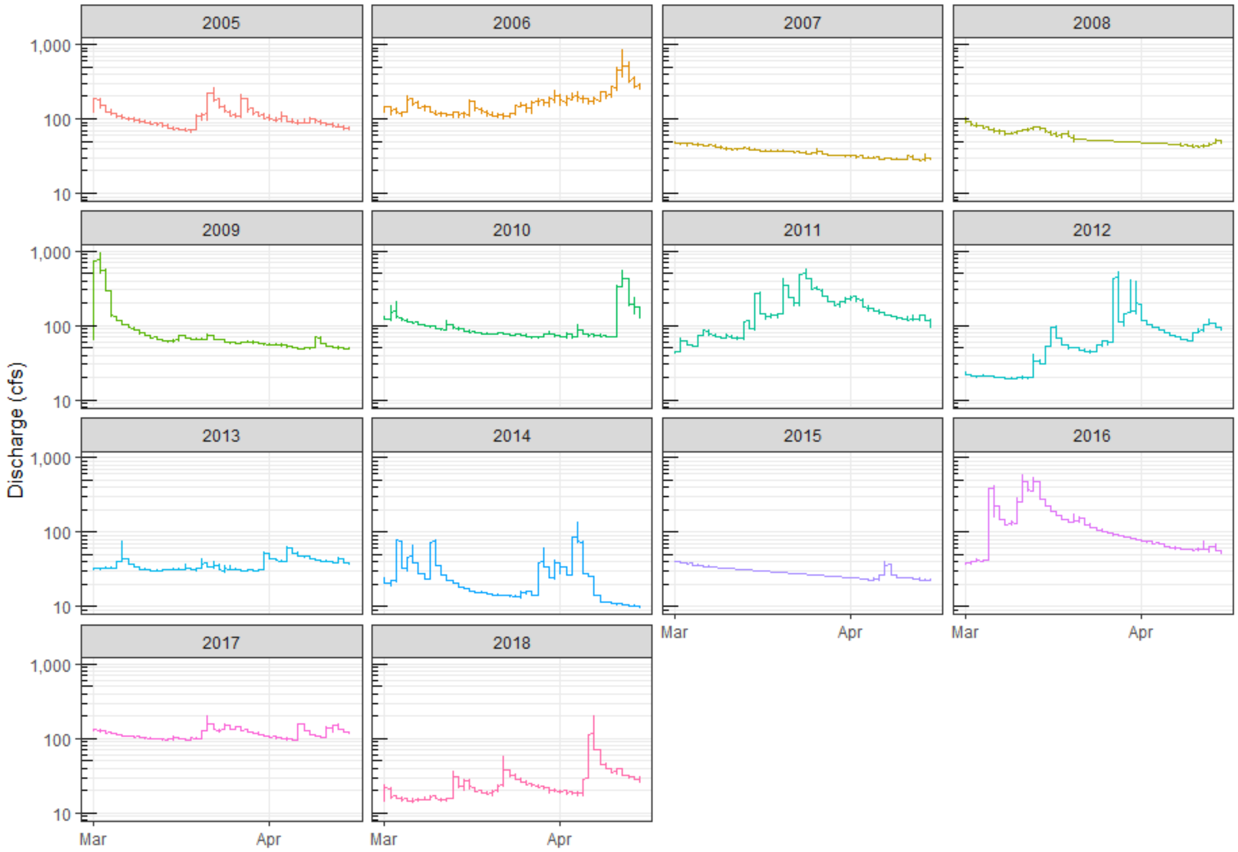

Figure O.3-135. Discharge (cfs) in Grass Valley Creek at USGS Gage 11525630 from March 1 through April 15, 2005 to 2018

Under Alternative 4, spring releases in the outlet channel will include pulse flows for channel maintenance and promotion of juvenile out-migration. Maintenance of the outlet channel through spring pulse flow releases of up to 100 cfs will promote natural geomorphic processes of erosion and deposition, control riparian vegetation, maintain spawning habitat quality by periodically mobilizing spawning gravel deposits and removing fine sediments, and transport and deposition of sands and fines. Under the No Action Alternative, flows in the outlet channel would remain at 6 cfs to 10 cfs year-round.

Water temperature effects on GVC under Alternative 4 compared with the No Action Alternative are anticipated to be minimal during spring releases for all water year types, as spring snowmelt and run-off dominate inflow into the reservoir, keeping water temperatures low. Fall flow releases to facilitate upstream migration and spawning of Coho Salmon would occur during October and November, typically a period when low flow and potentially high water temperature could occur in GVC (Table O.3-58 and Figure O.3-136). Water temperatures in dry and critically dry water year types in the Trinity River below Lewiston Dam are highest during June through October (Figure O.3-137). Given that high water temperatures typically extend through October in the Trinity River, similar conditions are likely to be present in GVC and Buckhorn Reservoir. Fall flow releases from Buckhorn Reservoir into the outlet channel are expected to increase flow at the USGS gage 11525630 to ≥10 cfs under Alternative 4 and range from 6 cfs to 10 cfs under the No Action Alternative during October and November, with the potential to affect water temperature in GVC; however, the intake for the outlet works is located approximately 58 ft below the spillway crest, providing cooler than surface water temperatures. Overall, no effect on water temperature in GVC is anticipated under Alternative 4 compared with the No Action Alternative.

Table O.3-58. Mean, Minimum, and Maximum Discharge (cfs) in Grass Valley Creek at USGS Gage 11525630 from October through November, 2004–2018

Year	Mean (cfs)	Minimum (cfs)	Maximum (cfs)	Water Year Type
2004	15	10	33	Wet
2005	16	11	53	Wet
2006	18.2	13	44	Extremely Wet
2007	12.1	9.6	23.3	Dry
2008	12.6	7.54	27.3	Dry
2009	12.6	6.38	64.8	Dry
2010	18.6	9.64	121	Wet
2011	18.1	11.4	45.2	Wet
2012	15.5	7.19	574	Normal
2013	8.77	7.49	14.4	Dry
2014	8.23	5.98	30.4	Critically Dry
2015	7.67	5.98	10.9	Dry
2016	21.4	6.72	66.9	Wet
2017	13.7	9.87	56.8	Extremely Wet
2018	11.2	6.97	664	Critically Dry
Average:	14	8.6	121.9	NA

Figure O.3-137. Water Temperature in the Trinity River below Lewiston Dam during the Driest Periods of the Year under the No Action Alternative and Alternative 4.

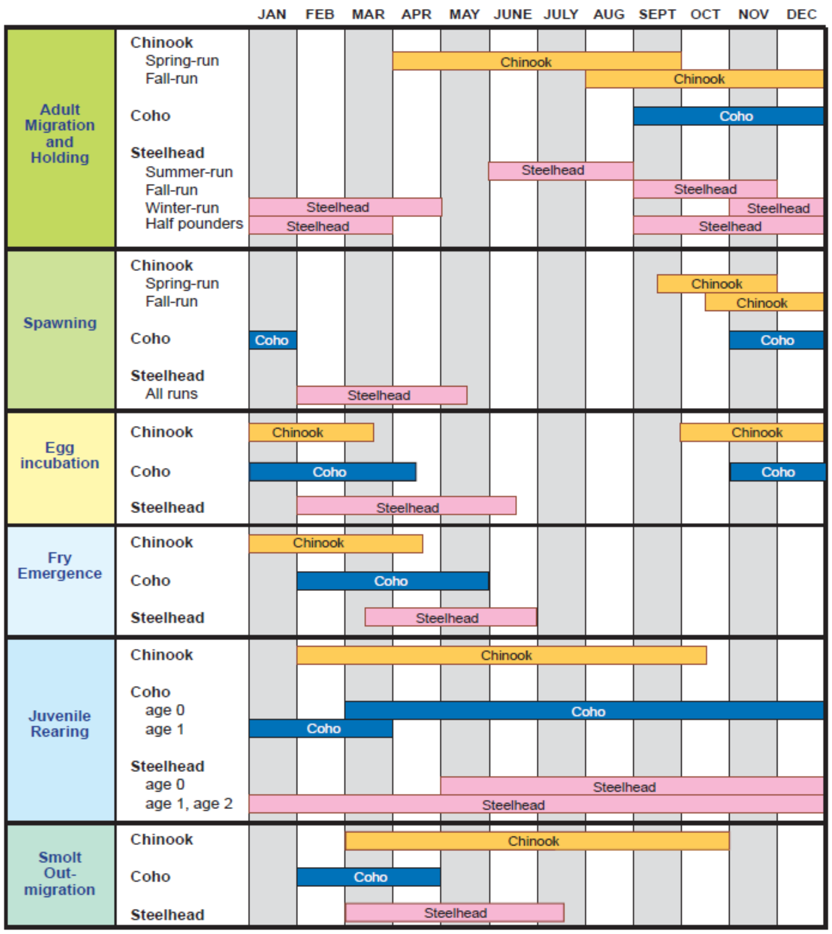
Potential changes to aquatic resources due to changes in pulse flows in Grass Valley Creek

Coho Salmon

Under Alternative 4, juvenile Coho Salmon in the GVC outlet channel would experience pulse flows from Buckhorn Dam from March 1 through April 15 when the Buckhorn Reservoir is above maximum capacity. Pulse flows are intended to incorporate a natural hydrograph element and would occur during spring runoff period, cuing juvenile Coho Salmon to begin their downstream migration to the Trinity River and eventually the ocean. Flow releases to the outlet channel under Alternative 4 would be up to 100 cfs and sufficient to mobilize gravel compared with the No Action Alternative, under which releases are kept at 6 cfs to 10 cfs year-round. In 2011, prior to restoration in the outlet channel occurring in 2012, juvenile Coho Salmon were documented below the exposed bedrock outcrop located approximately 600 ft downstream of the outlet works (Gutermuth 2011). Depending on the outlet channel complexity and the availability of high flow cover, newly emerged Coho Salmon may be subject to displacement downstream during pulse flows.

Under Alternative 4, incubating Coho Salmon eggs could be negatively affected by pulse flow releases. Coho Salmon egg incubation in the Trinity River occurs from November until mid-April (Figure O.3-138). A main goal of the spring pulse flows is to maintain the outlet channel through bed mobilization, an action that could negatively affect egg incubation. It is unlikely flows of 100 cfs will disrupt Coho Salmon redds in the outlet channel, but the potential for redd scour does exist if redds are located at constriction points.

Fall flow releases to attract and provide sufficient flows for migration of adult Coho Salmon in GVC are proposed under Alternative 4 but not the No Action Alternative. These releases are anticipated to be beneficial to adult Coho Salmon in GVC, as they would provide a depth ≥ 0.6 ft at riffle crests in the outlet channel to aid with migration and predation avoidance. Overall, Alternative 4 is anticipated to have a net beneficial effect on Coho Salmon in the GVC compared with the No Action Alternative.



* A small percentage of chinook in the Trinity River overwinter and outmigrate at age 1, similar to coho age 1 life history.

Figure O.3-138. Diagram of the Timing and Duration of Various Life-History Events for Chinook Salmon, Coho Salmon, and Steelhead in the Trinity River (USFWS and Hoopa Tribe 1999)

Chinook Salmon (Spring-Run and Fall-Run)

Fall-Run Chinook Salmon are known to occur in GVC from its confluence with the Trinity River upstream 7.5 miles (Baldwin 2002). Spring-Run Chinook Salmon are not present in GVC, and it is unknown if they existed there historically (Moyle et al. 2017). Under Alternative 4 releases into the outlet channel only occur when the reservoir is at maximum capacity, producing a very similar, if not the same, hydrograph as the No Action Alternative for fish downstream of the confluence of the outlet channel with the spillway channel. Due to the distribution of Fall-Run Chinook Salmon in GVC, no effect is predicted under Alternative 4 compared with the No Action Alternative; however, if the distribution of Chinook spreads to the outlet channel, eggs and juvenile Chinook Salmon will experience similar effects to Coho Salmon.

Fall flow releases under Alternative 4 that meet specific depth and flow criteria will provide a positive effect on adult migration of Chinook Salmon compared with the No Action Alternative. These releases are anticipated to be beneficial to adult Chinook Salmon in GVC, as they would increase discharge to ≥10 cfs at the USGS gage near Lewiston and aid with migration and predator avoidance.

Steelhead (Winter-Run and Summer-Run)

Winter-Run Steelhead are known to occur in GVC from its confluence with the Trinity River upstream to the outlet channel pool, located immediately downstream of the outlet works (Baldwin 2002). GVC is one of the most productive Winter-Run Steelhead tributaries in the upper Trinity River (Hill 2010). Summer-Run Steelhead are not present in GVC, and it is unknown if they existed there historically (Moyle et al. 2017). Pulse flows under Alternative 4 are intended to incorporate a natural hydrograph element and would occur during spring runoff peaks, cuing juvenile Winter-Run Steelhead in the outlet channel to begin their downstream migration to the Trinity River and eventually the ocean. Flow releases to the outlet channel under Alternative 4 would be up to 100 cfs and sufficient to mobilize gravel compared with the No Action Alternative, under which releases are kept at 6 cfs to 10 cfs year-round. Depending on the outlet channel complexity and the availability of high flow cover, newly emerged Winter-Run Steelhead may be subject to displacement downstream during pulse flows.

Under Alternative 4, Winter-Run Steelhead eggs could be negatively affected by pulse flow releases. Steelhead egg incubation in the Trinity River occurs from February through mid-June (Figure 4). A main goal of the spring pulse flow release is to maintain the outlet channel through bed mobilization, an action that could negatively affect egg incubation. It is unlikely flows of 100 cfs will disrupt Winter-Run Steelhead redds in the outlet channel, but the potential for redd scour does exist if redds are located at constriction points.

Fall flow releases under Alternative 4 that meet specific depth and flow criteria will provide a positive effect on adult Winter-Run Steelhead migration compared with the No Action Alternative. These flow releases are anticipated to be beneficial to adult Winter-Run Steelhead in GVC, as they would increase discharge to ≥10 cfs at the USGS gage near Lewiston and aid with migration and predator avoidance. Overall, Alternative 4 is predicted to have a net beneficial effect on Winter-Run Steelhead in GVC compared with the No Action Alternative.

Pacific Lamprey

Ammocoetes (juvenile lamprey) of potential Pacific Lamprey and Pit-Klamath Brook Lamprey have been recorded in GVC; however, without genetic testing ammocoetes of these two species cannot be differentiated. Based on habitat characteristics of GVC and species distribution, Pacific Lamprey are suspected to occur in GVC from its confluence with the Trinity River upstream to the outlet channel pool (Reid 2017). Pulse flows under Alternative 4 are intended to incorporate a natural hydrograph element and would occur during spring runoff peaks, cuing Pacific Lamprey ammocoetes in the outlet channel to begin their downstream migration to the Trinity River and eventually the ocean. A main goal of the spring pulse flows is to maintain the outlet channel through bed mobilization, an action that could negatively affect the ammocoete life stage. Because Pacific Lamprey spend the majority of the ammocoete life stage in the substrate, bed mobilizing flows have the potential to disrupt this life stage.

Under Alternative 4 Pacific Lamprey eggs could be negatively affected by bed mobilizing pulse flow releases in the outlet channel. Egg incubation in the Trinity River occurs from February through June; however, minimal Pacific Lamprey spawning habitat was recorded in the outlet channel in 2017 (Reid 2017). It is unlikely flows of 100 cfs will disrupt Pacific Lamprey redds in the outlet channel, but the potential for scouring does exist if redds are located at constriction points.

Fall flow releases under Alternative 4 that meet specific depth and flow criteria will provide no effect on Pacific Lamprey adults due to migration occurring from January through April. Overall, Alternative 4 is anticipated to have a net beneficial effect on Pacific Lamprey in the GVC compared with the No Action Alternative.

O.3.9.2 *Sacramento River*

Potential changes to aquatic resources in the Sacramento River from seasonal operations

Under all the Project alternatives, flows in the upper Sacramento River result from controlled releases from Shasta and Keswick reservoirs, as well as transfers from the Trinity River and natural accretions. Dry hydrologic conditions often lead to inadequate storage in Shasta Reservoir for operators to provide suitable conditions for salmonids and other native species in the upper Sacramento River. In most cases, water temperature rather than flow is the limiting factor creating unsuitable conditions, as discussed below. The primary differences between the No Action Alternative and Alternative 4 for the Sacramento River flow and water temperature management upstream of the Delta is that Alternative 4 would manage instream flow releases with a target of realizing 55% of unimpaired flows. Reclamation would release water from Shasta Reservoir to meet this flow target at the Sacramento River above Red Bluff and the confluence with the Feather River. However, during Shasta critically dry years (defined as year when forecasted inflow to Shasta Reservoir is less than 3.2 MAF), Reclamation would reduce instream flow releases to less than the 55% target to maintain water in storage for coldwater pool. The No Action Alternative includes NMFS's 2009 BO RPAs to operate Shasta Reservoir for management of cold water in the reservoir and river to protect anadromous salmonids, and includes requirements for Fall X2 flow releases, but Alternative 4 includes neither requirement.

CalSim II modeling indicates that average flow released at Keswick Dam under Alternative 4 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 4 flows would be substantially lower than the No Action Alternative flows (Table O.3-59). Moderately lower mean flows are expected for a few other months and water year types during summer (e.g., July of critically dry water years). The higher September and November flows under the No Action Alternative result from Fall X2 releases, which are not included in Alternative 4. Table O.3-59 shows that the highest mean monthly flows for both alternatives occur primarily during winter of wet and above normal water years and during summer of all water year types. Flow releases are high during summer to satisfy downstream demands of water users and Delta water quality and to meet water temperature requirements of incubating Winter-Run Chinook Salmon eggs and alevins downstream of Keswick Dam.

HEC-5Q modeling was used to compare water temperature effects of the No Action Alternative and Alternative 4. Based on recent investigations of Winter-Run Chinook Salmon mortality in the upper Sacramento River (Martin et al. 2017; Anderson 2018), this effects analyses uses an upper water temperature threshold of 53.5°F for suitable salmonid egg and alevin incubation in the Sacramento River. An important caution regarding the HEC-5Q water temperature modeling results, particularly with regard to meeting water temperature criteria (e.g., 56°F water temperature at Bend Bridge criterion), relates to the time step used in the modeling. HEC-5Q, like the CalSim II model on which it relies for flow data, has a monthly time step and provides estimates of monthly mean water temperatures. However, most of the regulatory requirements to meet water temperature criteria apply to daily mean (or shorter duration) water temperatures. Daily means are almost always much more variable than monthly means and, therefore, the monthly mean water temperature estimates provided by HEC-5Q are not directly comparable to the regulatory criteria. For example, even with constant flows releases, downstream daily water temperatures would fluctuate around the mean in response to variation in solar radiation and other meteorological conditions within a given month. In view of this limitation, it is helpful to consider the comparisons of temperature effects among the alternatives as indicating the relative likelihoods of exceeding temperature criteria, rather than whether or not the criteria are actually met. These considerations apply to the CalSim II flow data as well, but are less important for flow because there are fewer regulatory criteria for flow and, except during storm events, flow tends to be less variable than water temperature.

During the summer and much of the fall, water released from Keswick Dam warms downstream, resulting in warmer water temperatures in more downstream habitats. Therefore, the effects of the alternatives on fish populations depend on the habitat distributions of the populations as well as the results of temperature management operations. Winter-Run mostly spawn from Keswick Dam to about 6 miles downstream of the Clear Creek temperature gage, Spring-Run from Keswick Dam to about Balls Ferry, fall-run from Keswick Dam to about RBDD, late fall-run spawning distribution is similar to that of Winter-Run, and Green Sturgeon spawn downstream of the Cow Creek confluence to the GCID oxbow near Hamilton City (NMFS 2018b). Steelhead spawning areas in the upper Sacramento River are poorly known.

Based on the HEC-5Q modeling, the mean monthly water temperatures at Keswick Dam are roughly equal under the No Action Alternative and Alternative 4, except for August of dry and critically dry water years and October of all except critically dry water years (Table O.3-60). For all these months and water year types, the mean monthly water temperature under Alternative 4 is between 1.0 and 1.5°F cooler under Alternative 4 than under the No Action Alternative. Summer mean monthly water temperatures are consistently below the 53.5°F temperature threshold, except in critically dry water years during July through September under the No Action Alternative and August and September under Alternative 4. The October monthly mean water temperatures are above the critical water temperature threshold for all water year types under the No Action Alternative and below the threshold under all but critically dry water years under Alternative 4 (Table O.3-60), which would be expected to benefit salmonid eggs and alevins. A more detailed examination of this difference shows that mean October water temperatures are predicted to be less than the temperature threshold in 20% of the years under the No Action Alternative, while under Alternative 4 they are predicted to be less than the threshold in 70% of the years (Figure O.3-18). Similarly, in August the mean water temperatures are predicted to be less than the temperature threshold in 75% of the years under the No Action Alternative and in 93% of the years under Alternative 4 (Figure O.3-19). By November, monthly mean water temperatures for all water year types are above the critical water temperature threshold under both alternatives (Table O.3-60). The temperature reductions for August of dry and critically dry water years under Alternative 4 would also be expected to benefit for salmonid eggs and alevins. The largest predicted increase in mean water temperature under Alternative 4 is 0.8°F for January of critically dry water years and September of Above Normal water years (Table O.3-60). Both of these increases occur over ranges well below the critical temperature threshold and are therefore unlikely to have much effect on the salmonids.

Table O.3-60. HEC-5Q Monthly Average Water Temperature (°F) by Water Year Type and Month at Keswick Dam for No Action Alternative, Alternative 4 and Differences between Them

Alternative[1,2,3] / Water Year Type[4]	Monthly Temperature (°F) Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep

1 Results based on the 82-year simulation period.

2 Results displayed with calendar year - year type sorting.

3 All scenarios are simulated at ELT (Early Long-Term) Q5 with 2025 climate change and 15 cm sea level rise.

4 Water year types as defined by the Sacramento Valley 40-30-30 Index Water Year Hydrologic Classification (SWRCB D-1641, 1999).

5 Percent of years of each type given in parentheses.

6 Bold green font indicates greater than 1°F reduction in temperature, bold red font indicates greater than 1°F increase in temperature.

The HEC-5Q results indicate that late spring through early fall water temperatures in the Sacramento River at Clear Creek are slightly warmer than those at Keswick Dam, and temperature reductions in October and August are similar but slightly smaller (Table O.3-61). The results also show increases in September water temperature between the No Action Alternative and Alternative 4 during wet and above normal water years, similar to those found for the other alternatives (e.g., Tables O.3-7 through O,3-11). The reductions in October and August result in Alternative 4 water temperatures more suitable for salmonid eggs and alevins, but the increases in September result in water temperatures approach or exceed the threshold (Table O.3-61). Summer mean monthly water temperatures are below the 53.5°F temperature threshold, except in drier water years, especially in August and September. All mean temperatures for October and November under both alternatives are above the threshold, except for October of wet and above normal water years under Alternative 4 (Table O.3-61). At Balls Ferry, the temperatures are warmer still and the October and August reductions are slightly lower, while the September increases are larger (Table O.3-62). October and November mean water temperatures are above the threshold under both alternatives. The mean September water temperatures for wet and above normal water years at Balls Ferry exceed the threshold under Alternative 4, but not under the No Action Alternative (Table O.3-62). The exceedance plot of annual mean September temperatures indicate that water temperatures are below the threshold 40% of years under the No Action Alternative and about 15%

of years under Alternative 4 (Figure O.3-31). As discussed previously, the monthly mean water temperatures provide a rough estimate of the probability of mean daily water temperatures exceeding a temperature threshold. Therefore, when the monthly mean water temperature exceeds the temperature threshold, the probability or frequency of the daily mean temperature exceeding the threshold is greater than when the monthly mean water temperature is less than the threshold.

The downstream trends in water temperature conditions noted for Keswick Dam, Clear Creek and Balls Ferry continue to RBDD, with reduced differences in water temperatures between the alternatives, except for substantially warmer temperatures in September of wet and above normal water years under Alternative 4 (Table O.3-63). The growing downstream differences in wet and above normal water year temperatures for September can be seen in Figures O.3-20, O.3-30, O.3-31, and O.3-22. The temperature differences are largely limited to the cooler 50% of years. Under both the No Action Alternative and Alternative 4, the mean water temperatures at RBDD for April through October are above the 53.5°F critical water temperature threshold in all water year types, except April of wet water years under Alternative 4. The pattern of increasing water temperatures differences in September of wet and above normal water years between the No Action Alternative and Alternative 4 continues downstream to Hamilton City and Knights Landing (Table O.3-64 and O.3-65; Figures O.3-23 and O.3-24). There is less late spring to late summer water temperature reduction at these locations from the No Action Alternative to Alternative 4 than that found for the other alternatives (Tables O.3-10, O.3-11, O.3-30, O.3-31, O.3-48, O.3-49, O.3-64, O.3-65), but there are reductions of 0.9 and 1.1°F between the No Action Alternative and Alternative 4 during June of dry water years at Hamilton City and Knights Landing, respectively (Table O.3-64 and O.3-65; Figure O.3-90 and O.3-91). These reductions may result from moderate increases in flow for June of dry years under Alternative 4 relative to the No Action Alternative, but for the other months and water year types there are smaller late spring to late summer flow increases from the No Action Alternative to Alternative 4 at these locations than those found for the other alternatives (Tables O.3-13, O.3-14, O.3-33, O.3-34, O.3-51, O.3-52, O.3-66, and O.3-67).

The reduced downstream warming of the river in September of wet and above normal under the No Action Alternative relative to the Alternative 4 is due, at least in part, to the much higher flow releases for Fall X2, as noted above (Table O.3-59). Note that November Fall X2 flow releases under the No Action Alternative do not result in higher water temperatures under Alternative 4 (e.g., Table O.3-65), presumably because November air temperatures would, on average, be similar to or lower than the water temperatures.

It is expected that, in general, water temperatures between the No Action Alternative and Alternative 4 would be largely similar, with the exception of September of wet and above normal water years, when water temperatures are warmer under the Alternative 4, because this alternative would not include the Fall X2 flows that reduce downstream warming under the No Action Alternative, and with the exception of August of dry and critically dry water years and October of all but critically dry water years at the sites upstream of RBDD, when water temperatures would be lower under Alternative 4 (Tables O.3-60, O.3-61, O.3-62).

O.3.9.2.1 Sacramento River Winter-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Winter-Run Chinook Salmon adults spawn from May through August with peak spawning during June and July (Section O.2.4.2.1, *Winter-Run Chinook Salmon*). Fry emergence occurs up to 3 months after eggs are spawned, so effects of flow and water temperature on Winter-Run eggs and alevins may occur from May through November, but primarily occur during June through October.

As previously noted, CalSim II modeling indicates that mean monthly flow released at Keswick Dam under Alternative 4 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 1 flows would be substantially lower than the No Action Alternative flows (Table O.3-59). By September in most years, a large proportion of Winter-Run redds still contain incubating alevins. Assuming flows are stable enough to avoid dewatering the redds, which is generally true in September, the most important effect of flows on alevins is to transport dissolved oxygen to the developing alevins and to flush potentially toxic metabolites out of the redds. Although the mean September wet and above normal water year flows are substantially lower under Alternative 1 than under the No Action Alternative, the flows under Alternative 1 flows remain moderately high (>6,000 cfs) (Figure O.3-25). Flows at this level are expected to provide sufficient flow velocity to keep the redds clean and well oxygenated. With regard to redd dewatering, reductions in fall flow releases to conserve storage would be balanced by needs to maintain suitable water temperatures, minimize dewatering redds of Winter-Run and other salmonids, and avoid stranding rearing juveniles. Therefore, differences in flow between the No Action Alternative and Alternative 1 are expected to have little effect on Winter-Run Chinook Salmon spawning and incubation habitat.

Differences between the No Action Alternative and Alternative 4 in water temperature during the Winter-Run spawning period may be important. As described in the previous section, HEC-5Q mean October water temperatures are predicted to be below the 53.5°F water temperature threshold in the majority of years under Alternative 4 and above the threshold in most years under the No Action Alternative (Figure O.3-18), and in August, the mean water temperatures are predicted to be above the threshold in about 25% of years under the No Action Alternative and 7% of years under Alternative 4 (Figure O.3-19). September water temperatures are expected to be higher under Alternative 4 than under the No Action Alternative, but the increases are expected only for the most downstream portion of the Winter-Run spawning distribution and primarily for wet and above normal water years, for which the mean temperatures for both alternatives would mostly be below the water temperature threshold (Tables O.3-60 and O.3-61; Figure O.3-20).

Recent investigations of Winter-Run Chinook Salmon mortality in the upper Sacramento River (Martin et al. 2017; Anderson 2018) yielded models for estimating mortality of Winter-Run Chinook Salmon eggs and alevins under different water temperature conditions. These models, referred to hereinafter as the Martin and Anderson models, were used to compare water-temperature-related mortality of Winter-Run Chinook Salmon eggs and alevins under Alternative 4 and the No Action Alternative. The modeling was based on the HEC-5Q water temperature estimates for the years used in the HEC-5Q modeling (1922 to 2002). <The egg mortality results for Alternative 4 are not yet available. Conclusions will be provided after egg mortality results become available.>

Juvenile Rearing and Emigration

Winter-Run Chinook Salmon juveniles rear in the Sacramento River primarily from late summer to late winter, and emigrate from the river to the Delta beginning in November (see Section O.2.4.2.1, *Winter-*

Run Chinook Salmon). The proportion of juveniles surviving to emigrate to the Delta depends largely on habitat conditions, including flow and water temperature. Inundated floodplain habitat has been shown to benefit growth and survival of juvenile salmon (Sommer et al. 2001, 2005; Katz et al. 2017), but natural flood flows largely determine the availability of this habitat, rather than operations of the CVP and SWP dams.

Sacramento River flow during the Winter-Run juvenile rearing and emigration period differs substantially between the No Action Alternative and ALT4, especially during September and November of wet and above normal water years (Tables O.3-59, O.3-66 through O.3-68). The juveniles rear primarily in the upper and middle Sacramento River until about October, when they begin to appear in the lower river (e.g., Knights Landing) (del Rosario et al. 2013). As noted previously, because the No Action Alternative includes Fall X2 releases but not Alternative 4 does not, the mean monthly flows during September and November are much lower under Alternative 4 than under the No Action Alternative, which would potentially reduce suitable rearing habitat for juveniles (Tables O.3-59 and O.3-66 through O.3-68; Figures O.3-25, O.3-28 and O.3-29).

Emigration of juvenile Winter-Run from the Sacramento River is triggered by pulse flows of about 14,000 cfs and above (at Wilkins Slough) (del Rosario et al. 2013). CalSim II September flows at Wilkins Slough exceed this threshold in about 18% of years under the No Action Alternative and never exceed it under Alternative 3, but September is too early for juvenile Winter-Run to emigrate to the Delta (del Rosario et al. 2013). For November, when Winter-Run juveniles are ready to emigrate, monthly mean flow at Wilkins Slough is much higher under the No Action Alternative than under Alternative 3, but remains below the 14,000 cfs threshold for both alternatives, except for the highest 9% of flows (Figure O.3-29). There are no differences between the alternatives at these highest flows. An important limitation with this analysis is that the CalSim II flow estimates are monthly averages and Winter-Run emigration can be triggered by flow pulses that exceed 14,000 cfs for only a few days (del Rosario et al. 2013), so the flow differences in Figure O.3-29 incompletely represent the likelihood of triggering pulse flows occurring under the two alternatives.

Results from a more recent analysis suggest that the reduction in November flows from the No Action Alternative to Alternative 3 during wet and above normal water years could adversely affect Winter-Run juveniles emigrating at that time. The NMFS Southwest Fisheries Science Center ran statistical models using 2012-2017 tagging data from Spring-Run Chinook Salmon and Fall-Run Chinook Salmon and found a significant increase in smolt survival when Sacramento River flow at Wilkins Slough was above 9,100 cfs during the smolts out-migration period (Cordoleani et al. 2019). The CalSim II results for November at Wilkins Slough indicate that, under the No Action Alternative, 50% of years would have mean monthly flows that exceed the 9,100 cfs threshold, but that under Alternative 3 only 20% of years would exceed the threshold (Figure O.3-29). If these results apply to Winter-Run juveniles emigrating in November, they indicate a potential adverse effect of Alternative 3 on emigrating Winter-Run juveniles. The applicability of the results to Winter-Run are currently unknown, so the effect on Winter-Run is uncertain.

The USEPA (2003) gives 61°F as the critical 7 day average daily maximum (7DADM) water temperature for Winter-Run Chinook Salmon juveniles rearing in the upper Sacramento River and 64°F (7DADM) for those rearing in the middle Sacramento River (Knights Landing). Under the No Action Alternative, NMFS's RPA 1.2.4 requires Reclamation to maintain water temperature from May 15 through October 31 in the Sacramento River at no more than 56°F at compliance locations between Ball's Ferry and Red Bluff Diversion Dam. Under Alternative 3, SWRCB's WRO 90-5 has similar but more flexible water temperature requirements for Reclamation. Therefore, under both alternatives, juveniles rearing in the upper Sacramento River are likely to be well protected from water temperature extremes through the end of October in all but the driest years.

Under the No Action Alternative and Alternative 3, mean monthly water temperatures at Keswick exceed the 61°F threshold in only about 5% of years in September and October, with no appreciable water temperatures differences between the alternatives for water temperatures greater than the 61°F threshold (Figures O.3-18 and O.3-20). The monthly average temperatures for these months should reasonably estimate daily mean temperatures because operations at Shasta and Keswick dams create relatively stable summer and fall flow and water temperature conditions in the upper Sacramento River. From November through March, by which months most juvenile Winter-Run have emigrated to the Delta, there are only minor differencs in mean water temperatures at all locations from Keswick Dam to Knights Landing (Tables O.3-26 through O.3-31).

The water temperature effects on juvenile Winter-Run Chinook Salmon rearing in or emigrating from the Sacramento River resulting from Alternative 4 would be less-than-significant relative to the No Action Alternative, but the flow effects are potentially significant because the reductions in September flows in wet and above normal water years could reduce rearing habitat and the reductions November flows in wet and above normal water years could reduce smolt survival.

Adult Upstream Migration and Holding

Winter-Run Chinook Salmon adults enter the Sacramento River from the Delta and make their way to the upper Sacramento River, beginning as early as December. They hold in the upper River within 10 to 15 miles of Keswick Dam until they are ready to spawn, which may extend through August (Windell et al. 2017).

There are no flow or temperature requirements for the middle Sacramento River designed to protect fish. However, releases from Shasta Reservoir during November through early May may be reduced to conserve water for the May through October Winter-Run and Spring-Run spawning and incubation periods, resulting in reduced flow in the middle river (NMFS 2011: RPA I.2.2; SWRCB 1990: WRO 90-5). Lower flow in the Sacramento River relative to flow from the lower Yolo and Sutter bypasses and agricultural drains may affect navigation cues and straying of Winter-Run adults into canals and behind weirs, increasing their stranding risk. Once the adults reach holding habitat in the upper Sacramento River, they are more directly affected by Shasta and Keswick reservoir operations designed to preserve cold water for the Winter-Run and Spring-Run spawning and incubation periods. During the December through August period of adult Winter-Run immigration and holding, the mean monthly flows under Alternative 4 at Keswick Dam, RBDD, Hamilton City and Wilkins Slough would generally be similar to or greater than flows under the No Action Alternative, except during June of critically dry water years and August of below normal water years (Tables O.3-59 and O.3-66 through O.3-68). The mean monthly CalSim II flows in July of critically dry years and August of below normal years are greater than 4,500 cfs at all four sites under Alternative 4, which is high enough to avoid obstructing upstream passage of the adults. In any case, most Winter-Run adults have migrated upstream of RBDD by late May (see Section O.2.4.2.1, *Winter-Run Chinook Salmon*) and, therefore, would not be affected by July or Augst flow reductions downstream of RBDD.

The USEPA (2003) gives 68°F as the critical 7DADM water temperature for Winter-Run Chinook Salmon adults migrating upstream in the Sacramento River and 61°F for adult Winter-Run holding in the upper river. There are no major differences in HEC-5Q water temperature estimates between the No Action Alternative and Alternative 4 during any of the months that adult Winter-Run migrate upstream in the Sacramento River or hold in the upper river (Tables O.3-60 through O.3-65). However, the monthly mean water temperatures are moderately cooler under Alternative 4 at sites upstream of RBDD during August of dry and Criticial water years (Tables O.3-60, O.3-61, and O.3-62). Under both alternatives, the mean monthly water temperatures in the middle Sacramento River (Knights Landing) would be below the 68°F threshold for immigrating adults from December through April, but would exceed the threshold in May of critically dry water years and June through August of all water year types (Table O.3-65). Most Winter-Run adults have migrated upstream of RBDD by late May (see Section O.2.4.2.1, *Winter-Run Chinook Salmon*) and would therefore not be adversely affected by the elevated downstream summer water temperatures. In the upper Sacramento River from Keswick to Balls Ferry, the mean water temperatures would be well below the 61°F threshold for holding adults from December through August under both alternatives, (Table O.3-60, O.3-61, and O.3-62).

Alternative 4 is expected to have a less-than-signficant effect on Winter-Run Chinook Salmon adult upstream migration and holding relative to the No Action Alternative.

O.3.9.2.2 Central Valley Spring-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Spring-Run Chinook Salmon adults spawn from August through October with peak spawning in September (see Section O.2.4.2.2, *Spring-Run Chinook Salmon*). Monitoring Spring-Run spawning in the mainstem Sacramento River is complicated due to lack of spatial/geographic segregation and temporal isolation from Fall-Run Chinook Salmon. Most spring-sun spawning occurs between the Keswick Dam and Ball Ferry Bridge (NMFS 2017b). Fry emergence occurs up to 3 months after eggs are spawned (Moyle 2002), so effects of flow in the upper Sacramento River on incubating Spring-Run eggs and alevins potentially occur from August through January, peaking in December.

As previously noted, CalSim II modeling indicates that mean monthly flow released at Keswick Dam under ALT4 would generally be higher than or similar to flow under No Action Alternative, except in wet and above normal water years during September and November, when the Alternative 4 flows would be substantially lower than the No Action Alternative flows (Table O.3-59). Spawning and incubating eggs and alevins could be negatively or positively affected by the flow reductions. Assuming flows are stable enough to avoid dewatering the redds, which as noted previously is an important criterion for operators of Shasta and Keswick dams, the most important effect of flows on eggs and alevins is to transport dissolved oxygen to the developing eggs and alevins and to flush potentially toxic metabolites out of the redds. Although the mean September and November wet and above normal water year flows are substantially lower under Alternative 4 than under the No Action Alternative, the flows under Alternative 4 flows remain sufficiently high (5,500 and >6,700 cfs for September and November, respectively) to provide the flow velocity needed to keep most redds clean and well oxygenated (Figures O.3-25). Therefore, differences in flow between the No Action Alternative and Alternative 4 are expected to have little effect on Spring-Run Chinook Salmon spawning and incubation habitat.

Differences in water temperature during the Spring-Run spawning period may be important. As described previously, HEC-5Q monthly mean October water temperatures at Keswick Dam under Alternative 4 are predicted to be moderately lower than those under the No Action Alternative. A consequence of these water temperature reductions is that, for all but critically dry water years, the monthly mean water temperatures under the No Action Alternative are above the 53.5°F temperature threshold and those under Alternative 4 are below the threshold (Tables O.3-60). In critically dry water years, the mean temperatures are well over the threshold for both alternatives. For the yearly mean October water temperatures (Figure O.3-18), water temperatures are above the threshold in about 90% of years under the No Action Alternative and 30% of years under Alternative 4. Summer mean monthly water temperatures at Keswick Dam are roughly equal under the No Action Alternative and Alternative 4, except for August of dry and critically dry water years, which have a 1.1 and 1.5°F lower mean water temperatures, respectively, under Alternative 4 than under the No Action Alternative (Table O.3-60). Summer mean monthly water temperatures are consistently below the 53.5°F temperature threshold, except in critically dry water years during July through September. The largest predicted increases in mean water temperature under Alternative 4 are less than 1°F. Between the Clear Creek confluence and Balls Ferry, where more of the Spring-Run spawning occurs, more of the October mean monthly water temperatures under Alternative 4 exceed the threshold, especially in drier years, but most of them continue to be below the No Action Alternative means (Tables O.3-61 and O.3-62). September water temperatures in wet and above normal water years are expected to be higher under Alternative 4 than under the No Action Alternative, especially downstream of Keswick Dam (Tables O.3-61 through O.3-65), and the increases would result in more years with mean water temperatures exceeding the 53.5°F water temperature threshold (Figures O.3-30 and O.3-31). The critical temperature threshold for spawning adult Chinook Salmon in the Sacramento River is the same as that for eggs and alevins, 53.5°F (Martin et al. 2017) or 55.4°F (USEPA 2003).

The HEC-5Q modeling results show increased exceedance of the 53.5°F water temperature threshold during September under ALT4 relative to the No Action Alternative, and reduced exceedance of the threshold in October in all but critically dry water years, especially at Keswick Dam. It is concluded that Alternative 4 would have no net effect on Spring-Run spawning and egg and alevin incubation. Therefore, Alternative 4 would have a less-than-significant impact on Spring-Run Chinook Salmon spawning and egg and alevin incubation with respect to flow and water temperature.

Juvenile Rearing and Emigration

Spring-Run Chinook Salmon juveniles rear in the Sacramento River primarily from November through early May and most emigrate to the Delta during December and again in March and April (see Section O.2.4.2.2, *Spring-Run Chinook Salmon*). Migratory cues, such as increased flow and/or turbidity from runoff, may spur emigration of juveniles from the upper Sacramento River basin when they have reached the appropriate stage of maturation (NMFS 2009).

Based on the CalSim II modeling results, during most of the Spring-Run juvenile rearing and emigration period, Sacramento River flow would be higher under Alternative 4 than under the No Action Alternative at all locations and many of the increases would be greater than 5% (Tables O.3-59 and O.3-14). However, the mean monthly flows for November of wet and above normal water years would be much lower under Alternative 4, because of the Fall X2 flows that are included in the No Action Alternative but not Alternative 4. Despite the reductions, the November flows under Alternative 4 remain relatively high (Tables O.3-59 and O.3-66 through O.3-68; Figures O.3-28 and O.3-29), so they are not expected to substantially affect rearing juveniles. Furthermore, as noted above, emigration occurs primarily in December and in the spring.

Results from a recent study suggest that for Spring-Run that do emigrate as early as November, the Alternative 4 flow reductions in November of wet and above normal water years would have a potentially adverse effect. The NMFS Southwest Fisheries Science Center ran statistical models using 2012-2017 tagging data from Spring-Run Chinook Salmon and Fall-Run Chinook Salmon and found a significant increase in smolt survival when Sacramento River flow at Wilkins Slough was above 9,100 cfs during the smolts emigration period (Cordoleani et al. 2019). The CalSim II results for November at Wilkins Slough indicate that 50% of years would have mean monthly flows that exceed the 9,100 cfs threshold under the No Action Alternative, and 20% of years would have flows that exceed the threshold under Alternative 4 (Figure (O.3-29). As shown by recent sampling at RBDD (Figure O.3-22) almost all Spring-Run juveniles emigrate from the upper Sacramento River after November, so the percentage of Spring-Run juveniles that would be affected by the expected reductions in November flows at Wilkins Slough would be small. Therefore changes in flow resulting from Alternative 4 are not expected to substantially affect rearing and emigrating juvenile Spring-Run Chinook Salmon.

The USEPA (2003) gives 61°F as the critical 7 day average daily maximum (7DADM) water temperature for Spring-Run Chinook Salmon juveniles rearing in the upper Sacramento River and 64°F (7DADM) for those rearing in the middle Sacramento River (Knights Landing). Under the No Action Alternative and Alternative 4, HEC-5Q estimates of mean monthly water temperatures from Keswick to RBDD do not exceed the 61°F threshold during any month and water year type during the November through May rearing period (Tables O.3-60 through O.3-63). The mean monthly water temperatures for Hamilton City do not exceed the 64°F threshold for the middle Sacramento River during any of the months, but the mean monthly water temperatures for May exceed the middle river threshold at Knights Landing in all water year types under both alternatives. However, there are no meaningful differences between the Alternative 4 and No Action Alternative temperatures at Knights Landing (Table O.3-64). These results indicate that water temperature conditions would be too warm for juvenile Spring-Run Chinook Salmon rearing and emigrating in the middle Sacramento River during May. It should be noted that May is the last month during spring or summer that Spring-Run Chinook Salmon juveniles are found in the middle river, and it is likely that when water temperatures are too high they emigrate to the ocean before May, However, early emigration could have other adverse effects.

The flow and water temperature effects resulting from Alternative 4 would have a less-than-significant effect relative to the No Action Alternative on juvenile Spring-Run Chinook Salmon in the Sacramento River.

Adult Upstream Migration and Holding

Spring-Run Chinook Salmon adults enter the Sacramento River from the Delta as early as January and make their way to the upper Sacramento River beginning in February, where they hold until ready to spawn in late summer and early fall (Windell et al. 2017). Adults may continue migrating upstream until August, and holding continues until October when spawning is complete. There are no flow or temperature requirements for the middle Sacramento River designed to protect fish. Once the adults reach holding habitat in the upper Sacramento River, they are more directly affected by Shasta and Keswick reservoir operations designed to preserve cold water for the Winter-Run and Spring-Run spawning and incubation periods.

During the January through August period of adult Winter-Run immigration, the mean monthly CalSim II flows under Alternative 4 at Keswick, RBDD, Hamilton City, and Wilkins Slough would generally be similar to or greater than those under the No Action Alternative, except during July of critically dry water years (Tables O.3-59 and O.3-66 through O.3-68). However, the mean July flows under both alternatives would remain high enough (>4,500 cfs) to allow upstream passage. During the holding period, September flow would be much lower under Alternative 4 than under the No Action Alternative (Tables O.3-59 and O.3-66 through O.3-68; Figure O.3-25), but the mean September Alternative 4 flows at Keswick Dam would not fall below 6,000 cfs over the range of flows for which the alternatives have major flow differences (i.e., upper 50% in Figure O.3-25). A flow of 6,000 cfs would presumably be sufficient to maintain good water quality conditions in the Spring-Run holding habitats. Note that monthly mean flows for these months should reasonably estimate daily mean flows because operations at Shasta and Keswick dams create relatively stable summer and fall flow and water temperature conditions in the upper Sacramento River.

The USEPA (2003) gives 68°F as the critical 7DADM water temperature for Spring-Run Chinook Salmon adults migrating upstream in the middle Sacramento River and 61°F for adult Spring-Run holding in the upper river. Throughout the January through August period of Spring-Run upstream migration, HEC-5Q water temperatures for Alternative 4 are similar to or slightly lower than those for the No Action Alternative at all locations, including greater than 1°F reductions in mean monthly water temperature for June of dry water years at Knights Landing (Tables O.3-60 through O.3-65). Under both alternatives, the mean monthly water temperatures in the middle Sacramento River (Knights Landing) would be below the 68°F threshold for immigrating adults from December through April, but would exceed the threshold in May of critically dry water years and in June through August of all water year types (Table O.3-65). The high May through August water temperatures would be likely to adversely affect any Spring-Run adults that were migrating upstream in those months. High water temperatures were found to cause adult Spring-Run Chinook Salmon in Butte Creek to terminate their upstream migrations, which made them more susceptible to mortality from rising water temperatures (Mosser et al. 2012). The June temperature reduction under Alternative 4 occurs in a range slightly above the 68°F threshold and, therefore, would likely have a beneficial effect on upstream migrating adults. In the upper Sacramento River at Keswick Dam to Balls Ferry, the mean water temperatures under both alternatives would be well below the 61°F threshold for holding adults from February through October (Tables O.3-60 through O.3-62). As previously noted, flow below Keswick Dam is relatively stable during the summer and fall months, so monthly mean flows and temperatures are likely to be fairly representative of daily means in those months.

With respect to flow and water temperature, Alternative 4 is expected to have a less-than-significant effect relative to the No Action Alternative on Spring-Run Chinook Salmon adult migration and holding.

O.3.9.2.3 Central Valley Steelhead

Spawning and Egg Incubation

CV steelhead adults spawn from November through April with peak spawning from January through March. Based on the general timing of hatching and fry emergence, eggs and alevins may occur from November through May. Little is known about steelhead spawning locations in the Sacramento River, but it is generally assumed that spawning occurs primarily between Keswick Dam and RBDD.

During the steelhead spawning and incubation period, CalSim II modeling indicates that Alternative 4 flows in wet and above normal years would be substantially lower in November, and generally higher during the winter and spring months (Table O.3-59). Based on PHABSIM results (flow versus weighted usable area [WUA] relationships) for steelhead in the Sacramento River between Keswick Dam and Battle Creek (see O.3.3 Alternative 1, Central Valley Steelhead Spawning and Egg Incubation), lower flows in November of wet and above normal years under Alternative 4 correspond to an average 15% increase in spawning WUA, while higher flows in subsequent months correspond to average reductions in spawning WUA of less than 10% (Figure WUA-SH-S). Therefore, changes in flows under Alternative 4 would have both positive and negative effects on the availability of steelhead spawning habitat relative to the No Action Alternative.

HEC-5Q modeling for Alternative 4 indicates that the water temperatures in the upper Sacramento River during the steelhead spawning and incubation period (November through May) would be similar to those under the No Action Alternative (Tables O.3-60 through O.3-63). Based on the steelhead spawning and incubation threshold of 53°F (see O.3.3 Alternative 1, Central Valley Steelhead Spawning and Egg Incubation), both alternatives would maintain suitable water temperatures for spawning and incubation through April or May in the reach between Keswick Dam and Clear Creek, and there would be no major differences in the frequency and magnitude of water temperatures exceeding 53°F in other months or locations with the primary spawning (Keswick Dam to RBDD). Therefore, changes in water temperatures under Alternative 4 would not likely have significant effects on spawning adults, eggs, and alevins relative to the No Action Alternative.

Juvenile Rearing and Emigration

CV steelhead rear year-round in the Sacramento River, and use the river downstream from spawning areas as both a rearing and migration corridor. The timing of downstream migration is variable but generally peaks in the upper river at RBDD in spring and summer (March through June) and in the lower river at Knights Landing in winter and spring (January through May) (NMFS 2009). The peak migration of yearling and older juveniles through the Delta occurs in March and April (NMFS 2009).

CalSim II modeling indicates that the largest differences in Sacramento River flows between Alternative 4 and the No Action Alternative would occur in the late summer and fall (September and November) of above normal and wet years, and in winter and spring of most water year types, potentially affecting fry and juvenile rearing habitat (Table O.3-59). Based on the flow-habitat relationships for Late Fall-Run Chinook Salmon fry and juvenile life stages (see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration), lower flows under Alternative 4 in the fall of wet and above normal water years would increase the amount of juvenile rearing habitat (as measured by WUA), while higher flows in winter and spring of most water year types would generally reduce the amount of fry and juvenile rearing habitat (Figures O.3-39 and O.3-40). For example, in wet years, reductions in average flows of approximately 6,200 cfs in September and 3,900 cfs in November would increase juvenile WUA by approximately 40% relative to the No Action Alternative. In below normal years, increases in average winter and spring flows (averaging 700 cfs to 1,600 cfs higher than No Action Alternative flow) would reduce juvenile WUA by 10% or less relative to the No Action Alternative. During the fry rearing period (March through May, the largest effect on fry WUA would be a 15% reduction in fry WUA in March of below normal years. Therefore, changes in flows under Alternative 4 would have both positive and negative effects on the availability of steelhead rearing habitat relative to the No Action Alternative.

In the upper Sacramento River, HEC-5Q modeling for Alternative 4 and the No Action Alternative indicates that average water temperatures between Keswick Dam and RBDD would be maintained at or below the "core rearing area threshold" of 61°F (see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration) throughout the year except in summer (July through September) of critical water years (Table O.3-63). During summer, water temperatures under Alternative 4 would be similar to those under the No Action Alternative except in September of wet and above normal years when water temperatures would average up 3.3°F higher at RBDD (Tables O.3-63); however, there would be no major differences in the frequency and magnitude of temperatures above 61°F (Figure O.3-22). Similarly, water temperatures during the steelhead emigration season (January through June) are expected to similar or cooler than those under the No Action Alternative (Table O.3-63 to O.3-65). For example, although water temperatures at Knights Landing would frequently exceed the 64°F "non-core rearing area" threshold in May under both alternatives (Figure O.3-41), higher spring flows under Alternative 4 would reduce average water temperature by up to 1.1°F (dry water years) (Table O.3-65). Therefore, changes in water temperature under Alternative 2 would not likely have significant effects on rearing and emigrating steelhead relative to the No Action Alternative.

Adult Upstream Migration and Holding

Adult steelhead immigration into Central Valley streams potentially occurs during all months of the year but typically begins in August and continues through March or April (McEwan 2001; NMFS 2014a). In the Sacramento River, adults migrate upstream past RBDD during all months of the year, but primarily during September and October (NMFS 2009). Adults may hold until the spawning season which generally extends from November through April.

During the steelhead immigration and holding period, lower flows in September and November of wet and above normal water years under Alternative 4 could affect immigrating and holding adults. However, mean monthly flows would be maintained at a minimum of 3,250 under both alternatives, and would not differ substantially in frequency and magnitude between the alternatives until flows exceed approximately 5,000 cfs (Figures O.3-25, O.3-27, and O.3-29). Within this flow range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Under both Alternative 4 and the No Action Alternative, HEC-5Q modeling indicates that suitable water temperatures for steelhead immigration in the Sacramento River (based on the immigration threshold of 68°F; see O.3.3 Alternative 1, Central Valley Steelhead Adult Upstream Migration and Holding) would generally not occur until September or October (Table O.3-65). However, under Alternative 4, substantially lower flows in September of wet and above normal water years would increase the frequency of water temperatures exceeding this threshold, resulting in potential delays in migration or adverse physiological effects on migrating adults relative to the No Action Alternative. For example, at Knights Landing, mean monthly water temperatures in September exceeded 68°F approximately 82% of the time compared to 52% of the time under the No Action Alternative (Figure O.3-24). Therefore, changes in water temperatures under Alternative 4 in September would have a potentially adverse effect on immigrating adult steelhead in the Sacramento River relative to the No Action Alternative. Lower flows in September would also result in higher water temperatures in the upper Sacramento River, potentially affecting holding adults. However, no major differences would be expected to occur in the frequency and magnitude of water temperatures exceeding the threshold for holding adults (61°F; see O.3.3 Alternative 1, Central Valley Steelhead Adult Upstream Migration and Holding) (Figure O.3-22).

O.3.9.2.4 Southern DPS Green Sturgeon

Spawning and Egg Incubation

Green Sturgeon spawn in deep pools (averaging about 28 feet deep) (NMFS 2018b). Eggs from spawning Southern DPS Green Sturgeon have been found in the middle and upper Sacramento River from the GCID oxbow (RM 207) to Inks Creek (RM 265) and spawning is believed to extend upstream to the confluence with Cow Creek (RM 277) (Heublein et al. 2017b). Green Sturgeon spawn primarily from April through July, although they periodically spawn in late summer and fall (as late as October) (Heublein et al. 2009, 2017b, NMFS 2018b). Eggs hatch about a week after fertilization (at 60ºF) (Heublein et al. 2017b). Because the incubation time for Green Sturgeon is so short, the effects analysis period for incubating eggs is considered to be the same as the spawning period. Based on laboratory studies for Northern DPS Green Sturgeon, Heublein et al. 2017b) concluded that the optimal range for normal embryo development of Southern DPS Green Sturgeon is 53 to 64°F, and impaired fitness occurs below 52°F and above 71°F.

During the April through July Green Sturgeon spawning period, CalSim II estimates of mean monthly flows at RBDD (RM 244) under the No Action Alternative and Alternative 4 range from about 5,000 cfs for April of critically dry water years to about 14,900 cfs in July of Above Normal water years (Table O.3-66). Mean flows during most of this period are moderate (~8,000 cfs to ~12,000 cfs). These flow levels are likely to be suitable for Green Sturgeon spawning and egg incubation, and no adverse effects are expected to result.

Differences in flows between Alternative 4 and the No Action Alternative are small in most months, but flows are moderately higher for Alternative 4 in April during all water years except critically dry water years and June during below normal, dry and critically dry water years (Table O.3-66). During the August through October period, when Green Sturgeon spawning occurs in occasional years, the flows under both alternatives tend to be lower than those in April through July, but the mean flows would be close to or above 5,000 cfs for all water year types in all three months. Large reductions in mean flows from the No Action Alternative to Alternative 4 are predicted for September of wet and above normal water years and, although the resulting Alternative 4 mean flows are greater than 5,000 cfs, the flow reductions are so large (about 46%) that conditions for Green Sturgeon spawning and egg incubation are likely to be adversely affected (Table O.3-32). However, September spawning occurs only sporadically, so any effect on the Green Sturgeon population would be minor (NMFS 2018b). Therefore, the September flow reductions are expected to have a minor adverse impact on Green Sturgeon.

Based on the HEC-5Q modeling, mean water temperatures during the April through July primary spawning period of Green Sturgeon are below the 53 and 52°F lower temperature thresholds for Green Sturgeon egg development at Clear Creek and Balls Ferry during many of the months and water year types (Tables O.3-61 and O.3-62). As discussed previously, daily water temperatures are likely to be more variable than monthly mean temperatures, so the reductions of the mean temperatures below the 52 and 53°F thresholds probably underestimate the largest daily reductions below the thresholds.

The HEC-5Q modeling results show little difference in Clear Creek confluence and Balls Ferry mean water temperatures between Alternative 4 and the No Action Alternative during the April through July primary Green Sturgeon spawning and incubation period (Table O.3-61). Therefore, Alternative 4 is unlikely to cause a reduction in water temperatures relative to the No Action Alternative and thereby would not adversely affect Green Sturgeon spawning and egg incubation.

Larval and Juvenile Rearing and Emigration

As discussed under Alternative 1 (Section O.3.3, *Alternative 1*), the larval period for Green Sturgeon is considered to be April through September. The downstream distribution of Green Sturgeon larvae in the Sacramento River is uncertain, but is estimated to extend to the Colusa area, at RM 157 (Heublein et al. 2017b). The upstream limit is the Cow Creek confluence. Green Sturgeon juveniles rear in the Sacramento River from about May through December (NMFS 2017b). During most of this period, the juveniles are likely to be found anywhere from the upstream spawning habitat near the Cow Creek confluence to the Delta.

CalSim modeling for the Sacramento River at RBDD indicates that mean monthly flows during the April through September period of larval rearing are greater in April (wet through dry years) and June (below normal to critically dry years) under Alternative 4 than under the No Action Alternative. During the months of July (critically dry years), August (below normal years) and September (wet to below normal years) there is a decrease in flows (Table O.3-66). The September reductions in flow from the No Action Alternative to Alternative 4 during wet and above normal years are substantial and would potentially affect Green Sturgeon larvae adversely because, as discussed for Alternative 1 (Section O.3.3, *Alternative 1*), there appears to be a positive relationship between annual outflow and abundance of White Sturgeon larvae and juveniles. However, the applicability of the relationship to Green Sturgeon is uncertain.

CalSim modeling for the Sacramento River at Hamilton City indicates that mean monthly flows during the period of juvenile rearing and emigration, May through December, are higher in June (below normal to critically dry years) and December (wet and above normal years) (Table O.3-66). Reductions in flows occur in September and November (wet and above normal years). These reductions in flow could adversely affect Green Sturgeon juveniles under Alternative 4 because, as noted above, there may be a positive relationship between annual outflow and abundance of Green Sturgeon.

There are few notable differences in the HEC-5Q mean monthly water temperature estimates at RBDD or Hamilton City between the No Action Alternative and Alternative 4 during the Green Sturgeon larval and juvenile rearing and emigration period in any month, except for September (Tables O.3-63 and O.3-64). During over half of the years in September, the Alternative 4 water temperature at RBDD is greater than the No Action Alternative temperature, with a maximum difference of about 3°F (Figure O.3-22). Over the range of years for which there are temperature differences, the water temperatures of both the No Action Alternative and Alternative 4 are under the 63°F lower limit of the optimal range for larvae. However, the Alternative 4 water temperatures are closer to the optimal range and therefore would potentially provide more favorable conditions for larval growth and survival. For the juveniles at RBDD, the September water temperatures under the No Action Alternative are below the 59°F lower limit of the optimal temperature range in about half of the years, and under Alternative 4 they are below the optimal range in about a third of the years (Figure O.3-22). The September HEC-5Q temperature estimates for Hamilton City also fall within or are closer to the optimal ranges of Green Sturgeon larvae and juveniles in more years under the Alternative 4 than the No Action Alternative, however overall temperatures are slightly lower in the other months (Table O.3-64; Figure O.3-23).

The CalSim II flow results indicate that Alternative 4 would not have an adverse impact on rearing larval and juvenile southern DPS Green Sturgeon relative to the No Action Alternative, and the HEC-5Q water temperature modeling results indicate that Alternative 4 would provide a minor potential benefit to rearing larval and juvenile Green Sturgeon relative to the No Action Alternative.

Adult Upstream Migration and Holding

Green Sturgeon adults enter the Sacramento River from the Delta as early as February and ultimately make their way upstream to spawn in deep pools from the GCID oxbow (near Hamilton City) to the Cow Creek confluence (Heublein et al. 2017b). After spawning, the adults hold in the river for varying amounts of time, but typically emigrate back to the San Francisco Estuary and the ocean from about October through December (Heublein et al. 2017b).

Flows during the February through December period of Green Sturgeon immigration, spawning and holding are greater during February to April, June and December at RBDD and Hamilton City under Alternative 4 versus No Action Alternative. Wilkins Slough also shows increased flows during these months, but under fewer of the water year types (Tables O.3-66 through O.3-68). A moderate decrease in flows occurs at all of these locations during July (critically dry years), September (wet and above normal years), and November (wet and above normal years). All of the more notable flow differences occur within a range of river flows (~5,000 cfs to 14,000 cfs) that are not expected to substantially affect upstream passage of migrating Green sturgeon, but the September and November flow reductions under Alternative 4 at Hamilton City and RBDD could result in reduced habitat quality in holding pool habitats, adversely affecting holding adults.

There are few major differences in mean monthly water temperatures between the No Action Alternative and Alternative 4 in the Sacramento River at Knights Landing during the February through April period that most adult Green Sturgeon migrate upstream or during the later months (through December) when the sturgeon migrate downstream after spawning (Table O.3-65). Temperatures are lower during June of dry years, which would benefit migrating adults by bringing temperatures closer to the 66 degree threshold. However, increases of more than 4°F are expected in September of wet and above normal water years. The means exceed the 66°F threshold for migrating Green Sturgeon adults in both water year types under Alternative 4 and in neither water year type under the No Action Alternative. The mean monthly water temperatures at Knights Landing also exceed the 66°F threshold under both alternatives during June through August of all water year types and May of all but wet years (Table O.3-65). Adults migrating downstream from May through September would potentially be adversely affected by the high water temperatures. However, adults migrating upstream would be less affected because most upstream immigration occurs before late spring (Heublein et al. 2009), when water temperatures are below the 66°F threshold.

During the May through December spawning and post-spawn holding period for Green Sturgeon, the HEC-5Q mean monthly water temperatures at Hamilton City are generally similar between the No Action Alternative and Alternative 4, except for higher temperatures under Alternative 4 in September (Table O.3-64). The mean monthly water temperatures during the hottest months of this period, July through September, range from 58°F to 68°F (both in September). The temperatures frequently exceed the 63°F threshold for spawning adults and the 61°F threshold for holding adults during these months. During September, the mean water temperatures only exceed the 61°F threshold in wet and above normal years under Alternative 4 but not under the No Action Alternative. September water temperatures are cooler at RBDD and there is no difference at this location between Alternative 4 and the No Action Alternative in the frequency of the threshold exceedances (Figure O.3-22). During October through December, the mean monthly water temperatures stay below both thresholds in every water year type (Table O.3-63).

The CalSim II modeling results indicate that for adult southern DPS Green Sturgeon holding in September or November, reduced flows under Alternative 4 would have a potentially significant adverse impact on holding habitat relative to the No Action Alternative. The HEC-5Q modeling results indicate that the water temperatures for September of wet and above normal water years would more often exceed the 66, 63 and 61°F thresholds for migrating, spawning and holding adult Green Sturgeon under Alternative 4 than under the No Action Alternative, would be substantially higher under Alternative 4 than under the No Action Alternative, and would exceed the 61°F thresholds for migrating, spawning and holding adult Green Sturgeon only under Alternative 4. In conclusion, the HEC-5Q results for Alternative 4 are expected to result in substantially less favorable water temperatures for Green Sturgeon in September of wet and above normal water years. In combination, the reduced flows in September and November of wet and above normal water years and increased water temperatures in September of wet and above normal water years are expected to have a significant adverse impact on southern DPS Green Sturgeon adults.

O.3.9.2.5 Fall-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Fall-Run Chinook Salmon migrate upstream past RBDD on the Sacramento River between July and December, typically spawning in upstream reaches from October through January, with a peak in October and November. Eggs and alevins are present from October through April. The primary spawning area used by Fall-Run Chinook Salmon in the Sacramento River is the area from Keswick Dam downstream to RBDD. Spawning densities for all Chinook Salmon runs are highest in this reach, but the distribution of spawning fall-run generally extends downstream to spawning areas below RBDD (Gard 2013).

During the Fall-Run Chinook Salmon spawning and incubation period, relatively large reductions in flows in November of wet and above normal water years under Alternative 4 would increase the amount of available spawning habitat, while moderate increases in flow in subsequent months would decrease available spawning habitat. For example, in wet years, a reduction in average flow of approximately 3,800 cfs in November would increase the amount of available spawning habitat (as measured by WUA) by 81%, while an increase in average flow of approximately 1,900 cfs in December would decrease available spawning habitat by 25% (Figure O.3-35). Therefore, changes in flows under Alternative 4 would have both positive and negative effects on the availability of spawning habitat relative to the No Action Alternative.

HEC-5Q modeling indicates that Alternative 4 would not substantially affect the frequency of water temperatures exceeding the 53.5°F threshold (see O.3.3.1.2, Sacramento River, *Potential changes to aquatic resources in the Sacramento River from seasonal operations*) during the Fall-Run Chinook Salmon spawning and incubation period (October through April) (Table O.3-60). Both alternatives would maintain suitable water temperatures for spawning and incubation through April in the reach between Keswick Dam and Clear Creek, and there would be no major differences in the frequency and magnitude of water temperatures exceeding 53.5°F in other months or locations within the primary spawning area (Keswick Dam to RBDD) (e.g., Figure O.3-22). Therefore, changes in water temperatures under Alternative 4 are not likely to have significant effects on steelhead spawning and incubation relative to the No Action Alternative.

Juvenile Rearing and Emigration

Fall-Run Chinook Salmon juveniles rear in the Sacramento River primarily from December through May. Following emergence, juveniles rear for variable lengths of time in the Sacramento River before entering the Delta and estuary, and may emigrate as fry, parr, or smolts. The timing of emigration is variable but generally peaks in the upper river from January through April and in the lower river from January through May (NMFS 2009).

Under Alternative 4, higher winter and spring flows in the Sacramento River relative to the No Action Alternative could affect rearing and emigrating Fall-Run Chinook Salmon. Based on the flow-habitat relationships for Fall-Run Chinook Salmon fry and juvenile life stages (see O.3.3 Central Valley Fall-Run Chinook Salmon, Juvenile Rearing and Emigration), higher winter and spring flows under Alternative 4 would generally reduce the amount of available fry and juvenile rearing habitat in the upper Sacramento River. CALSIM II modeling indicates that the largest differences in flows between Alternative 4 and the No Action Alternative would occur in December of wet years (averaging approximately 1,900 cfs) and in January of below normal water years (averaging approximately 1,600 cfs). Based on the flow-habitat relationships, these flow increases correspond to a 7% reduction in fry WUA in December of wet years and a 15% reduction in fry WUA in January of below normal years (Figures O.3-36 and O.3-37). While these results indicate that Alternative 4 would potentially reduce the availability of suitable rearing habitat for Fall-Run Chinook Salmon relative to the No Action Alternative, uncertainty exists in the importance of this reduction relative to other factors that affect the quantity and quality of rearing habitat for juvenile Chinook Salmon in the Sacramento River.

In the upper Sacramento River, HEC-5Q modeling for Alternative 4 and the No Action Alternative indicates that both alternatives would maintain suitable water temperatures (≤ 61°F; see O.3.3 Alternative 1, Central Valley Steelhead Juvenile Rearing and Emigration) between Keswick Dam and RBDD during the Fall-Run Chinook Salmon fry and juvenile rearing period (December through May) (Tables O.3-60 through O.3-63). Farther downstream, mean monthly water temperatures in the lower river at Knights Landing would be similar or slightly cooler under Alternative 4 (Table O.3-65), but there would be no differences in the frequency and magnitude of temperatures exceeding the 64°F "non-core rearing area threshold" (Figure O.3-41). Therefore, changes in Sacramento River water temperatures under Alternative 4 would not likely have significant effects on rearing and emigrating juvenile Fall-Run Chinook Salmon relative to the No Action Alternative.

Adult Upstream Migration and Holding

Fall-Run Chinook Salmon migrate upstream past RBDD on the Sacramento River between July and December. Adults may hold until the spawning season, which occurs primarily from October through January.

CALSIM II modeling indicates that mean monthly flows in the Sacramento River under Alternative 4 would be substantially lower in September and November of wet and above normal water years relative to the No Action Alternative (Tables O.3-59, O.3-66, and O.3-67), potentially affecting immigrating and holding adults. However, flows under both alternatives would be maintained at or above 3,250 cfs throughout the immigration and holding period. Although flows would differ substantially in September and November, the differences would be limited to flows exceeding approximately 5,000 cfs (Figures O.3-25, O.3-25, and O.3-29). Within this range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Under both Alternative 4 and the No Action Alternative, HEC-5Q modeling indicates that suitable water temperatures for Fall-Run Chinook Salmon immigration in the Sacramento River (based on the immigration threshold of 68°F; see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding) would generally not occur until September or October (Table O.3-65). However, under Alternative 4, substantially lower flows in September would increase the frequency of water temperatures exceeding this threshold, resulting in potential delays in migration or adverse physiological effects on migrating adults relative to the No Action Alternative. For example, at Knights Landing, mean monthly water temperatures in September exceeded 68°F approximately 82% of the time under Alternative 4 compared to 52% of the time under the No Action Alternative (Figure O.3-24). Therefore, changes in water temperatures under Alternative 4 in September would have a potentially adverse effect on immigrating adult Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative. Lower flows in September would also result in higher water temperatures in the upper Sacramento River, potentially affecting holding adults. However, no major differences would be expected to occur in the frequency and magnitude of water temperatures exceeding the threshold for holding adults (61°F; see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding) (Figure O.3-22).

O.3.9.2.6 Late Fall-Run Chinook Salmon

Spawning and Egg/Alevin Incubation

Late Fall-Run Chinook Salmon spawn primarily from December through April, and eggs and alevins are present in the gravel from December through June. In the Sacramento River, most adults spawn upstream of Red Bluff Diversion Dam, with the majority spawning between Keswick Dam and the ACID Dam.

CALSIM II modeling indicates that Sacramento River flows under Alternative 4 would generally be higher than or similar to the flows under the No Action Alternative during the Late Fall-Run Chinook Salmon spawning and incubation period (December through June) (Table O.3-59). The largest increases in flow are expected to occur in the winters of wet, above normal, and below normal years. Based on PHABSIM results (flow-habitat relationships) for the Sacramento River between Keswick Dam and Battle Creek (USFWS 2003a), higher flows under Alternative 4 would reduce the amount of available spawning habitat for Late Fall-Run Chinook Salmon (as measured by WUA) (Figure O.3-38). For example, spawning habitat WUA would be reduced by approximately 17% in December of wet years, 5% in January of below normal years, and 8% in March of below normal years. While these results indicate that Alternative 4 would potentially reduce the availability of suitable spawning habitat for Late Fall-Run Chinook Salmon relative to the No Action Alternative, uncertainty exists in the importance of this reduction relative to other factors that affect the quantity and quality of spawning and incubation habitat for Late Fall-Run Chinook Salmon in the Sacramento River.

HEC-5Q modeling for Alternative 4 indicates that the water temperatures in the upper Sacramento River during the Late Fall-Run Chinook Salmon spawning and incubation period (December through June) would be similar to those under the No Action Alternative (Tables O.3-60 through O.3-63). Based on the spawning and incubation threshold of 53.5°F (see O.3.3.1.2, Sacramento River, *Potential changes to aquatic resources in the Sacramento River from seasonal operations*, both alternatives would maintain suitable water temperatures from spawning and incubation through May or June in the primary spawning reach (Keswick Dam and Clear Creek) (Table O.3-61), and there would be no major differences in frequency and magnitude of water temperatures exceeding this threshold (Figure O.3-139). Therefore, changes in water temperatures under Alternative 2 are not likely to have significant effects on spawning adults, eggs, and alevins relative to the No Action Alternative.

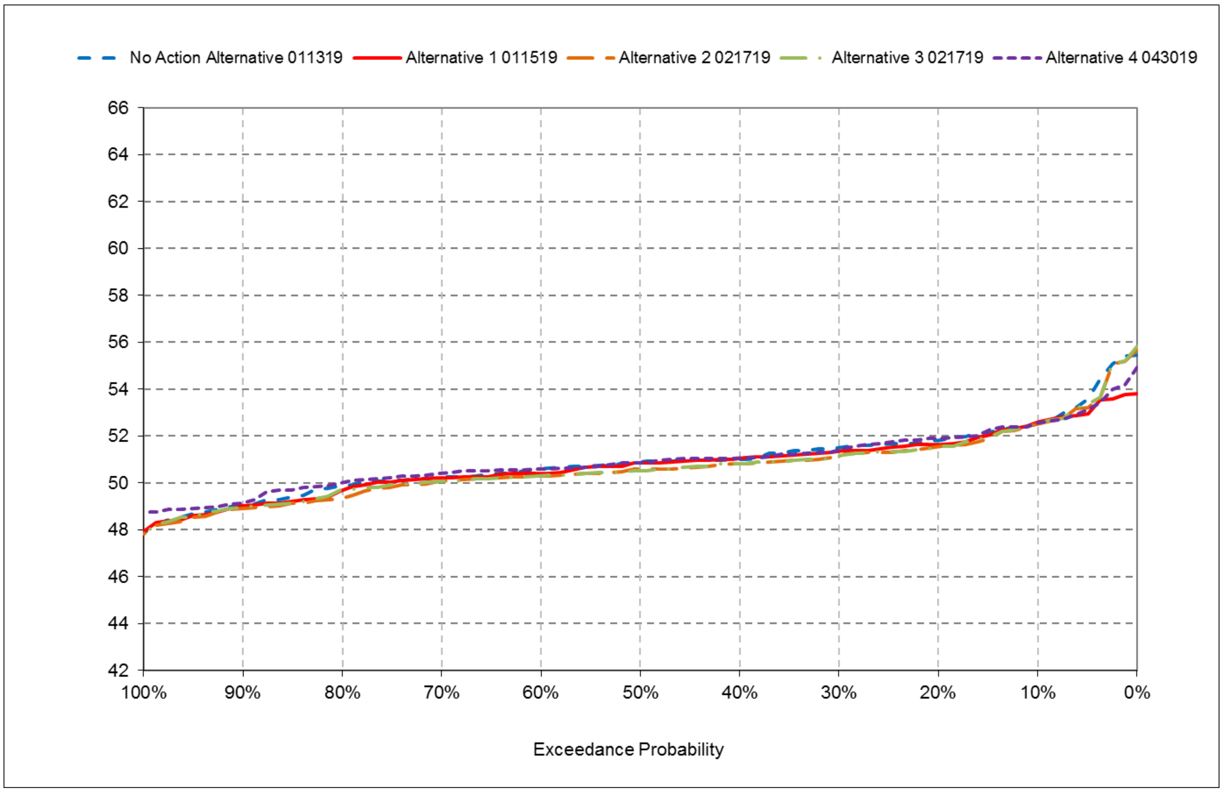

Figure O.3-139. HEC-5Q Sacramento River Water Temperatures at Clear Creek Confluence under the No Action Alternative, Alternative 1, Alternative 2, Alternative 3, and Alternative 4; May

Juvenile Rearing and Emigration

Late fall–run Chinook Salmon fry generally emerge from March through June, and juveniles rear in the Sacramento River through the summer before emigrating at a relatively large size (150- to 170-mm fork length) primarily from November through May.

CalSim II modeling indicates that Sacramento River flows under Alternative 4 would generally be higher than or similar to flows under the No Action Alternative during the Late Fall-Run Chinook Salmon rearing period except in September and November of wet and above normal water years when flows would be substantially lower (Table O.3-59). Based on PHABSIM results (flow-habitat relationships) for fry and juvenile rearing in the upper Sacramento River (USFWS 2005), generally higher spring flows in above normal, below normal, and dry water years would reduce the amount of rearing habitat, while lower fall flows in wet and above normal years would increase the amount of rearing habitat (Figures O.3-39 and O.3-40). For example, higher flows in March of below normal years (averaging 1,200 cfs lower than No Action Alternative flows) correspond to a 15% reduction in fry WUA, while lower flows in September of wet years (averaging approximately 6,200 cfs) would increase juvenile rearing habitat (as measured by WUA) by approximately 40%. Therefore, changes in flows under Alternative 4 would have both positive and negative effects on the availability of rearing habitat relative to the No Action Alternative.

In the upper Sacramento River, HEC-5Q modeling for Alternative 4 and the No Action Alternative indicates that average water temperatures between Keswick Dam and RBDD would be maintained at or below the “core rearing area threshold” of 61°F throughout the year except in the summer (July through September) of critically dry water years (Tables O.3-63). During summer, water temperatures under Alternative 4 would be similar or cooler than those under the No Action Alternative except in September of wet and above normal years when average water temperatures would be up to 3.3°F higher (Tables O.3-63); however, there would be no major differences in the frequency and magnitude of temperatures above 61°F (Figure O.3-22). Similarly, water temperatures during the Late Fall-Run Chinook Salmon emigration season (November through May) are expected to similar or cooler than those under the No Action Alternative (Table O.3-63 to O.3-65), but there would be no differences in the frequency of temperatures exceeding the 64°F “non-core rearing area threshold” (Figure O.3-41). Therefore, changes in water temperature under Alternative 4 would not likely have significant effects on rearing and emigrating Late Fall-Run Chinook Salmon relative to the No Action Alternative.

Adult Upstream Migration and Holding

In the Sacramento River, adult Late Fall-Run Chinook Salmon migrate from October through April, with a peak during January through March (NMFS 2009). Adults hold for 1 to 3 months prior to spawning, which occurs primarily from December through April.

CALSIM II modeling indicates that flows in the Sacramento River during the Late Fall-Run Chinook Salmon immigration period would be similar or higher than those under the No Action Alternative except in November of wet and above normal water years when flows would be substantially reduced relative to the No Action Alternative (Tables O.3-59, O.3-66, and O.3-67). However, flows under both alternatives would be maintained at or above 3,250 cfs throughout the immigration and holding period. Although flows would differ substantially in November, the differences would be limited to flows exceeding approximately 5,000 cfs (Figures O.3-25, O.3-27, and O.3-29). Within this flow range (>5,000 cfs), no adverse effects on migrating and holding adults would be expected; flows of this magnitude would presumably be sufficient to maintain suitable passage and holding conditions under both alternatives.

Based on the water temperature thresholds for immigration (68°F) and holding (61°F) (see O.3.3 Alternative 1, Central Valley Fall-Run Adult Upstream Migration and Holding), Alternative 4 and the No Action Alternative would maintain suitable water temperatures for Late Fall-Run Chinook Salmon throughout the immigration and holding period (October through April) (Tables O.3-63 and-O.3-65). Therefore, changes in water temperatures under Alternative 4 would not likely have significant effects on immigrating and holding Late Fall-Run Chinook Salmon in the Sacramento River relative to the No Action Alternative.

O.3.9.2.7 White Sturgeon

Spawning and Egg Incubation

White sturgeon spawn in deep water in the middle and lower Sacramento River from Verona (RM 80) to just upstream of Colusa (~RM 156) from late February to early June, but primarily during March and April, (Moyle et al. 2015; Heublein et al. 2017). The adults typically return promptly to the Delta/Estuary after spawning.

During the March and April spawning and egg incubation period of White Sturgeon, CalSim II estimates of mean monthly flows at Wilkins Slough under the No Action Alternative and Alternative 4 range from about 5,300 cfs for April of critically dry water years to about 18,000 cfs for March of wet water years (Table O.3-68). These flow levels are likely to be adequate for White Sturgeon spawning and egg incubation, so no adverse effects are expected to result. Differences in flows between Alternative 4 and the No Action Alternative are small in both months, but flows are moderately higher for Alternative 4 in April of wet to below normal water years (Table O.3-59). It is concluded that Alternative 4 would have no flow effects on White Sturgeon eggs and embryos relative to the No Action Alternative.

The HEC-5Q water temperature modeling results for March and April indicate that mean monthly water temperatures at Knights Landing are below the 63°F threshold for optimal temperatures (see Section O.3.3.1.2, *Sacramento River*), except in April of critically dry water years (Table O.3-65). There are no appreciable differences in water temperatures between Alternative 4 and No Action Alternative in March or April (Table O.3-65; Figures O.3-43). During June, the warmest month of the full spawning and egg incubation period, the mean monthly water temperatures are predicted to exceed the 68°F lethal temperature in all water year types, but the water temperatures are lower for Alternative 4 than for the No Action Alternative in drier water years (Table O.3-65). It is concluded that Alternative 4 would have no water temperature effects on White Sturgeon eggs and embryos relative to the No Action Alternative.

Larval and Juvenile Rearing and Emigration

During the March through June larval period, water temperature modeling indicates that water temperatures frequently exceed these water temperature thresholds (61°F and 68°F, see Section O.3.3.1.2, *Sacramento River*) at Knights Landing under the No Action Alternative and Alternative 4 (Table O.3-65), especially, as noted above, in June. Such high levels of temperature threshold exceedances suggest that typical water temperature conditions in the lower Sacramento River may be highly stressful for white sturgeon larvae. In any case, the water temperatures, especially in June, are slightly lower under Alternative 4 than under the No Action Alternative (Table O.3-65). It is concluded that Alternative 4 compared to the No Action Alternative will not have an adverse effect on larval and juvenile rearing.

During the White Sturgeon juvenile emigration period, approximately April to July, CalSim II results indicate that flows at Wilkins Slough during April and June would increase with Alternative 4 compared to No Action Alternative and in July would increase of Above Normal years and decrease in critically dry years (Table O.3-14).

Adult Upstream Migration and Holding

White Sturgeon adults to initiate their upstream spawning migrations during late winter and early spring, presumably in response to elevated flows (Heublein et al. 2017). CalSim II flows at Wilkins Slough for

December through February are are generally similar between Alternative 4 and No Action Alternative or moderately higher for Alternative 4. Increased flows potentially benefice White Sturgeon migration, but all flows are between 7,800 and 19,000 cfs, which are adequate for migration. There are no appreciable temperature differences from December through February for Knights Landing. Alternative 4 would have no flow or water temperature effects on White Sturgeon adults.

The CalSim II flow results for Wilkins Slough and the HEC-5Q water temperature results for Knight Landing indicate that Alternative 4 would have no adverse effect on White Sturgeon relative to the No Action Alternative.

O.3.9.2.8 Sacramento Splittail

Sacramento splittail occur in the Sacramento River upstream of the Delta from about December through May. The adults spawn in river-margin and inundated floodplain habitats in February through April (Feyrer et al. 2005, 2006; Sommer et al. 2007; Moyle et al. 2015). The larvae hatch several days after spawning then rear for about a month in habitat similar to the spawning habitat (Moyle et al. 2004). The juveniles rear upstream and then begin their downstream migration during April and May, as the river level recedes back to the channel (Moyle et al. 2004; Feyrer et al. 2005). Floodplain spawning in wet years overwhelmingly dominates production, but spawning in side channels and channel margins is important during low-flow years when floodplains are not inundated. In the Sacramento River drainage, splittail spawn from Colusa to Knights Landing, but the most important spawning areas are the inundated floodplains of the Yolo and Sutter bypasses (Feyrer et al. 2005).

High flows benefit adults migrating upstream (Feyrer et al. 2006), and greatly enhance spawning and rearing habitat for larvae and early juveniles (Crain et al. 2004). Mean monthly flows at Wilkins Slough during January through March of wet and above normal water years consistently equal or exceed 17,000 cfs under both alternatives (Table O.3-68). Figure O.3-44 shows the expected mean February flows for each year of the CalSim II record. About 15% of the years have mean February flows greater than 22,500 cfs, which is the approximate flow at which the Tisdale Weir begins to spill into the Sutter Bypass (DWR 2010b). In any case, differences between Alternative 4 and the No Action Alternative in flows at Wilkins Slough during December through May are relatively minor and generally result from higher flow under the Alternative 4, especially in April during wet, above normal and below normal water years and January and March of below normal years (Table O.3-67). It is concluded that Alternative 4 would have no flow effects on Sacramento Splittail relative to the No Action Alternative.

Preferred water temperature for Sacramento splittail ranges from about 66°F for adults to about 75°F for juveniles, and the “upper limit of safe temperatures” ranges from about 75°F for adults and 81°F for juveniles (Young and Cech 1996). Mean monthly water temperatures during December through May at Knights Landing, which is at the approximate downstream limit of splittail spawning in the Sacramento River, exceed 68°F under both alternatives in May of critically dry water years (Table O.3-65). There are no meaningful water temperature differences between the alternatives at Knights Landing during the December through May period that Sacramento Splittail occupy the river upstream of the Delta (Table O.3-65). There is evidence that some juvenile splittail remain in the Sacramento River well upstream of the Delta through the entire year (Feyrer et al. 2005), but summer water temperatures in the more upstream locations where they have been found are considerably cooler than those at Knights Landing (compare Tables O.3-64 and O.3-65). Therefore, Alternative 4 is considered to have no water temperature effects on splittail relative to the No Action Alternative.

The CalSim II flow results for Wilkins Slough and the HEC-5Q water temperature results for Knight Landing indicate that Alternative 4 would not have an adverse impact on Sacramento Splittail relative to the No Action Alternative.

O.3.9.2.9 Pacific Lamprey

Sacramento River Pacific Lamprey adults enter the Sacramento River from the Delta primarily during about March through June and hold in the river for about a year prior to spawning (Moyle et al. 2015). Spawning occurs in gravel redds in the upper river from March through July. The eggs and pro-larvae incubate for about 1 to 1.5 months. After the larvae (ammocoetes) emerge, they drift downstream and burrow into fine sediments primarily in off-channels habitats, where they rear (Schultz et al. 2014; Moyle et al. 2015). After 5 or more years, the ammocoetes metamorphose to the macropthalmia (juvenile) stage and migrate downstream to the Delta and ocean, typically migrating from March through June during pulse flow events (Moyle et al. 2015).

River flow potentially affects survival of Pacific Lamprey eggs and larvae, and migratory habitat of the juveniles and adults. Pacific lamprey build their spawning redds in shallow water (about 0.5 to 3.5 feet) (Gunckel et al. 2009; Schultz et al. 2014; Moyle et al. 2015), so reductions in water level can dewater the redds. The larvae select habitats, often off-channel, with fine sediments, low flow velocity, and shallow depths (~1 ft), so they are vulnerable to stranding by reductions in water level. Migrations of the juveniles and adults may be triggered by surges in flow (Moyle et al. 2015).

The types of variations in flow that potentially affect Pacific Lamprey, as described above, often occur on a time scale of hours or days, and therefore may not be detectable using the CalSim II monthly time-step modeling results. However, the CalSim II results mostly show no large differences in Sacramento River flow between the No Action Alternative and Alternative 4, so there is no reason to expect much difference in short period flow fluctuations between the alternatives. The biggest differences in monthly mean flows occur in September and November of wet and above normal water years, when flows are much lower under Alternative 4 than the No Action Alternative because Alternative 4 operations do not include releases for Fall X2 flows (Table O.3-66; Figures O.3-25 and O.3-28). Pacific lamprey are generally done spawning by late July and the prelarvae have finished emerging from their redds by early September. In contrast, the larvae are present in the river yearround and so could be vulnerable to flow reductions during September and November. However, water levels during these months are generally relatively stable because they are largely determined by Shasta and Keswick dam releases rather than runoff. The adults and juveniles carry out their migrations primarily during March through June. CalSim II modeling flow results for these months are generally higher under Alternative 4 than under the No Action Alternative (Table O.3-67 and O.3-68). Therefore, Alternative 4 and the No Action Alternative are expected to similarly affect Pacific Lamprey with respect to flow in the Sacramento River.

As described for Alternative 1, laboratory studies conducted on Columbia River Pacific Lamprey indicated that survival of incubating eggs and pre-larvae and of young larvae was greatest at a water temperature of 64°F and lowest at the highest water temperature included in the study, 72°F (Meeuwig et al. 2005). HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River between Keswick and RDBB during the March through August spawning and egg/prelarvae incubation period would be consistently below 64°F, with minor differences between the alternatives (Tables O.3-60 through O.3-63). During September, when Pacific Lamprey larvae would be present in the river, mean water temperatures would exceed the 64°F optimal temperature at RBDD in critically dry water years under the No Action Alternative. September has the highest water temperatures of the year upstream of RBDD. Mean September water temperatures at RBDD for individual years exceed 64°F in about 7% of years for the No Action Alternative and about 5% of years for Alternative 4, but both alternatives are below 72°F for all years (Figure O.3-22). The downstream distribution of Pacific Lamprey larvae is uncertain, but if the larvae drift well downstream of RBDD or enter the Sacramento River from downstream tributaries, they would be subject to higher water temperatures, especially during July and August. However, there is little difference between July and August water temperatures at the downstream temperature modeling sites (Table O.3-64 and O.3-65; Figure O.3-45). There are no biologically meaningful differences in water temperature conditions for Pacific Lamprey between the No Action Alternative and Alternative 4.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 4 would have a less-than-significant impact on Pacific Lamprey relative to the No Action Alternative.

O.3.9.2.10 River Lamprey

River Lamprey adults migrate from the ocean to spawning areas during the fall and late winter (Beamish 1980). Spawning is believed to occur from February through May in small tributary streams (Moyle 2002). The redds are built at the upstream end of small riffles (Moyle 2002). After the larvae (ammocoetes) emerge, they drift downstream and burrow into sediments in pools or side channels where they rear. After several years, the larvae metamorphose in late July and the juvenile (macrothalmia) migrate downstream in the following year from May to July (Moyle 2002).

River flow potentially affects survival of River Lamprey eggs and larvae, and migratory habitat of the juveniles and adults. River lamprey build their spawning redds in shallow water (Moyle et al. 2015), so reductions in water level can dewater the redds. Assuming River Lamprey larvae habitat requirements are similar to those of Pacific Lamprey, the larvae select habitats, often off-channel, with low flow velocity and shallow depths, so they are vulnerable to stranding by reductions in water level.

The types of variations in flow likely to cause redd dewatering and stranding of larvae often occur on a time scale of hours or days and, therefore, may not be detectable using the CalSim II monthly time-step modeling results. However, the CalSim II results mostly show little difference in Sacramento River flow between the No Action Alternative and Alternative 4, so there is no reason to expect much difference in short period flow fluctuations between the alternatives. The biggest differences in monthly mean flows occur in September and November of wet and above normal water years, when flows are lower under Alternative 4 than the No Action Alternative because Alternative 4 operations do not include releases for Fall X2 flows (Table O.3-66; Figures O.3-25 and O.3-28). River lamprey are generally done spawning by May and, assuming their incubation times are similar to those of Pacific Lamprey, the prelarvae complete their emergence from redds by June or July. In contrast, the larvae are present in the river yearround and so could be vulnerable to flow reductions during September and November. However, water levels during these months are generally relatively stable because they are largely determined by Shasta and Keswick dam releases rather than runoff.

The juveniles carry out their migrations during May through July. CalSim II modeling flow results for Hamilton City and Wilkins Slough show similar to slightly lower flows during May under Alternative 4, moderately higher flows during June of drier water year types, and moderately higher flow in July of Above Normal water years but moderately lower flow in July of critically dry years (Table O.3-67 and O.3-68). The adults migrate upstream primarily in the fall and winter and could be adversely affected by the reductions in flow under Alternative 4 relative to the No Action Alternative during September and November (Tables O.3-67 and O.3-68), but little is known about flow needs of migrating adult River Lamprey. Overall, Alternative 4 and the No Action Alternative are expected to similarly affect River Lamprey with respect to flow in the Sacramento River.

The water temperature requirements of River Lamprey have not been studied, but they are assumed to be similar to those of Columbia River Pacific Lamprey with 64°F for maximum survival of eggs and prelavae and 72°F and above for minimum survival (Meeuwig et al. 2005). HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River between Keswick and RDBB during the February through May spawning and egg/prelarvae incubation period would be consistently below 64°F, with minor differences between the alternatives (Tables O.3-60 through O.3-63). It should be noted that River Lamprey are believed to spawn in tributary streams rather than the mainstem, but this is uncertain (Moyle et al. 2015). During September, when River Lamprey larvae would be present in the river, mean water temperatures would exceed the 64°F optimal temperature at RBDD in critically dry water years under the No Action Alternative. September has the highest water temperatures of the year upstream of RBDD. Mean September water temperatures at RBDD for individual years exceed 64°F in about 7% of years for the No Action Alternative and about 5% of years for Alternative 4, but both alternatives are below 72°F for all years (Figure O.3-22). The downstream distribution of River Lamprey larvae is uncertain, but if the larvae drift well downstream of RBDD or enter the Sacramento River from downstream tributaries, they would subject to higher water temperatures, especially during July and August. However, there is little difference between July and August water temperatures at the downstream temperature modeling sites (Table O.3-64 and O.3-65; Figure O.3-45). There are no biologically meaningful differences in water temperature conditions for River Lamprey between the No Action Alternative and Alternative 4.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 4 would have a less-than-signficant impact on River Lamprey relative to the No Action Alternative.

O.3.9.2.11 Hardhead

Hardhead are believed to spawn in riffles, runs, and heads of pools, primarily during April and May (Moyle et al. 2015). Most spawning probably occurs in tributaries rather than in the Sacramento River mainstem (Moyle et al. 2015). Larvae and juveniles likely inhabit stream margins with abundant cover, and move into deeper habitats as they grow larger. Adults occupy the deepest part of pools. Juvenile and adult Hardhead are present in the Sacramento River year-round. They tend to prefer water temperatures near 67°F (Thompson et al. 2012), but have been captured at RBDD, where water temperatures are generally much cooler (USFWS 2002) (Table O.3-9).

Spawning success of Hardhead in the lower Tuolumne River is highest when there are higher flows during in April and May (Brown and Ford 2002), which is likely true for the Sacramento River Hardhead as well. The CalSim II results for Keswick, Red Bluff, Hamilton and Wilkiuns Slough indicate that monthly mean flow would be moderately higher under Alternative 4 than under the No Action Alternative during the April of all but critically dry water years (Tables O.3-59, O.3-66 through O.3-68). During most of the other months, flows would generally be similar between Alternative 4 and the No Action Alternative, but from Keswick Dam to Wilkins Slough they would be up to 20% lower under Alternative 4 in July during critically dry water years and 26 to 46% lower in September and November of wet and above normal water years. The large flow reductions in all three months would likely have little effect on Hardhead because they are predicted for months and water year types when flows are generally moderate to high, and because by September and November, hardhead hatched in the spring would be well developed and have gravitated to deeper water. On balance, the flow effects of Alternative 4 are not expected to substantially affect Hardhead.

Hardhead juveniles and adults performed well in laboratory tests at water temperatures from about 61 to 70°F (Thompson et al. 2012). They consistently preferred a mean water temperature of 67°F and avoided temperatures above about 79°F. HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River would be below 79°F at all locations under both alternatives (Tables O.3-60 through O.3-65). There would be only minor differences in mean water temperatures between the alternatives, except for large increases under Alternative 4 during September of wet and above normal water years. However, these Alternative 4 mean water temperatures would be only slightly warmer than the Hardhead preferred temperature, and only at Knights Landing (Table O.3-64). There are no biologically meaningful differences in water temperature conditions for Hardhead between the No Action Alternative and Alternative 4.

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 4 would have no impact on Hardhead relative to the No Action Alternative.

O.3.9.2.12 Central California Roach

As discussed for Alternatives 1 through 3, due to the adaptability of California Roach to different habitat types and its water temperature tolerances, Alternative 4 is expected to have no impact on Central California Roach relative to the No Action Alternative.

O.3.9.2.13 Striped Bass

Striped Bass spawn in the Sacramento River primarily between about Verona (RM 78) and Wilkins Slough (RM 121) during April through June (Moyle 2002). No spawning occurs until water temperature reaches 57°F (Moyle 2002). The eggs are free-floating and negatively buoyant and hatch in about two days after spawning (at 66°F) as they drift downstream. Low flows can result in eggs settling on the bottom, which they cannot survive for long. The larvae may inhabit shallow, open water of the lower river from April to mid-June and then are carried by flows to the Delta and Suisun Bay (Stevens 1966; Moyle 2002). Adult striped bass are found in the upper Sacramento River at RBDD and upstream, primarily from late spring through early fall, where they forage heavily on juvenile salmon and other fish (Tucker et al. 1998).

High flows in April through June benefit striped bass eggs because they help prevent them from settling to the river bottom. High flows likely also accelerate transport of Striped Bass larvae to their nursery habitats in the Delta and Suisun Bay (Moyle 2002). CalSim II flow results for Wilkins Slough indicate that mean monthly flow during April and June under Alternative 4 would be similar to or higher than flow under the No Action Alternative, but would be generally similar during May (Table O.3-68). The greatest reductions in flow resulting from Alternative 4 would occur in September and November of wet and above normal water years. Adult Striped Bass may reside throughout the Sacramento River in September (Tucker et al. 1998). However, although the Alternative 4 mean monthly flows are reduced from the No Action Alternative flows in wet and above normal years, they remain close to or well above 5,000 cfs (Table O.3-66 through O.3-68), which is likely adequate for foraging Striped Bass.

Optimal spawning temperature range for Striped Bass is 59 to 68°F and spawning ceases at about 70°F (Moyle 2002). The eggs can withstand temperatures of about 54 to 75°F, with the optimum being about 64°F (Emmett et al. 1991). Larvae tolerate temperatures of 50 to 77°F, but optimal temperatures for survival are 59 to 72°F (Emmett et al. 1991). The adults appear to prefer water temperatures ranging from about 68 to 75°F (Emmett et al., 1991) and juveniles prefer rearing temperatures of 61 to 66°F (Hasler 1988). Adults are under stress at temperatures over 77°F, and temperatures over 86°F are lethal (Moyle 2002).

HEC-5Q modeling results indicate that mean monthly water temperatures in the Sacramento River at Knights Landing during the April through June spawning period would be within the optimal range for spawning in April of all but wet years and in May of all but critically dry years, but would be above the optimal range in June during all water year types (Table O.3-65). The mean monthly temperatures would be below the optimal range for adults during April and May of all water year types except critically dry years in May, but would be within this range in all water year types in June. The temperatures would be acceptable for eggs and optimal for larvae throughout the spawning period (Table O.3-65). Juvenile striped bass generally do not occur in the Sacramento River upstream of the Delta. The adults, as noted earlier, may forage in the river upstream to and above RBDD from about May through early October. Mean monthly water temperatures at RBDD throughout this period would be well below the optimal range for adults (Table O.3-63).

The largest difference in monthly mean water temperatures between the No Action Alternative and Alternative 4 at Knights Landing during the Striped Bass spawning season is a moderate reduction in June of dry water years (Table O.3-65). This reduction would move the mean water temperatures under Alternative 4 closer to the optimal range for spawning, providing a minor benefit. The largest temperature differences at any time of year are substantial increases under Alternative 4 for September of wet and above normal water years. These increases would be potentially beneficial for foraging Striped Bass adults because the No Action Alternative water temperatures for these months and water year types would be well below the optimal range for adults throughout the river (Tables O.3-63 through O.3-65).

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 4, with regard to flow and water temperature, would have a less-than-significant impact on Striped Bass relative to the No Action Alternative.

O.3.9.2.14 American Shad

American shad migrate upstream in the Sacramento River starting in March, and typically spawn from April to June. Water temperature influences the timing of runs, with peak runs and spawning usually occurring at water temperatures of 62 to 75°F (Moyle 2002). Shad eggs drift downstream from spawning areas and hatch in 3 to 12 days, depending on water temperature (MacKenzie et al. 1985). Larval shad are planktonic for about 4 weeks, after which they metamorphose to actively swimming juveniles. Juveniles spend the next several months in freshwater, and seem to prefer temperatures of 63 to 77°F. In the Sacramento River, summer rearing habitat occurs in the main river from Colusa to the north Delta (Stevens et al. 1987). As the season progresses, juvenile shad move downstream and enter salt water primarily during September through November (Moyle 2002). In general, variations in river discharge and temperature during early larval development are considered important regulators of year-class strength and recruitment of American shad (Hinrichsen et al. 2013). Although the importance of various potential mechanisms is unknown, the abundance of juvenile American shad in the Sacramento-San Joaquin Delta has been shown to be positively correlated with freshwater inflow during the April through June spawning and nursery periods (Stevens et al. 1987, Kimmerer 2002, Kimmerer et al. 2009).

During the spawning and larval rearing period (April through June), CalSim II modeling results at Wilkins Slough indicates that average monthly flows in April and June under Alternative 4 would be higher than those under the No Action Alternative, which may have a minor positive effect on spawning and early rearing success of American shad (Table O.3-52). Flows would be largely similar in May HEC-5Q modeling results indicate that there are few meaningful differences in mean monthly temperatures in the lower Sacramento River (Knights Landing) during May through June (Table O.3-49 in this appendix and the ROC LTO BA). The largest differences in flows and water temperatures in the Sacramento River between Alternative 4 and the No Action Alternative would occur in September and November of wet and above normal water years (Table O.3-65 and O.3-68). However, the importance of river inflows and river temperatures for juvenile shad in September and November is unknown. Correlations between Delta inflows and abundance of juvenile shad have been demonstrated for the months of April through August, with the highest correlations in April through June, suggesting that the principal factors influencing abundance occur during periods of larval dispersal and transport. Alternative 4 is considered to have a less-than-significant effect on American Shad.

O.3.9.2.15 Largemouth Bass

The Sacramento River above the Delta generally provides poor habitat conditions for Largemouth Bass because of large seasonal flow fluctuations, relatively cold water, and lack of suitable nesting and rearing habitat. Consequently, Largemouth Bass populations in the Sacramento River above the Delta are largely dependent on upstream sources, including reservoirs, floodplain ponds and sloughs, and irrigation canals that provide suitable conditions for spawning and rearing during the late spring and summer months.

Largemouth bass spawning activity typically starts in April when water temperatures reach 59 to 61°F, and continues through June (Moyle 2002). Nests are typically constructed at a depth of about 3 feet (Brown et al. 2009a). Optimal temperatures for successful spawning and incubation are 68 to 70°F, although spawning is generally observed over a range of 55 to 79°F (Stuber et al. 1982). Eggs hatch in 2 to 7 days after spawning and the sac fry usually spend 5 to 8 days in the nest until they begin actively feeding (Moyle 2002). Optimal temperatures for growth of juvenile and adult bass range from 77 to 86°F, although growth will occur over a much wider range (50 to 95°F) (Moyle 2002).

The CALSIM II and HEC-5Q modeling results for Alternative 4 indicate that Sacramento River mean flows are higher and water temperatures are slightly lower in June relative to the No Action Alternative, potentially affecting largemouth bass spawning and incubation, while differences in May are too small to be meaningful (Tables O.3-65 and O.3-68). However, based on modeled mean monthly water temperatures in the lower Sacramento River at Knights Landing, no substantial changes would be expected to occur in the frequency of suitable water temperatures for spawning and incubation (Figures O.3-41 and O.3-91). The relatively large changes in flows and water temperatures in September and November of wet and above normal years under Alternative 4 (Tables O.3-65 and O.3-68) could affect habitat conditions for juvenile and adult bass, but water temperatures would remain below optimum levels for growth under both alternatives. Consequently, the generally poor habitat conditions for largemouth bass in the Sacramento River under the No Action Alternative would persist under Alternative 4. Therefore, changes in Sacramento River flows and water temperatures associated with Alternative 4 would have a less-than-significant effect on largemouth bass in the Sacramento River relative to the No Action Alternative.

O.3.9.2.16 Smallmouth Bass

The optimal temperature range for Smallmouth Bass spawning is 55 to 70°F (Brown et al. 2009b) and the optimal for adult growth is approximately 77 to 80°F, but rapid growth of has been seen in the wild at temperatures as high as 84°F, providing prey is abundant (Moyle 2002). Populations are rarely established in water temperatures that do not exceed 66°F in summer for extended periods, and most smallmouth populations in California are present where summer temperatures are typically 69°F to 71°F. In northern California reservoirs most spawning takes place in May and June, but spawning in streams may occur into July, depending on flows and temperatures. Males start making nest depressions when water temperatures reach 55°F to 61°F. The nests are typically built at depths of about 3 to 8 feet (Brown et al. 2009). In streams, nesting and reproduction can be disrupted by flow reductions that lead to nest dewatering or elevated flows that wash embryos and fry out of nests or lower water temperatures excessively (Graham and Orth 1986; Lukas and Orth 1995).

CalSim II results for Wilkins Slough flow for Alternative 4 compared to No Action Alternative during the May through July spawning season indicate moderately increased flow during June of the drier water year types and slightly reduced flow in July, except for moderately increased flow in above normal years and moderately reduced flow in critically dry water years (Table O.3-68). Higher flows could adversely affect embryos and fry by dewatering nests or washing them out of the nests, but it is unknown what magnitude of flows would have these effects.

HEC-5Q monthly mean water temperatures at Hamilton City consistently fall within the 55°F to 70°F optimal spawning range during the spawning season of May through July under both Alternative 3 and the No Action Alternative (Table O.3-64). At Knights Landing, however, the temperatures fall within the optimal range during May of all water year types, but lie above the range during June and July of most water year types (Table O.3-65). The mean water temperatures under Alternative 4 are generally similar to those under the No Action Alternative, except for moderately lower flow in June of dry years. The monthly mean summer water temperatures at Hamilton City consistently fall below the 66°F threshold that has been found to be a minimum for Smallmouth Bass to establish populations in California (Moyle 2002), except for critically dry water years in August and September (Table O.3-64). At Knights Landing, however, the 66°F threshold is exceeded in all summer months and water year types except September of wet and above normal years under the No Action Alternative (Table O.3-65). Note that the large wet-and-above-normal-year September water temperature increases under Alternative 4 result in water temperatures exceeding the threshold, which may benefit Smallmouth Bass. The mean water temperatures are consistently well below the optimal range for adult growth, 77°F to 80°F, at both locations.

The CalSim II flow and HEC-5Q water temperature results indicate that Alternative 3 would have a less-than-significant impact on Smallmouth Bass relative to the No Action Alternative with regard to flow and water temperature.

O.3.9.2.17 <u>Spotted Bass</u>

Spotted Bass inhabit streams and reservoirs and prefer moderate-size, clear, low-gradient sections of rivers and reservoirs (McKechnie 1966). They prefer pool habitat and slower, more turbid water than Smallmouth Bass, but faster water than Largemouth Bass (Moyle 2002). Their summer water temperature preference is 75°F to 87°F (Moyle 2002). In streams, nests are constructed in low-current areas on bottoms ranging from debris to gravel (Moyle 2002). Spawning depths are deeper than those of largemouth bass (Aasen and Henry 1981). They spawn in the spring when water temperatures rise to 59°F to 64°F (Aasen and Henry 1981; Howland 1931). Spawning continues through late May and early June, until temperatures reach 71°F to 73°F.

During the spring (April through June) spawning season, CalSim II results for Wilkins Slough monthly mean flows under Alternative 4 are mostly higher than the No Action Alternative flows in April and June, but little different in May (Table O.3-68). Higher flows could adversely affect embryos and fry by dewatering nests or washing them out of the nests, but it is unknown what magnitude of flows would have these effects.

HEC-5Q monthly mean water temperatures at Knights Landing during the spawning season of April through June would largely be within the 59°F to 64°F spawning range in April under Alternative 4 and the No Action Alternative, but would exceed the range in May and June under both alternatives. The preferred summer water temperatures range of 75°F to 87°F would be available only in critically dry water years, especially in August, under both Alternative 4 and the No Action Alternative (Table O.3-65).

The CalSim II flow results and the HEC-5Q water temperature results indicate that Alternative 4, with regard to flow and water temperature, would have a less-than-significant impact on Spotted Bass relative to the No Action Alternative.

Potential changes to aquatic resources in the Sacramento River from Shasta cold water pool management

Shasta Cold Water Pool Management will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to the effects of this action. However, Alternative 4 and the No Action Alternative have very different management guidelines, which results in differences in their effects on flow and water temperature and, ultimately, on the focal fish species. Operations of all the alternatives are regulated by SWRCB's D-1641 decision, which requires flow releases to meet Delta standards, and their WRO 90-5 decision, which requires cold water releases to meet temperature targets at compliance points in the upper Sacramento River. However, the No Action Alternative also includes NMFS's 2009 BO RPAs to operate Shasta Reservoir for management of cold water in the river for protection of salmon and steelhead, and includes requirements for Fall X2 flow releases, but Alternative 4 includes neither requirement. And Alternative 4 includes new operations criteria not included in the No Action Alternative. These criteria would manage Shasta Reservoir to increase instream flow releases with a target of 55% of unimpaired flows in the Sacramento River above Red Bluff and at the Feather River confluence. However, balancing instream flow releases with storage needed to maintain the coldwater pool for fish would continue to be critical to operations. Other rivers in the basin with major reservoirs would have similar flow targets. The effects of the differences in operations between Alternative 4 and the No Action Alternative on water temperatures and flows in the Sacramento River and the potential effects of resulting water temperature and flow differences on the focal fish species in the river are discussed above in the assessments for the individual fish species in the *Potential changes to aquatic resources in the Sacramento River from seasonal operations* section for the Sacramento River under Alternative 4.

Potential changes to aquatic resources in the Sacramento River from spring pulse flows

Spring Pulse Flows for fish will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

Potential changes to aquatic resources in the Sacramento River from fall and winter refill and redd maintenance

Fall and winter refill and redd maintenance will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

Potential changes to aquatic resources in the Sacramento River from rice decomposition smoothing

Rice decomposition smoothing will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

Potential changes to aquatic resources in the Sacramento River from spring management of spawning locations

Rice decomposition smoothing will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this action.

O.3.9.3 *Clear Creek*

O.3.9.3.1 Whiskeytown Reservoir Operations

Alternative 4 would incorporate the same assumptions of Alternative 1 but would also include flow objectives based on unimpaired instream flow.

Under current operations and the No Action Alternative, Whiskeytown Lake is annually drawn down 13 feet (approximately 35 TAF) between November and April for flood control purposes, although it can be lowered as much as 30 feet as needed for maintenance. Model output for Whiskeytown Lake predicts that compared to the No Action Alternative, minimum reservoir volumes would be lower under Alternative 4 during the months of May and July (2.0 TAF and 59.8 TAF lower, respectively), although this is only anticipated to occur in approximately 2% to 3% of years (Figure O.3-140, Table O.3-69). During those two months, water surface elevations would also be lower under Alternative 4 compared to the No Action Alternative. In April, water surface elevations would be 2.8 TAF higher under Alternative 4 compared to the No Action Alternative. In all other months, Whiskeytown Lake storage volumes under Alternative 4 would be either identical to, or 0.1 TAF higher that those predicted under the No Action Alternative.

Whiskeytown Storage / monthly statistics (5-2-16-1b):

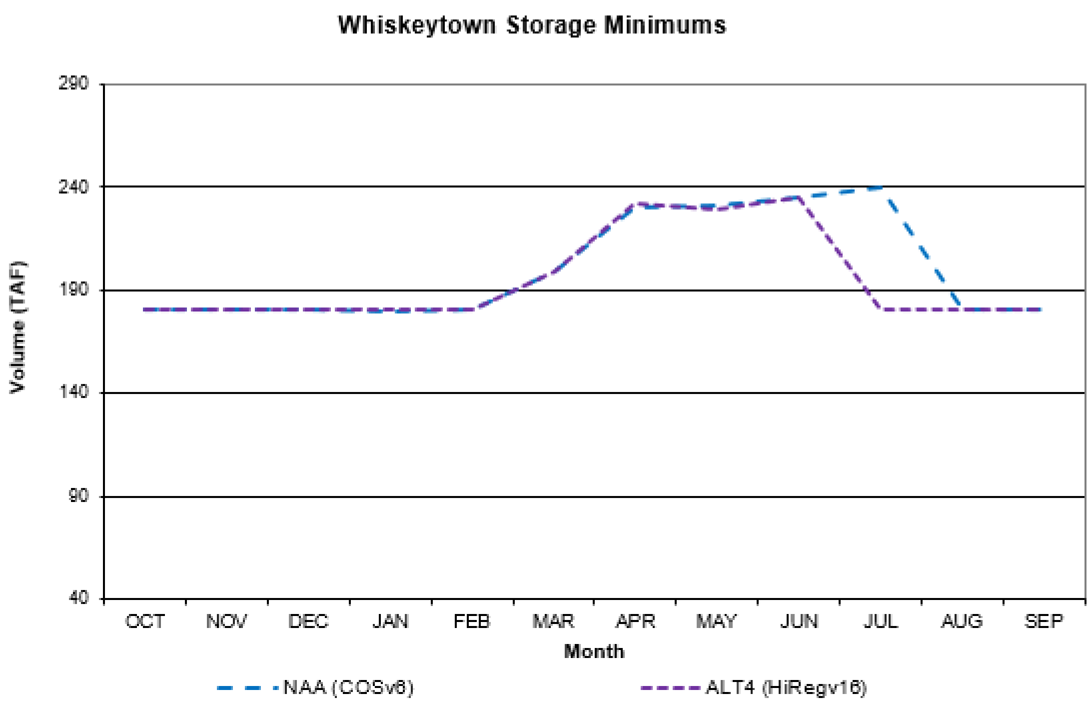

Figure O.3-140. Modeled Whiskeytown Lake Monthly Minimum Storage Volume under the No Action Alternative and Alternative 4 during all Water Year Types

Table O.3-69. Modeled Differences in Whiskeytown Lake Monthly Minimum Storage Volumes from March to July under Alternative 4 Relative to the No Action Alternative

Month	Change in Volume from No Action Alternative (TAF)
October	0.0
November	0.1
December	0.1
January	0.1
February	0.0
March	0.1
April	2.8
May	-2.0
June	0.1
July	-59.8
August	0.0
September	0.0

The seasonal draw-down in July under Alternative 4 could cause an increase in bank and bed erosion in newly exposed areas of tributary stream mouths where they are devoid of stabilizing riparian vegetation. This scour could cause channel incision (i.e., down-cutting) and result in increased lake water turbidity. Channel incision can create erosional nick points that propagate upstream until they encounter scour-resistant grade-controlling materials such as bedrock, at which point a cascade can form. A draw-down of this magnitude would also occur under the No Action Alternative, but approximately one month later. The earlier draw-down therefore represents a change in timing and duration of lower water surface elevation but not a new type or mechanism of disturbance, and channel incision may have already occurred and stabilized as a result of past operations.

Potential changes to aquatic resources in Clear Creek from seasonal variation in water surface elevation

Hardhead

Hardhead migrate from the reservoir into tributaries in April and May to spawn upstream of Whiskeytown Lake. The timing of proposed increased draw-downs in May and July under Alternative 4 could affect Hardhead if the lower water surface elevations in May expose any previously submerged cascades at tributary mouths or create new ones. No such cascades have been documented, but if they are present or created by tributary incision at low water, they could present barriers to migration that would prevent reservoir-dwelling adult Hardhead from spawning in tributary streams. Alternately, higher water surface elevation in April may benefit migrating Hardhead at the start of their upstream migration season. The larger June-August drawdown (Figure 4) would occur after upstream migration has concluded and would therefore not be expected to affect Hardhead access to tributary spawning areas.

Hardhead are not a cold-water species, so drawing additional cold water from the bottom layers of the reservoir would not be expected to affect them directly. Hardhead have shown sensitivity to high sediment loads (Gard 2002), so increased reservoir turbidity due to varial zone erosion during draw-down periods could reduce suitability of reservoir and downstream waters for Hardhead persistence.

Annual variations in reservoir water surface elevation under Alternative 4 could cause Hardhead to be affected by reducing habitat connectivity and increasing water turbidity. However, changes to storage volume and seasonal timing of water surface elevation in Whiskeytown Lake are likely to be negligible due to low frequency of occurrence under Alternative 4 compared to the No Action Alternative, and higher water surface elevation in April could benefit migrating Hardhead at the start of their upstream migration season.

Other Fish Species

Central California Roach are not likely to be affected by changes in reservoir operations because, although they are found in upstream tributaries, they do not reside in Whiskeytown Lake, having likely been extirpated from the reach after the reservoir was originally filled in 1963. Future operations of Whiskeytown Dam under Alternative 4 are therefore unlikely to affect either individuals or populations.

Annual variations in reservoir water surface elevation under Alternative 4 compared to the No Action Alternative could cause varying effects to stocked and introduced nonnative game species in Whiskeytown Lake. Stocked species would not be expected to be affected by changes in reservoir operations. Rainbow Trout, Brown Trout, Kokanee Salmon, and Brook Trout typically spawn in tributary streams, but they are capable of spawning in lakes if they are unable to access moving water. Whiskeytown Lake Kokanee spawn in the fall, a period when no differences in water levels are expected under Alternative 4 compared to the No Action Alternative. Pond species such as Largemouth Bass, Smallmouth Bass, Spotted Bass, Bluegill, Black Crappie, Channel Catfish, and Brown Bullhead are able to tolerate a wide range of conditions, but the basses and panfish spawn in relatively shallow lake areas when water warms to at least 50°F in late spring or summer. Reducing reservoir volume in May and July could put some of their nests at risk of being dewatered in years when springtime and early summer conditions are warm. However, these species have rapid reproductive rates which can enable them to recover from episodic recruitment failures which could occur with very low frequency (2% to 3% of years).

O.3.9.3.2 Clear Creek Flows

Under Alternative 4 Reclamation proposes to operate flows in Clear Creek based on downstream water rights, the 1963 Reclamation proposal to USFWS and NPS, and predetermined CVPIA 3406(b)(2) flows, as done under the No Action Alternative. Under Alternative 4, however, the minimum instream flow requirements are based on 55% of unimpaired flow rather than a requirement of 50 cfs to 100 cfs as under the No Action Alternative. Channel maintenance and pulse flows would also be based on the unimpaired inflow, whereas under the No Action Alternative channel maintenance flows would occur in congruence with flood operations, and two pulse flows would be released in May and June of at least 600 cfs for at least 3 days per pulse per year.

Modeling results indicate that Clear Creek average flow below Whiskeytown Dam under Alternative 4 would generally exceed flow under the No Action Alternative from late fall through spring in all water year types (Figure O.3-141). On average, the peak difference in flow between Alternative 4 and No Action Alternative scenarios occurs in February, with Alternative 4 flow surpassing 600 cfs and No Action Alternative flow at approximately 200 cfs (Figure O.3-141).

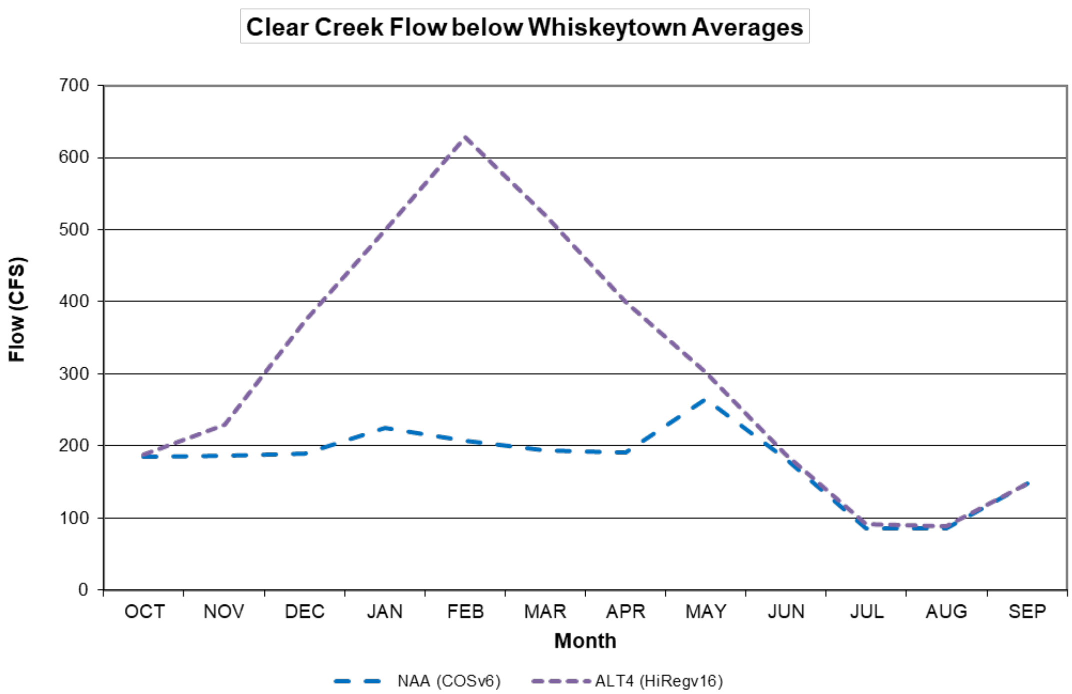

Figure O.3-141. CalSim II Estimates of Average Flow below Whiskeytown under the No Action Alternative and Alternative 4.

Potential changes to aquatic resources in Clear Creek from variation in flow

Spring-Run Chinook Salmon

Under Alternative 4, Clear Creek flow would increase compared to flow under the No Action Alternative from October through May of all water years, with the peak difference occurring in February (Figure O.3-141); flow is otherwise similar from June through September. These changes in flow would coincide with the seasonal occurrence of various life stages of Spring-Run Chinook Salmon in Clear Creek, including migrating adults (March to June), eggs and fry (September to October), and rearing and outmigrating juveniles (November to May). Increased flow would benefit adults by increasing attraction flow, pool connectivity, and available habitat; juveniles by increasing foraging habitat and shelter and increasing DO; and eggs and fry by lowering temperatures and increasing DO.

Alternative 4 also allows for greater flexibility in the timing of channel maintenance and pulse flows, so releases could be scheduled in a manner beneficial to various life stages of Spring-Run Chinook Salmon based on their seasonal occurrence in Clear Creek. Relative to the No Action Alternative, Alternative 4 would potentially benefit Spring-Run Chinook Salmon in Clear Creek.

Fall-Run Chinook Salmon

Under Alternative 4, Clear Creek flow would increase compared to flow under the No Action Alternative from October through May of all water years, with the peak difference occurring in February (Figure O.3-141); flow is otherwise similar from June through September. These changes in flow would coincide with the seasonal occurrence of various life stages of Fall-Run Chinook Salmon in Clear Creek including migrating adults (June to April), eggs and fry (October to April), and rearing and outmigrating juveniles (April to June). Increased flow would benefit adults and juveniles by pool connectivity and available habitat. Increased flow would also lower temperatures and increase DO, benefiting eggs, fry, and juveniles.

Alternative 4 also allows for greater flexibility in the timing of channel maintenance and pulse flows, so releases could be scheduled in a manner beneficial to various life stages of Fall-Run Chinook Salmon based on their seasonal occurrence in Clear Creek. Relative to the No Action Alternative, Alternative 4 would potentially benefit Fall-Run Chinook Salmon in Clear Creek.

Central Valley Steelhead

Under Alternative 4, Clear Creek flow would increase compared to flow under the No Action Alternative from October through May of all water years, with the peak difference occurring in February (Figure O.3-141); flow is otherwise similar from June through September. These changes in flow would coincide with the seasonal occurrence of California Central Valley DPS Steelhead holding adults (December to March), migrating adults (September to October), rearing to outmigrating juveniles (January to May), and eggs and fry (January). Increased flow would benefit adults and juveniles by increasing pool connectivity and available habitat. Increased flow would also lower temperatures and increase DO, benefiting eggs, fry, and juveniles.

Alternative 4 also allows for greater flexibility in the timing of channel maintenance and pulse flows, so releases could be scheduled in a manner beneficial to various life stages of Central Valley Steelhead based on their seasonal occurrence in Clear Creek. Relative to the No Action Alternative, Alternative 4 would potentially benefit Central Valley Steelhead in Clear Creek.

Pacific Lamprey

Under Alternative 4, Clear Creek flow would increase compared to flow under the No Action Alternative from October through May of all water years, with the peak difference occurring in February (Figure O.3-141); flow is otherwise similar from June through September. These changes in flow would coincide with the seasonal occurrence of various life stages of Pacific Lamprey in Clear Creek, including spawning adults (January to May), ammocoetes (year-round), and outmigrating adults (early winter to spring). Increased flow would benefit adults by increasing pool connectivity and available habitat. Increased flow would also lower temperatures and increase DO, benefiting ammocoetes.

Alternative 4 also allows for greater flexibility in the timing of channel maintenance and pulse flows, so releases could be scheduled in a manner beneficial to various life stages of Pacific Lamprey based on their seasonal occurrence in Clear Creek. Relative to the No Action Alternative, Alternative 4 would potentially benefit Pacific Lamprey in Clear Creek.

Potential changes to aquatic resources in Clear Creek from variation in water temperature due to flow objectives

Water temperatures under Alternative 4 would be controlled by flow objectives, rather than specific water temperature objectives as under the No Action Alternative. Under the No Action Alternative, these objectives are a daily water temperature of 60°F at the Igo gage from June 1 through September 15 and 56°F from September 15 through October 31.

Modeling results indicate that average water temperatures in Clear Creek above the Sacramento River would be nearly identical under the No Action Alternative and Alternative 4 (Figure O.3-142); however, maximum temperatures do differ between the two scenarios (Figure O.3-143). Under the No Action

Alternative, modeled maximum water temperatures exceed those under Alternative 4 in September and October by up to 7°F (Figure O.3-143).

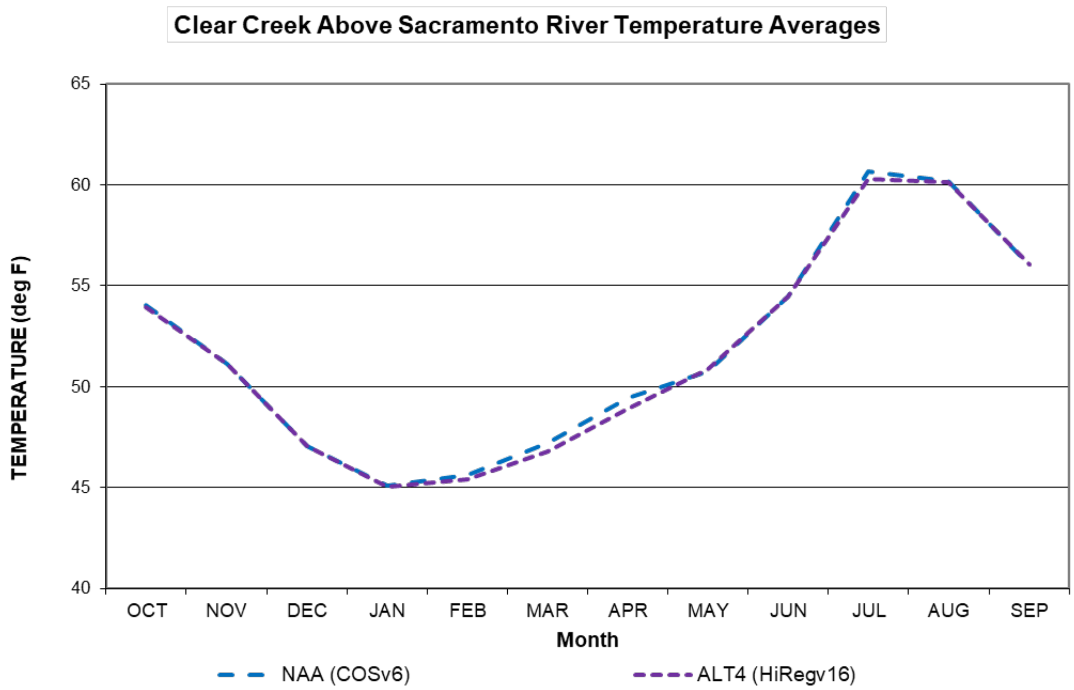

Figure O.3-142. Average Modeled Water Temperatures in Clear Creek above the Sacramento River under the No Action Alternative and Alternative 4.

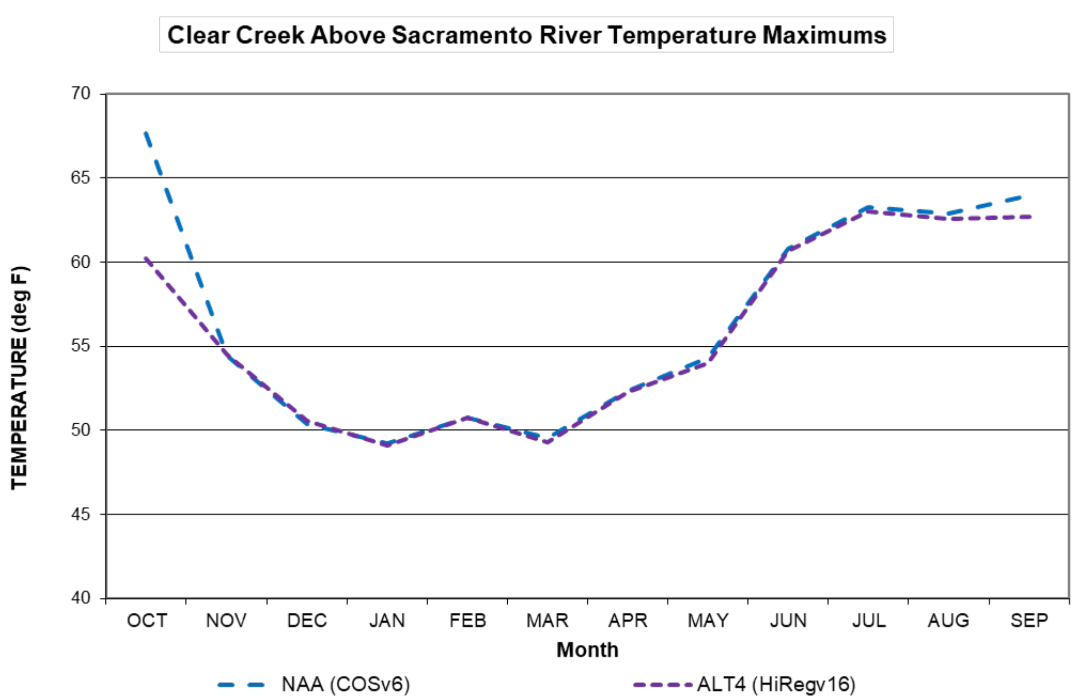

Figure O.3-143. Maximum Modeled Water Temperatures in Clear Creek above the Sacramento River under the No Action Alternative and Alternative 4.

Table O.3-70. Water Temperatures Suitable for Spring-Run and Fall-Run Chinook Salmon, and Central Valley Steelhead by Life Stage

Life Stage	Peak Occurrence	Optimal	Suboptimal	Stress-inducing
Spring-Run Chinook Salmon				
Eggs to fry	September to October	< 54°F	54°F to 58°F	> 58°F
Rearing to out-migrating	November to May	< 60°F	60°F to 65°F	> 65°F
Migrating adults	March to June	< 56°F	56°F to 65°F	> 65°F
Adult holding	May to August	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Fall-Run Chinook Salmon				
Eggs to fry	October to April	48.2°F to 55.4°F	55.4°F to 62.6°F	> 62.6°F
Rearing to out-migrating	April to June	55.4°F to 68°F	68°F to 75.2°F	> 75.2°F
Migrating adults	June to April	50°F to 68°F	68°F to 69.8°F	> 69.8°F
Central Valley Steelhead				
Eggs to fry	January	46°F to 52°F	52°F to 55°F	> 55°F
Rearing to out-migrating	January to May	< 65°F	65°F to 68°F	> 68°F
Migrating adults	September to October	< 52°F	52°F to 70°F	> 70°F
Adult holding	December to March	< 60.8°F	60.8°F to 66.2°F	> 66.2°F

Sources: NMFS 2016a; Stillwater Sciences 2006; CDFG 2012a, 2012b.

Spring-Run Chinook Salmon

Effects of water temperature on Spring-Run Chinook Salmon have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance in Clear Creek (Table O.3-70).

On average, modeled Alternative 4 and No Action Alternative water temperatures are essentially identical, so no difference in effects of water temperature on Spring-Run Chinook Salmon is generally expected. Maximum temperatures under the No Action Alternative, however, reach higher levels in September and October than they do under Alternative 4 (Figure O.3-143). Spring-Run Chinook eggs and fry are present during this period (Table O.3-70) and would be exposed to the possible adverse effects of elevated water temperature, including effects of physiologic stress such as slower growth rates and an inability to satisfy metabolic demand (Stillwater Sciences 2006; Martin et al. 2017). Maximum water temperatures under both scenarios exceed stress-inducing levels for Spring-Run Chinook eggs and fry in September and October, but maximum water temperatures under the No Action Alternative remain stress-inducing for a longer period (Figure O.3-143). Under Alternative 4, therefore, minimal difference in effects of water temperature on Spring-Run Chinook Salmon is expected, but there is potential for beneficial effects on eggs and fry when temperatures reach their maximum levels.

Fall-Run Chinook Salmon

Effects of water temperature on Fall-Run Chinook Salmon have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance in Clear Creek (Table O.3-70).

On average, modeled Alternative 4 and No Action Alternative water temperatures are essentially identical, so no difference in effects of water temperature on Fall-Run Chinook Salmon is generally expected. Maximum temperatures under the No Action Alternative, however, reach higher levels in September and October than they do under Alternative 4 (Figure O.3-143). Fall-Run Chinook eggs and fry are present during October (Table O.3-70) and would be exposed to the possible adverse effects of elevated water temperature, including effects of physiologic stress such as slower growth rates and an inability to satisfy metabolic demand (Stillwater Sciences 2006; Martin et al. 2017). Maximum water temperatures under Alternative 4 do not exceed stress-inducing levels for Fall-Run Chinook eggs and fry, but maximum water temperatures under the No Action Alternative do reach stress-inducing levels in October (Figure O.3-143). Under Alternative 4, therefore, minimal difference in effects of water temperature on Fall-Run Chinook Salmon is expected, but there is potential for beneficial effects on eggs and fry when temperatures reach their maximum levels.

Central Valley Steelhead

Effects of water temperature on Central Valley Steelhead have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance in Clear Creek (Table O.3-70).

On average, modeled Alternative 4 and No Action Alternative water temperatures are essentially identical, so no difference in effects of water temperature on Central Valley Steelhead is generally expected. Maximum temperatures under the No Action Alternative, however, reach higher levels in September and October than they do under Alternative 4 (Figure O.3-143). Migrating adult Steelhead are present during this period (Table O.3-70) and would be exposed to the possible adverse effects of elevated water temperature, including effects of physiologic stress such as an inability to satisfy metabolic demand (Stillwater Sciences 2006; Martin et al. 2017). Maximum water temperatures under both scenarios remain at suboptimal levels for migrating adult Steelhead throughout their September to October period of peak occurrence (Figure O.3-143). Under Alternative 4, therefore, minimal difference in effects of water temperature on Central Valley Steelhead is expected, but there is potential for beneficial effects on migrating adults when temperatures reach their maximum levels.

Pacific Lamprey

Pacific Lamprey temperature tolerance have been less studied than those of salmonids. Periods of life stage occurrence and associated temperatures for Pacific Lamprey are provided in Table O.3-71.

Table O.3-71. Summary Table of Water Temperatures Suitable for Pacific Lamprey by Life Stage

Life Stage	Peak Occurrence	Temperature Range
Ammocoetes	Year-round	< 82°F [1]
Spawning	January to May	50°F to 64°F, peak 57°F to 59°F
Adult out-migration	Early winter to spring	<68°F

Source: Stillwater Sciences 2014.
[1] Temperature of 82°F is lethal to ammocoetes of four North American species of lamprey; however, it is uncertain if Pacific Lampreys have similar tolerances.

On average, modeled Alternative 4 and No Action Alternative water temperatures are essentially identical, so no difference in effects of water temperature on Pacific Lamprey is generally expected. Maximum temperatures under the No Action Alternative, however, reach higher levels in September and October than they do under Alternative 4 (Figure O.3-143). Pacific Lamprey ammocoetes are present during this period (Table O.3-71) and would be exposed to the possible adverse effects of elevated water temperature, including effects of physiologic stress such as slower growth rates and an inability to satisfy metabolic demand (Stillwater Sciences 2006; Martin et al. 2017). Maximum water temperatures under both scenarios remain at suitable levels for Pacific Lamprey ammocoetes year-round (Figure O.3-143). Under Alternative 4, therefore, minimal difference in effects of water temperature on Central Valley Steelhead is expected, but there is slight potential for beneficial effects on ammocoetes when temperatures reach their maximum levels.

O.3.9.3.3 Spring Creek Debris Dam

Existing operations of the SCDD will continue under both Alternative 4 and the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources.

O.3.9.3.4 Clear Creek Restoration Program

The Clear Creek Restoration Program is being implemented under both Alternative 4 and the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources.

O.3.9.4 *Feather River*

O.3.9.4.1 FERC Project #2100-134

DWR, under Alternative 4, would operate Oroville Dam consistent with the NMFS, USFWS, and CDFW environmental requirements applicable for the current Oroville Complex FERC License (FERC Project #2100-134). Reclamation would operate Oroville Dam with minimum flows of 700 cfs to 800 cfs below the Thermalito Diversion Dam in the low flow channel (2006 Settlement Agreement), 750 cfs to 1,700 cfs below the Thermalito Afterbay outlet (1983 DWR-CDFG Agreement), and the DFG/DWR operation objective of 2,800 cfs at the mouth of the Feather River from April through September, with options to vary flow depending on year types. In addition, Alternative 4 includes a minimum instream flow requirement of a minimum of 55% of unimpaired flow and the inflow at Feather River above Yuba Conference.

Under the No Action Alternative, DWR would operate Oroville Dam in accordance with ongoing management policies, criteria, and regulations, including water right permits and licenses issued by the SWRCB and operational requirements of the 2008 USFWS BO and the 2009 NMFS BO. Under the No Action Alternative, DWR typically releases water from Lake Oroville to meet the requirements of instream flows and D-1641.

Table O.3-72. Feather River HFC Minimum Instream Flow Requirements

Preceding April to July Unimpaired Runoff (Percent of Normal)	Oct to Feb Minimum Instream Flow (cfs)	March Minimum Instream Flow (cfs)	April to Sept Minimum Instream Flow (cfs)
55% or greater	1,700	1,700	1,000
Less than 55%	1,200	1,000	1,000

Potential changes to aquatic resources in the Feather River due to seasonal variation in flow

CalSim II model output shows that Feather River flows under Alternative 4 and the No Action Alternative would comply with Feather River HFC minimum instream flow requirements during all months in wet, above normal, and below normal water years. In dry years where the preceding April to July unimpaired runoff is less than 55% of normal, Alternative 4 and the No Action Alternative would comply with minimum instream flow requirements in the HFC (Table O.3-72 and Figure O.3-144). In critically dry years where the preceding April to July runoff is less than 55% of normal, Alternative 4 would not comply with minimum instream flow requirements in the HFC in October and November (Table O.3-72 and Figure O.3-144).

Figure O.3-144. CalSim II Estimates of Feather River Long-Term Average Flow below Thermalito, All Scenarios in Wet, Above Normal, Below Normal, Dry, and Critically Dry Water Years.

Overall, simulated flows under the Alternative 4 and No Action Alternative scenarios are similar, but flows under the No Action Alternative are higher in September of wet and above normal years, and flows under Alternative 4 are higher in April and May of wet water years, from March through June of above normal water years, from January through May of below normal and dry water years, and in June of critically dry water years (Figure O.3-144).

Winter-Run Chinook Salmon

Winter-Run Chinook are not likely to be affected by changes in flow under Alternative 4 compared to the No Action Alternative due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Spring-Run Chinook Salmon would be exposed to the effects of Alternative 4 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Eggs and emerging fry of Spring-Run Chinook Salmon may occur in the Feather River from September through February (NMFS 2016a); juvenile Spring-Run Chinook Salmon occur in the Feather River year-round, with peak abundance from November through May; and adult Spring-Run Chinook Salmon peak in abundance in the Feather River from March through June. All life stages would thus be exposed to the effects of Alternative 4.

Spring-Run Chinook Salmon eggs and emerging fry would benefit from increased Alternative 4 flows, leading to increased dissolved oxygen in January and February of below normal and dry years when Alternative 4 flows are higher than No Action Alternative flows (Figure O.3-144). Juvenile Spring-Run Chinook Salmon would also benefit from increased Alternative 4 flows relative to No Action Alternative flows in April and May of wet years, March through May of above normal years, and January through May of below normal and dry years when the increased flows result in increased rearing and foraging habitat and higher dissolved oxygen content (Figure O.3-144). Adult Spring-Run Chinook Salmon would benefit from increased Alternative 4 flows relative to No Action Alternative flows in April and May of wet years, March through June of above normal years, March through May of below normal and dry years, and June of critically dry years due to the resulting increased attraction flows and holding habitat (Figure O.3-144). Because Spring-Run Chinook Salmon benefit from increased Alternative 4 flows relative to No Action Alternative flows during key months of all life stages and because Alternative 4 flows do not comply with minimum instream flow requirements only in dry and critically dry years (Table Table O.3-72, Figure O.3-144), flow-related actions under Alternative 4 would have beneficial effects on Spring-Run Chinook Salmon.

Fall-Run Chinook Salmon

Fall-Run Chinook Salmon would be exposed to the effects of Alternative 4 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Fall-Run Chinook Salmon occur in the Feather River year-round, with eggs and emerging fry occurring between January and April; juveniles out-migrating year-round with peaks from January to April and August to November; and holding and migrating adults occurring between April and July (NMFS 2016a). All life stages would thus be exposed to the effects of Alternative 4.

Fall-Run Chinook Salmon eggs and emerging fry would benefit from increased dissolved oxygen due to higher Alternative 4 flows in April and May of wet years, from March through April of above normal years, and from January through May of below normal and dry years (Figure O.3-144). Juvenile Fall-Run Chinook Salmon would benefit from increased Alternative 4 flows relative to No Action Alternative flows during the same periods when increased flows result in increased rearing and foraging habitat and higher dissolved oxygen content (Figure O.3-144). Migrating adult Fall-Run Chinook Salmon would benefit from increased Alternative 4 flows relative to No Action Alternative flows in April and May of wet, below normal, and dry years, from April through June of above normal years, and in June of critically dry years due to increased attraction flows and holding habitat (Figure O.3-144). Because Fall-Run Chinook Salmon benefit from increased Alternative 4 flows relative to No Action Alternative flows during key months of all life stages and because Alternative 4 flows do not comply with minimum instream flow requirements only in dry and critically dry years (Table O.3-72, Figure O.3-144), flow-related actions under Alternative 4 would have beneficial effects on Fall-Run Chinook Salmon.

Central Valley Steelhead

Central Valley Steelhead would be exposed to the effects of Alternative 4 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Central Valley Steelhead eggs and fry occur in the Feather River from December to May; rearing juveniles occur year-round and out-migrate from January to May; peak adult migration occurs in September and October; and adult holding occurs from December to March (NMFS 2016a).

Alternative 4 flows can affect Central Valley Steelhead by influencing water temperature, DO, sedimentation, substrate composition, habitat, food availability, predation, entrainment and stranding risk, habitat availability, and migration cues. During the January to May period in which Central Valley Steelhead juveniles are out-migrating, Alternative 4 flows are higher than No Action Alternative flows in April and May of wet years, March through May of above normal years, and January through May of below normal and dry years (Figure O.3-144). The increased flow under Alternative 4 during these periods can benefit juveniles via increased rearing and foraging habitat and higher DO content. The same is true for the December to May period in which Central Valley Steelhead eggs and fry are present in the Feather River. During the September and October adult peak migration period, No Action Alternative flows are higher than Alternative 4 flows in September of wet and above normal water years, which could create higher levels of flow attraction (Figure O.3-144); there are minimal differences during all other water years. During adult holding from December to March, differences between Alternative 4 and No Action Alternative flows are minimal except in below normal and dry water years when increased flows could increase available habitat (Figure O.3-144). Because Central Valley Steelhead benefit from increased Alternative 4 flows relative to No Action Alternative flows during key months of all life stages and because Alternative 4 flows do not comply with minimum instream flow requirements only in dry and critically dry years (Table O.3-72, Figure O.3-144), flow-related actions under Alternative 4 may have beneficial effects on Central Valley Steelhead.

North American Green Sturgeon

North American Green Sturgeon would be exposed to the effects of Alternative 4 based on their seasonal occurrence in the Feather River, minimum instream flow requirements in the HFC, and compliance with D-1641. Green Sturgeon eggs and larvae occur in the Feather River from March to July; larvae and juveniles occur from April to August; subadults occur year-round; and adults occur from March to August (NMFS 2016a).

For all water year types, modeled flow under Alternative 4 is higher than under the No Action Alternative at various points in the March to August period in which Green Sturgeon eggs, larvae, juveniles, and adults occur in the Feather River, thereby potentially benefiting these life stages with increased DO content, cooler water temperatures, and increased rearing and foraging habitat. Because subadults occur year-round, they would be exposed to the same potential benefits of increased Alternative 4 flow but also to the lower flow under Alternative 4 compared to the no action alternative in September of wet and above normal water years (Figure O.3-144). Because the majority of flow differences between Alternative 4 and the No Action Alternative during key periods of Green Sturgeon presence in the Feather River are indicate increased flow under Alternative 4 and flows below the minimum instream flow requirements occur only in dry and critically dry years (Table O.3-72, Figure O.3-144), flow-related actions under Alternative 4 may have beneficial effects on North American Green Sturgeon.

Potential changes to aquatic resources in the Feather River due to changes in water temperature

Water flow, combined with other environmental drivers, has the potential to affect aspects of water quality such as temperature. Water temperature has the potential to influence the condition and survival of fish species during all stages of their life cycle. Optimal water temperatures can facilitate physiological responses that range from faster growth rates to a heightened immune system, leading to a higher likelihood of survival. In contrast, effects of elevated water temperatures include an inability to satisfy metabolic demand and acute to chronic physiological stress, eventually leading to mortality (Stillwater Sciences 2006; Martin et al. 2017).

HEC-5Q/RecTemp modeling results provide predictions of water temperature at multiple locations in the Feather River HFC from below the Thermalito Afterbay to the mouth of the Feather River. Average water temperatures in the Feather River HFC at Gridley Bridge follow a seasonal pattern where they increase to a high point around 72°F in July or August and decrease to a low point around 47°F in January (Figure O.3-145). Flow releases from Oroville facilities influence Feather River water temperature primarily in summer and fall when these releases can help to lessen water temperatures when air temperatures and solar radiation levels are at their highest. Average water temperatures in the Feather River do not change substantially between water year type in winter, but water temperatures can reach levels up to 4°F warmer (approximately 75°F) in critically dry years than in wet years (approximately 71°F).

Alternative 4 was designed to follow flow regulation procedures similar to procedures under the No Action Alternative as a way to minimize potential adverse temperature-related effects on various fish species in the Feather River.

Table O.3-73. Maximum Daily Mean Water Temperature Objectives for the Feather River HFC

Period	Temperature (°F)
January 1 to March 31	56
April 1 to 30	61
May 1 to 15	64
May 16 to 31	64
June 1 to August 31	64
September 1 to 8	61
September 9 to 30	61
October 1 to 31	60
November 1 to December 31	56

Source: NMFS 2016a.

Modeled average water temperatures under both Alternative 4 and the No Action Alternative (Figure O.3-73) exceed the daily average water temperature objectives of 64°F from June 1 to August 31 and 61°F from September 1 to 30 (Table O.3-73). There is, therefore, potential for adverse temperature-related effects on Feather River anadromous fish species, although the presence and magnitude of these effects would vary between the different species and life stages. In particular, these modeled average temperatures would reach suboptimal or stress-inducing levels for Spring-Run Chinook eggs, fry, and adults, migrating Central Valley Steelhead, and Green Sturgeon eggs, fry, and post-spawn adults.

Modeling results indicate that water temperatures under Alternative 4 operations would be similar to temperatures under the No Action Alternative for much of the year (Figures O.3-145 and O.3-146). In August and September, though, the water in the Feather River HFC at Gridley Bridge would reach temperatures, on average, up to 1°F warmer than under the No Action Alternative (Figure O.3-145). The most pronounced difference in August and September water temperatures between Alternative 4 and No Action Alternative scenarios would occur in wet years when this temperature difference could reach as much as 4°F, whereas no difference is projected in drier water years (Figure O.3-146). In below normal water years, a difference in water temperature between Alternative 4 and No Action Alternative scenarios would also occur in August, when Alternative 4 water temperatures would surpass No Action Alternative temperatures by approximately 2°F (Figure O.3-146). These differences in water temperature between Alternative 4 and the No Action Alternative would therefore occur in summer months when water temperatures are higher (> 60°F) and more likely to lead to physiological stress and mortality. The effects of water temperature on fish in the Feather River vary among species and life stages; however, water temperatures under the No Action Alternative and Alternative 4 scenarios would surpass suboptimal levels for Chinook Salmon between 58°F and 75.2°F, for Steelhead between 55°F and 70°F, and for Green Sturgeon between 66°F and 70°F (Table O.3-74).

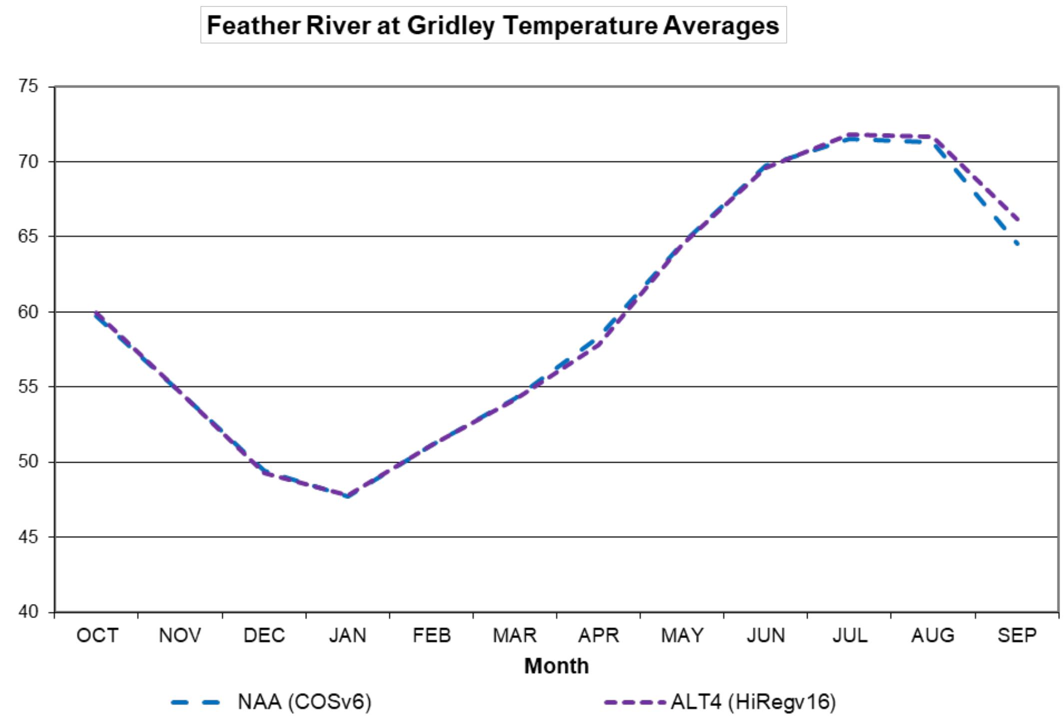

Figure O.3-145. RecTemp Average Feather River Water Temperatures at Gridley Bridge under the No Action Alternative and Alternative 4 Scenarios

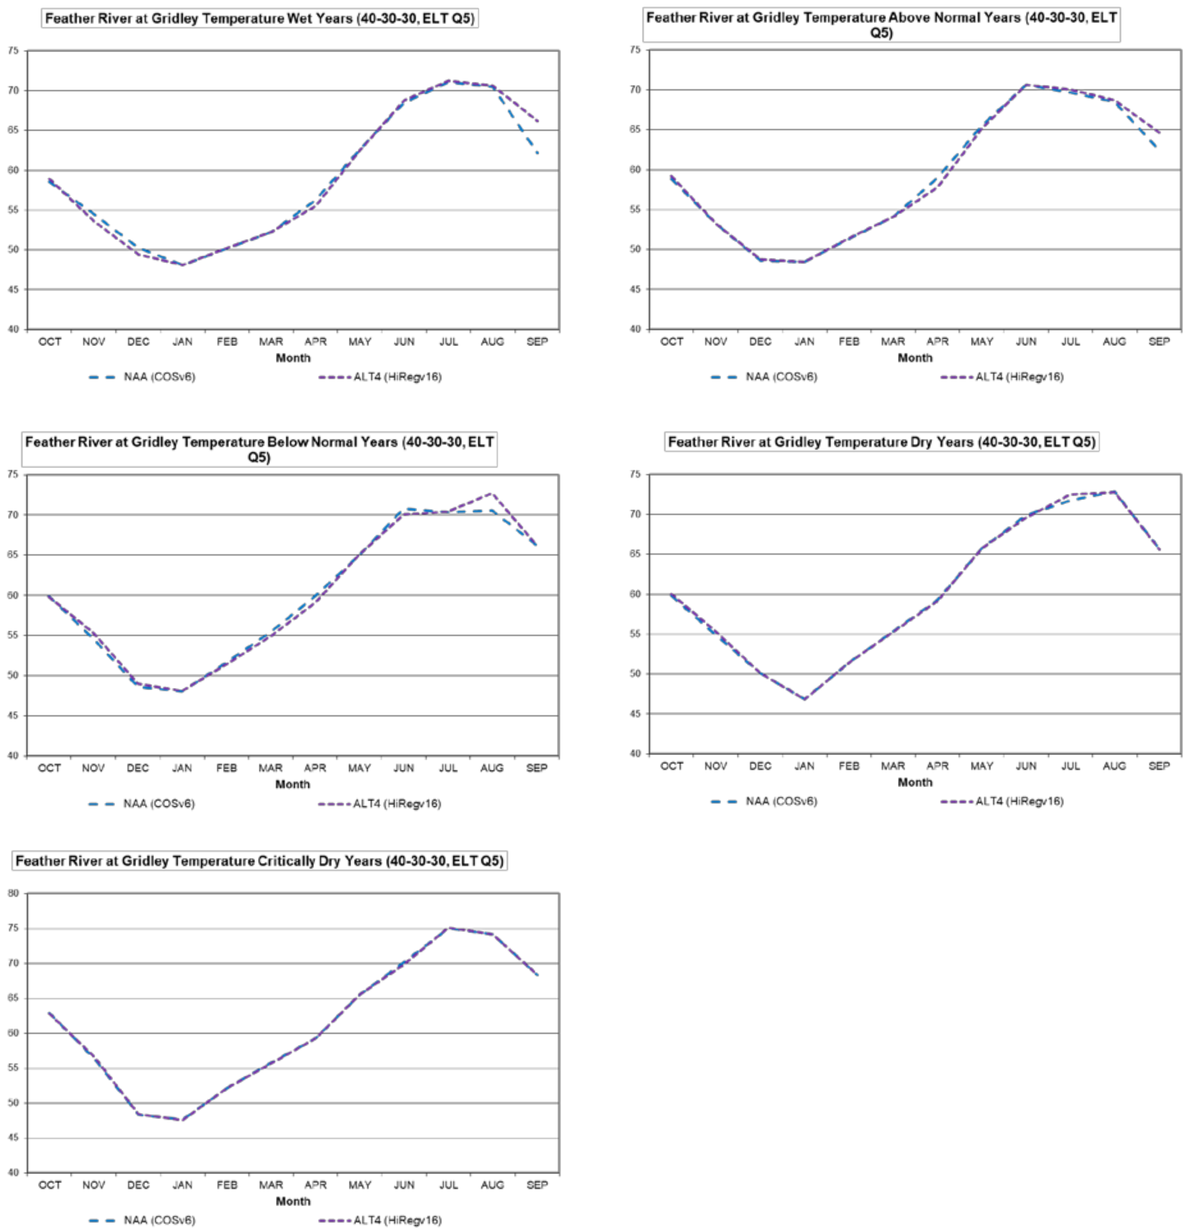

Figure O.3-146. RecTemp Average Estimated Feather River Water Temperatures at Gridley Bridge in Wet and Below Normal Water Year Types under the No Action Alternative and Alternative 4 Scenarios

Table O.3-74. Water Temperatures Suitable for Spring-Run and Fall-Run Chinook Salmon, Central Valley Steelhead, and Green Sturgeon by Life Stage

Life Stage	Peak Occurrence	Optimal	Suboptimal	Stress-inducing
Spring-Run Chinook Salmon				
Eggs to fry	September to October	< 54°F	54°F to 58°F	> 58°F
Rearing to out-migrating	November to May	< 60°F	60°F to 65°F	> 65°F
Migrating adults	March to June	< 56°F	56°F to 65°F	> 65°F
Adult holding	May to August	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Fall-Run Chinook Salmon				
Eggs to fry	October to April	48.2°F to 55.4°F	55.4°F to 62.6°F	> 62.6°F
Rearing to out-migrating	April to June	55.4°F to 68°F	68°F to 75.2°F	> 75.2°F
Migrating adults	June to April	50°F to 68°F	68°F to 69.8°F	> 69.8°F
Central Valley Steelhead				
Eggs to fry	January	46°F to 52°F	52°F to 55°F	> 55°F
Rearing to out-migrating	January to May	< 65°F	65°F to 68°F	> 68°F
Migrating adults	September to October	< 52°F	52°F to 70°F	> 70°F
Adult holding	December to March	< 60.8°F	60.8°F to 66.2°F	> 66.2°F
Green Sturgeon				
Eggs to fry	May to July	53°F to 65°F	65°F to 66°F	> 66°F
Rearing to out-migrating	May to October	58°F to 66°F	66°F to 69°F	> 69°F
Migrating adults	March to May	53°F to 64°F	64°F to 66°F	> 66°F
Post-spawn adults	March to August	46°F to 68°F	68°F to 70°F	>70°F

Winter-Run Chinook Salmon

Winter-Run Chinook are not likely to be affected by changes in water temperature due to differences in flow under Alternative 4 compared to the No Action Alternative due to their limited distribution in the Feather River.

Spring-Run Chinook Salmon

Effects of water temperature on Spring-Run Chinook have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance (Table O.3-74).

A difference in water temperature between Alternative 4 and No Action Alternative scenarios during the peak occurrence period for Spring-Run Chinook eggs and emerging fry would occur in in September of wet water years when temperatures under Alternative 1 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-54 and Table O.3-21). This would result in potentially adverse effects from the slightly higher water temperatures under Alternative 4 than under the No Action Alternative, yet water temperatures under both scenarios would fall in the stress-inducing range for this life stage (Table O.3-74). During the peak abundance periods of juveniles (November to May) and migrating adults (March to June), there is no projected difference between water temperatures under Alternative 4 and the No Action Alternative (Figure O.3-145 and Table O.3-74). For the majority of the peak occurrence range for holding adults, there is no difference in water temperature between Alternative 4 and the No Action Alternative (Figure O.3-145 and Table O.3-74); in August of below normal water years, however, water temperatures under Alternative 4 could be up to 2°F higher than under the No Action Alternative (Figure O.3-146). The effect on adult Spring-Run Chinook would likely be negligible because modeled water temperatures would cross the threshold for stress-inducing temperatures under both Alternative 4 and the No Action Alternative for this life stage (Figure O.3-146 and Table O.3-74).

Alternative 4 therefore has the potential for slightly adverse water temperature-related effects on eggs, fry, and holding adults relative to the No Action Alternative yet no difference in temperature-related effects on juveniles or migrating adults.

Fall-Run Chinook Salmon

Effects of water temperature on Fall-Run Chinook have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-74).

Modeling results indicate temperature differences between Alternative 4 and the No Action Alternative only in August and September (Figure O.3-146), and these months do not fall within the peak occurrence periods for Fall-Run Chinook eggs and fry, juveniles, or migrating adults in the Feather River (Table O.3-74). Therefore, no effects on Fall-Run Chinook Salmon due to differences in water temperature between the Alternative 4 and No Action Alternative scenarios are expected.

Central Valley Steelhead

Effects of water temperature on Central Valley Steelhead have been heavily studied, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage during its period of peak abundance (Table O.3-74).

Central Valley Steelhead eggs, fry, juveniles, and holding adults are present in the Feather River in winter and spring months when there is no projected difference between water temperatures under Alternative 4 and the No Action Alternative (Figure O.3-145 and Table O.3-74). Migrating (ocean to river) adult Steelhead peak in abundance in the Feather River between September and October (Table O.3-74). Modeled water temperatures for Alternative 4 and the No Action Alternative differ in September of wetter water years when temperatures under Alternative 4 could be up to 4°F higher than temperatures under No Action Alternative flows (Figure O.3-146), yet water temperatures would remain in the suboptimal range for migrating adults under both Alternative 4 and the No Action Alternative (Table O.3-74). Adverse effects of water temperature on this life stage are therefore anticipated to be slightly less severe under the No Action Alternative than under Alternative 4, yet Alternative 4 does have the potential for adverse water temperature-related effects on migrating adults relative to the No Action Alternative.

North American Green Sturgeon

Effects of water temperature on Green Sturgeon have been heavily studied in the Feather River, resulting in an understanding of the optimal (beneficial), suboptimal, and stress-inducing (adverse) temperature ranges for each life stage (Table O.3-74).

Green Sturgeon eggs and emerging fry occur in the Feather River from May to July and migrating adults from March to May (Table O.3-74), so neither life stage will be exposed to the modeled differences in water temperature between Alternative 4 and the No Action Alternative (Figure O.3-146). The peak occurrence period for juveniles and post-spawn adults includes August, when modeled Alternative 4 water temperatures can exceed No Action Alternative temperatures by up to 2°F in wet and below normal water years (Figure O.3-146), yet water temperatures remain at stress-inducing levels for both life stages under both flow scenarios (Table O.3-74). Juvenile Green Sturgeon are also present in the Feather River during September when, in wet water years, water temperatures under Alternative 4 flows could be up to 3°F higher than temperatures under No Action Alternative flows (Figure O.3-146 and Table O.3-74). Water temperatures in wet water years would drop from stress-inducing levels for juveniles to suboptimal levels and again to optimal levels later in the month under Alternative 4 than under the No Action Alternative (Figure O.3-146, Table O.3-74). Modeled water temperature differences between Alternative 4 and the No Action Alternative therefore indicate the potential for slightly adverse effects on juveniles and post-spawn adults in summer of wet and below normal water years.

O.3.9.5 *American River*

Potential changes to aquatic resources in the American River from flood control

Flood control would be similar under Alternative 4, compared to the No Action Alternative and would include following the USACE Water Control Manual, with the addition of working with the American River Stakeholders to define the “planning minimum”, an appropriate amount of storage in Folsom Reservoir that represents the lower bound for typical forecasting processes at the end of calendar year. The objective of the planning minimum is to preserve storage to protect against future drought conditions and to facilitate the development of the coldwater pool when possible. The objective of incorporating the planning minimum into the forecasting process is to provide releases of salmonid-suitable temperatures to the lower American River and reliable deliveries to American River water agencies. Analysis of Folsom Storage indicates that under average conditions, there would be little difference in flood control storage under Alternative 4 in comparison to the No Action Alternative for average, dry, and wet years (Figures O.3-55 through O.3-57).

Potential changes to Folsom Reservoir operations in the American River to meet Delta salinity requirements

Folsom Reservoir operations to address Delta water quality requirements under D-1641 would not change under Alternative 4, compared to the No Action Alternative. Folsom Reservoir flow requirements includes releases to meet Delta standards under D-1641, as needed. Since Folsom Reservoir is the closest reservoir to the Delta, releases from Folsom can more quickly address Delta water quality requirements. Releases to address Delta water quality objectives would be conducted, as needed, in coordination with the American River stakeholders. Releases to address Delta water quality objectives would improve water quality conditions, and thus habitat conditions for fish and other aquatic species in the Delta when hydrologic conditions are negatively affecting salinity levels.

Potential changes to aquatic resources from flows in the American River

Flow objectives for Alternative 4 are similar to the objectives for the No Action Alternative with the intent of providing suitable conditions for Fall Chinook and Steelhead. Flows under Alternative 4 are according to the 2017 Flow Management Standard, where additional flow measures include minimizing releases above 4,000 cfs during sensitive life stages, redd dewatering protective measures in January through May (holding releases relatively constant), providing spring pulse flows, and continued summer releases for instream temperature control. Although these objectives result additional flow measures, the modeling indicates that overall change to flows in the American River below Nimbus Dam are minor, and that instream flows during critical periods for Fall Chinook Salmon and Steelhead are driven more by hydrologic conditions (wet versus dry years) than the operations to meet objectives.

Flows in the American River below Nimbus Dam would be similar throughout the year under Alternative 4 with relatively minor differences in average flows (Figure O.3-58) and in wet years (Figure O.3-59), under Alternative 4 compared to the No Action Alternative. In dry and critically dry years, flows would be similar compared with the No Action Alternative with some differences in the late winter/early spring months and in the summer months, compared to the No Action Alternative (Figure O.3-60). Flows would be higher in February through March, slightly lower in July, and higher in August and September.

Changes to minimum flows in the American River below Nimbus Dam would be more evident in low water years, with lower minimum flows in October through January, higher minimum flows in February and March, and higher flows in July through September compared to the No Action Alternative (Figure O.3-60).

Potential changes to aquatic resources in the American River due to changes in water temperature

The water temperature objectives for Alternative 4 are similar the objectives for the No Action Alternative. The objectives address the needs for Steelhead incubation and rearing during the late spring and summer, and for fall–run Chinook Salmon spawning and incubation starting in late October or early November. Specific additional objectives for Alternative 1 are to maintain a daily average water temperature of 65°F (or other temperature as determined by the temperature modeling) or lower at Watt Avenue Bridge from May 15 through October 31, to provide suitable conditions for juvenile Steelhead rearing in the lower American River, and to provide cold water for Fall-Run Chinook Salmon spawning. In addition, the proposed alternative shutter configurations at Folsom Dam to allow temperature flexibility as part of adaptive management may provide for additional improved water temperatures.

Average water temperatures are similar throughout the year in the lower American River under Alternative 4, compared to the No Action Alternative (Figure O.3-62). Differences in water temperatures are more a function of hydrologic conditions than operations to meet objectives, wither lower summer high temperatures wet years (Figure O.3-63) than in dry years (Figure O.3-64). Maximum water temperatures are lower for Alternative 1 in summer months in comparison to the No Action Alternative and the other action alternatives, which would beneficially affect fishery resources (Figure O.3-65).

Potential changes to aquatic resources in the American River from habitat restoration

No additional habitat restoration is proposed under the No Action Alternative, therefore, there would be no changes to habitat in the lower American River under Alternative 4.

O.3.9.6 *Stanislaus River*

Effects would be expected to be similar under Alternative 4 to the potential effects as previously described for Alternative 1. A full description of potential effects for Alternative 1 are described in Section O.3.3.1.6.

O.3.9.7 *San Joaquin River*

Effects would be expected to be similar under Alternative 4 to the potential effects as previously described for the No Action Alternative. A full description of potential effects are described in Section O.3.2.7.

O.3.9.8 *Bay-Delta*

O.3.9.8.1 Delta Smelt

Potential changes to Delta Smelt due to seasonal operations

Relative to the No Action Alternative, potential effects on Delta Smelt from seasonal operations would vary under Alternative 2. The potential south Delta entrainment risk of Delta Smelt under Alternative 4 could be similar to the effects described under the No Action Alternative and Alternative 1 in winter (December–February) for adult Delta Smelt because of generally similar OMR flows (Appendix F, Attachment 3-2, Figures 40-9 through 40-11). For larval/juvenile Delta Smelt in spring (March–June), effects may generally be similar or slightly lesser or greater effects compared to the No Action Alternative, reflecting OMR flows (Appendix F, Attachment 3-2, Figures 40-12 through 40-15). Given the protective nature of the seasonal operations for entrainment risk, effects would be expected to be limited, consistent with the No Action Alternative.

With respect to other habitat attributes discussed previously under analysis of *Potential changes to Delta Smelt due to seasonal operations* for other alternatives, delivery of sediment to the Delta and resulting turbidity-related predation risk would be expected to be similar to the No Action Alternative, as indicated by general similarity of CalSim-modeled flows in the Sacramento River at Rio Vista during the higher flow winter/spring months (Appendix F, Attachment 3-2, Figures 32-9 through 32-15). Related to predation risk from Silversides, March to May south Delta exports would be less under Alternative 4 than the No Action Alternative (Appendix F, Attachment 3-3, Table 53-4), as generally would be June–September Delta inflow (as represented largely by Freeport flow; Appendix F, Attachment 3-2, Table 29-4) which could give greater predation risk under Alternative 4, based on the correlative analysis described in the ROC LTOBA). As discussed for other alternatives, there is uncertainty in this conclusion given that the relationships are correlations and do not necessarily imply causality and require further investigation (Reclamation 2019). Similar to Alternative 1, the inclusion of the USFWS (2008) fall X2 criteria under the No Action Alternative but not in Alternative 4 has the potential to affect Delta Smelt predation risk by resulting in less overlap of the low salinity zone with turbid habitat.

As described for other alternatives, various aspects of seasonal operations under Alternative 4 have the potential to affect Delta Smelt food availability relative to the No Action Alternative. There would be little difference in Yolo Bypass flooding and therefore little difference between Alternative 4 and the No Action Alternative in potential food effects for adult Delta Smelt in winter/spring (e.g., Appendix F, Attachment 3-2, Figures 25-2 through 25-6). In spring (March–May), Delta outflow would be greater and therefore X2 would be lower under Alternative 4 than the No Action Alternative, potentially producing positive effects on Delta Smelt prey (*E. affinis*), in contrast to the potential negative effects suggested for other alternatives (e.g., Alternative 1). Summer/fall subsidy of *P. forbesi* to the low salinity zone, as discussed for Alternative 1 for example, has the potential to be increased relative to the No Action Alternative, given the generally lower frequency of negative San Joaquin River at Jersey Point flows under Alternative 4 (Figures).3-70 through O.3-72).

Relative to the No Action Alternative and similar to Alternatives 2 and 3, under Alternative 4 the size of the low salinity zone in wet and above normal years would be expected to be considerably reduced (Figures O.3073 through O.3-75). Similar to other alternatives, the percentage of time that the low salinity zone is outside of Suisun Bay would also be expected to be considerably less under Alternative 4 than the No Action Alternative (Figure O.3-76), thereby potentially negatively affecting Delta Smelt under Alternative 4 relative to the No Action Alternative.

Based on the general similarity between Alternative 1 and Alternative 4 in operations during the summer/fall (June–October/November) period of potential harmful algal bloom occurrence (as reflected by OMR flows, for example: Appendix F, Attachment 3-2, Figures 40-7 and 40-8, 40-15 through 40-18), there would be expected to be little difference in modeled velocity (a potential indicator of harmful algal bloom disruption) between Alternative 4 and the No Action Alternative, given the similarity in velocity between the No Action Alternative and Alternative 1 (Reclamation 2019). This suggests that there would be little difference in harmful algal bloom potential between Alternative 4 and the No Action Alternative.

Potential changes to Delta Smelt from Delta Cross Channel operations.

The potential effects of DCC operations on Delta Smelt under Alternative 4 may be generally similar to those occurring under the No Action Alternative, given that both are based on D-1641 and NMFS (2009) BO RPA requiring consultation to avoid exceeding water quality standards. There is uncertainty in the effects that the DCC has on Delta Smelt, as described for Alternative 1.

Potential changes in Delta Smelt survival related to the Temporary Barriers Project

Under Alternative 4, potential effects of the three south Delta agricultural barriers on Delta Smelt generally would be expected to be similar to the effects under Alternative 1 (i.e., near-field predation and potential effects on transport of *P. forbesi* to the low salinity zone; see also ROC LTO BA p. 5-408), although the effects may be less because of greater OMR restrictions and therefore less risk of Delta Smelt being present in the south Delta under Alternative 4. As with Alternative 1, there may be less potential effect relative to the No Action Alternative because of no HOR barrier, although Delta Smelt would rarely be found near the HOR barrier based on historical observations.

Potential changes to Delta Smelt due to changes from Tracy and Skinner fish facilities improvements

The potential effects to Delta Smelt from the Tracy and Skinner fish facilities under Alternative 4 (i.e., mortality from pre-screen loss, collection, handling, transport, and release, with only a very small fraction potentially surviving the salvage process) could be similar to the effects described under the No Action Alternative and Alternative 1 in winter (December–February) for adult Delta Smelt because of generally similar OMR flows (see above discussion in *Potential changes to Delta Smelt due to seasonal operations*) and therefore potentially similar proportion of Delta Smelt entering the south Delta and being exposed to the south Delta fish facilities. Generally similar or slightly lesser or greater effects may occur under Alternative 4 compared to the No Action Alternative in spring (March–June).

The following project-level effects would be expected to be similar under Alternative 4 to the potential effects as previously described for Alternatives 2 and 3 because of limited potential for effect or because the operations are similar:

Potential changes to Delta Smelt from Contra Costa Water District operations

Potential changes to Delta Smelt from North Bay Aqueduct operations

Potential changes to Delta Smelt from water transfers

Potential changes to Delta Smelt from Clifton Court aquatic weed and algal bloom management

Potential changes to Delta Smelt due to changes from Suisun Marsh facilities

O.3.9.8.2 Longfin Smelt

Potential changes to Longfin Smelt due to seasonal operations

As described for the other alternatives, the principal potential effect of seasonal operations on Longfin Smelt would be changes in population abundance as a result of changes in Delta outflow. During the December–May period identified as important for Delta outflow by Nobriga and Rosenfield (2016), CalSim modeling suggests that under Alternative 4 Delta outflow generally would be greater than the No Action Alternative (Appendix F, Attachment 3.2, Table 41-2), thereby potentially positively affecting Longfin Smelt through increases in population abundance. As described for Alternative 1, however, the magnitude of the difference may be limited because of density-dependent effects, and there is appreciable variability in the estimates generated by the Nobriga and Rosenfield (2016) model, with other analyses finding stronger correlations with general hydrological conditions rather than Delta outflow specifically (Maunder et al. 2015).

Relative to the No Action Alternative, there is the potential for Longfin Smelt entrainment risk to vary under Alternative 4, as reflected by sometimes higher and sometimes lower OMR flow in December to May (Appendix F, Attachment 3.2, Figures 40-8 through 40-14) and generally similar or greater San Joaquin River flow at Jersey Point in January to March (Figures SJR_jan, SJR_feb, SJR_mar). However, as noted previously for other alternatives, it should be borne in mind that the modeling for Alternative 4 does not reflect continued adherence to the criteria of the CDFG (2009) SWP ITP, nor to any subsequent ITP that may govern Longfin Smelt south Delta entrainment protection. As previously noted for other alternatives, estimates of Longfin Smelt population-level entrainment loss during the D-1641-based regulatory period (i.e., prior to 2007, and what is included under Alternatives 2 and 3) suggest that low percentages (0–3.6%) of Longfin Smelt were lost to entrainment (ICF International 2016, Table 4.2-10 [p. 4-286] and Table 4.2-11 [p. 4-288]). This suggests that Longfin Smelt proportional entrainment loss under Alternative 4 would also be limited.

The following project-level effects under Alternative 4 would be expected to be somewhat less than Alternatives 1 through 3 because of greater OMR flow, therefore giving lower potential for Longfin Smelt to be in the south Delta; however, effects would be expected to be limited given low occurrence of the species in the south Delta:

Potential changes in Longfin Smelt survival related to the Temporary Barriers Project

Potential changes to Longfin Smelt due to changes from Tracy and Skinner fish facilities improvements

The following project-level effects would be expected to be similar under Alternative 4 to the potential effects as previously described for Alternatives 2 and 3 because of limited potential for effect or because the operations are similar:

Potential changes to Longfin Smelt from Contra Costa Water District operations

Potential changes to Longfin Smelt from North Bay Aqueduct operations

Potential changes to Longfin Smelt from water transfers

Potential changes to Longfin Smelt from Clifton Court aquatic weed and algal bloom management

Potential changes to Longfin Smelt from changes to Suisun Marsh facilities

O.3.9.8.3 Sacramento Winter-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Rearing Winter-Run Chinook Salmon are present in the Delta between October and May. Key habitat attributes relevant to seasonal operations in the Delta include out-migration cues and entrainment risk. Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to adversely affect juvenile Chinook Salmon in two distinct ways: 1) "near-field" mortality associated with entrainment to the export facilities, and 2) "far-field" mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team's (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver-linkage-outcome (DLO) framework for specifying how water project operations (the "driver") can influence juvenile salmonid behavior (the "linkage") and potentially cause changes in survival or routing (the "outcome"). The SST concluded altered "Channel Velocity" and altered "Flow Direction" were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O.3-147 provides a simplified conceptual model of the DLO defined by the CAMT SST.

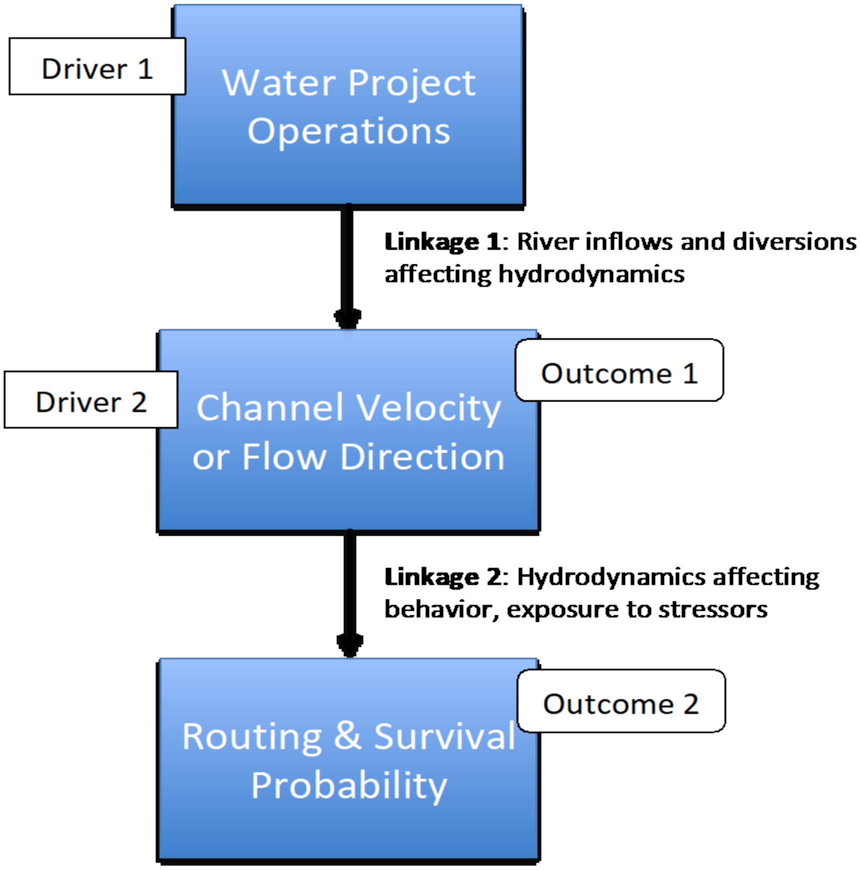

Figure O.3-147. Conceptual Model for Far-field Effects of Water Project Operations on Juvenile Salmonids in the Delta. This CM is a Simplified Version of the Information Provided by the CAMT SST.

To assess the potential for water project operations to influence survival and routing, Reclamation and DWR analyzed Delta hydrodynamic conditions by creating maps from DSM2 Hydro modeling. The maps are based on a comparative metric, proportion overlap (more below), to capture channel-level hydrodynamic details as a single number for color-scale mapping of Delta channels.

The objective of the comparative metric is to summarize the water velocity time series for each channel and scenario such the channel-level comparison is captured in a single number. For the proportion overlap metric, kernel density estimates are calculated on each time series. The kernel density estimates represent a non-parametric smoothing of the empirical distribution of time series values. The proportion overlap of two kernel density estimates is calculated with the following steps: 1) calculate the total area under the curve (AUC_t) as the sum of the AUC for each density estimate, 2) calculate the AUC of the overlapping portions (AUC_o) of the two density distributions being compared, and 3) calculate the overlapping proportion of the density distributions as AUC_o/AUC_t. Proportion overlap is naturally bound by zero and one; a value of zero indicates no overlap and a value of one indicates complete overlap. Lower values of proportion overlap identify channels demonstrating larger differences in a scenario comparison.

The proportion overlap metric is best applied over relatively short time periods because seasonal and annual variation in water velocity can overwhelm differences between scenarios. Thus, Reclamation calculated proportion overlap for every DSM2 channel for two seasons (Dec-Feb, Mar-May) in each water year (1922–2003). DSM2 output was excluded from water year 1921 to allow for an extensive burn-in period. The proportion overlap was calculated based on hourly DSM2 output. Because each season was roughly 90 days, each comparison involved roughly 4,300 DSM2 values (2 scenarios * 24 hours * 90 days) for each channel.

Because the proportion overlap was calculated for each channel in each water year, the proportion overlap values were summarized prior to mapping (i.e., not feasible to map proportion overlap for every comparison in every water year). To summarize, the minimum proportion overlap for each channel for each water year type for each comparison were found. The minimum values represent the maximum expected effect. Note that the year with the minimum proportion overlap for one channel might not be the same year as for another channel.

Entrainment

In the December through June period, the average total export rate, under Alternative 4, is similar to the export rate under No Action Alternative. Therefore, similar entrainment is expected compared to the No Action Alternative.

Zeug and Cavallo (2014) analyzed more than 1,000 release groups representing more than 28 million coded wire tagged juvenile fish including winter, late fall and Fall-Run Chinook Salmon. This data represents large release groups of tagged smolts where the number of fish representing each release group lost to entrainment at the export facilities has been estimated. Cavallo (2016) provided a supplemental assessment of Winter-Run Chinook Salmon entrainment risk (building upon Zeug and Cavallo 2014) that showed total CVP and SWP exports described entrainment risk better than OMR or other flow metrics. Entrainment loss results as reported below represents the proportion of coded wire tagged Winter-Run Chinook Salmon released upstream of the Delta which were entrained at South Delta export facilities. This proportion accounts for and includes expansion for sampling effort at the salvage facilities and also prescreen mortality. For December through February, Alternative 4 has an average total export rate greater than No Action Alternative (7,736 and 7,617 cfs respectively; Figure O1-1 in Appendix O, Attachment 1) and will therefore have similar entrainment risk. Entrainment losses should average 0.4% and not exceed 2.2%. In the March through June period, total exports for Alternative 4 will result in similar entrainment risk relative to No Action Alternative (3,610 vs. 4,164 cfs, respectively; Figure O1-2 in Appendix O, Attachment 1), and entrainment losses should average 0.09% and not exceed 1.5%.

Routing

Routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 4 were evaluated using DSM2. Juvenile Winter-Run Chinook Salmon are present in the Sacramento River at Sherwood Harbor upstream of the first distributary junctions between November and March with peak abundance in February and March (Reclamation 2019).

In the December to February period, velocity overlap between Alternative 4 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 92%, 76%, 63%, 71%, and 8% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-53 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 4 in all water year types indicating routing into the interior Delta would be lower relative to No Action Alternative (Perry et al. 2015; Figure O1-57 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 4 was more than 91%, 69%, 48%, 46%, and 62% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-54 in Appendix O, Attachment 1).

Abundance of juvenile Winter-Run Chinook Salmon at Chipps Island peaks in March and April but fish are collected between December and May (Reclamation 2019). During this time period, Winter-Run Chinook Salmon originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can potentially be exposed to hydrodynamic effects associated with the CVP and SWP that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 4 and the No Action Alternative (Figure O1-55 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 4 to the No Action Alternative in the March to May period (Figure O1-56 in Appendix O, Attachment 1).

Through-Delta Survival

Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases.

To examine potential effects of Alternative 4, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, there are higher velocities under Alternative 4 than the No Action Alternative in all water year types (Figure O1-57 in Appendix O, Attachment 1). At Steamboat Slough in the December through February period, there are higher velocities under Alternative 4 than the No Action Alternative in all water year types (Figure O1-58). In the March through May period at Walnut Grove, when Alternative 4 was compared to the No Action Alternative, velocity overlap ranged from 61.5-94.6% (Figure O1-59 in Appendix O, Attachment 1). Velocity overlap at Steamboat Slough in the March through May period ranged from 68.4% to 95.7% (Figure O1-60 in Appendix O, Attachment 1).

Overall, Alternative 4 results in similar or higher velocities in the Delta in the spring than under No Action Alternative, during the outmigrating juvenile time period. Survival probabilities are non-linear; however, the similar or higher discharge at Freeport in the spring under Alternative 4 results in similar or higher survival in the transition reaches. Higher flows also lead to lower probability of routing into the interior Delta, which has the lowest survival probability regardless of flow.

Potential changes to aquatic resources OMR Management

See section on seasonal operations above which integrate OMR management.

Potential changes to aquatic resources due to Delta Cross Channel operations

Under Alternative 4, the DCC may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Winter-Run Chinook Salmon in the Sacramento River at Sherwood Harbor, which is near the DCC, occurs from February through March (Reclamation 2019). Therefore, the DCC is closed for the majority of the juvenile Winter-Run Chinook Salmon migration period in the Sacramento River and as such the proportion of juvenile Winter-Run Chinook Salmon exposed to an open DCC would be negligible. Juvenile Chinook Salmon entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010; Perry et al. 2018).

Potential changes to aquatic resources due to the Temporary Barriers Project

Juvenile Winter-Run Chinook Salmon are not expected to co-occur in space or time with the agricultural barriers indicating no potential impacts.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 4 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a) and remain unchanged from the No Action Alternative.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory route for Winter-Run Chinook Salmon (NMFS 2017c), approximately 18 miles from the Sacramento River via the shortest route. Designated critical habitat for Winter-Run Chinook Salmon does not occur within Rock Slough, but is present further to the north in the Delta (NMFS 2017c, 2014). Salmonids are expected to avoid the area of the Rock Slough Intake during certain times of the year based on historical water temperatures.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Winter-Run Chinook Salmon presence near the Rock Slough Intake. Since 1994, fish monitoring has been conducted by CDFW and CCWD consistent with the separate biological opinions and permits that govern CCWD's operations. From 1994 through 1999, CDFW conducted fish monitoring at the Rock Slough Intake and in the Contra Costa Canal up to the first pumping plant. Over this 6-year period, CDFW captured a total of 13 juvenile Winter-Run Chinook Salmon from January through May (CDFG 2002c; NMFS 2017c). From 1999 to 2009, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected no juvenile or adult Winter-Run Chinook Salmon at the Rock Slough Headworks (Reclamation 2016; NMFS 2017c).

Since construction of the RSFS, operation of the hydraulic rake cleaning system has been shown to trap and kill adult Chinook Salmon and other non-listed fish (Reclamation 2016). From 2011-2018, 47 Salmon were recovered at the RSFS (Reclamation 2016, Appendix A; Tenera Environmental 2018a), but none of the captured fish were identified as Winter-Run Chinook Salmon (NMFS 2017c).

NMFS issued a biological opinion in 2017 (NMFS 2017c) that considered improvements to the RSFS facility including the hydraulic rake cleaning system, operations and maintenance (O&M) of the RSFS and associated appurtenances, and administrative actions such as the transfer of O&M activities from Reclamation to CCWD. NMFS determined that the O&M of RSFS may result in the incidental take of juvenile Winter-Run Chinook Salmon and provided an incidental take limit based upon the number of listed fish collected in the pre and post-construction RSFS monitoring (NMFS 2017c). The incidental take provided in NMFS 2017c is five juvenile Winter-Run Chinook Salmon per year.

CCWD's Fish Monitoring Program also samples behind the fish screens at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Winter-Run Chinook Salmon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD's operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at

maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Winter-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Salmon can be “drawn” into the south Delta under reverse flows and high CVP and SWP pumping rates. One indicator of reverse flows is the net flow in Old and Middle Rivers (OMR). Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect OMR, and any effect that diversions at Rock Slough Intake would have in the Old and Middle River corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants.

However, diversions at the Rock Slough Intake could affect flows in the San Joaquin River at Jersey Point, which is approximately 14 river miles from the Rock Slough Intake (via the shortest route through Franks Tract). Mean velocity in a river channel can be calculated by dividing the flow rate by the cross-sectional area of the channel. The maximum effect of Rock Slough diversions on the channel velocity would be the maximum diversion rate (350 cfs) divided by the minimum cross-sectional area of the channel. This calculation assumes that all water diverted at Rock Slough comes from the San Joaquin River at Jersey Point, which is a conservative assumption (i.e., overestimates the effect on velocity). The cross-sectional area of the San Joaquin River at Jersey Point is approximately 60,500 square feet (sf), but varies depending on the tidal stage from approximately 56,000 sf (at low tide and low San Joaquin River flow) to 68,000 sf (at high tide and high San Joaquin River flow) as shown in Figure O.3-148.

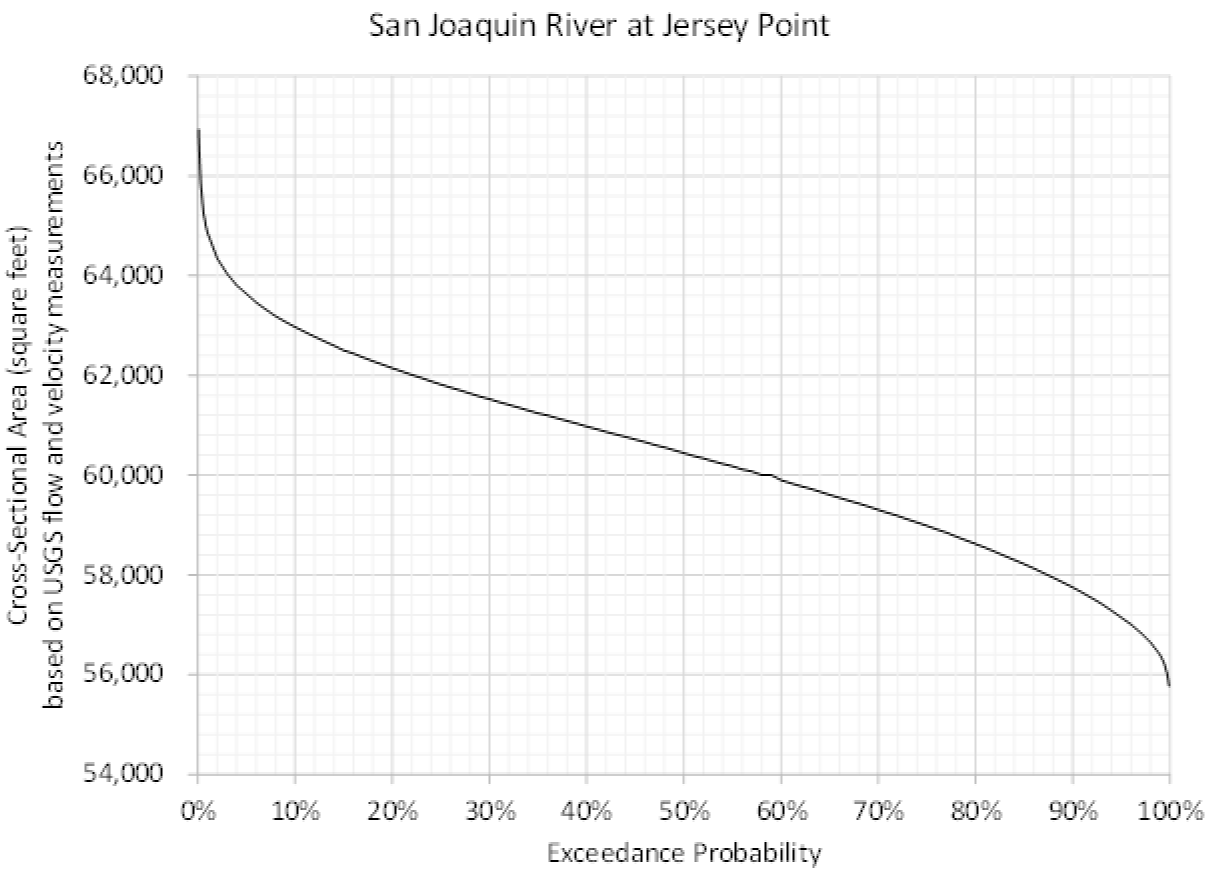

Figure O.3-148. Cross-sectional area of the San Joaquin River at Jersey Point (Station: 11337190) Calculated from USGS Measurements of Flow and Velocity every 15 Minutes for Water Years 2014 through 2018.

The maximum effect of water diversions at Rock Slough Intake on velocity in the San Joaquin River at Jersey Point is calculated as 350 cfs divided by 56,000 square feet; resulting in 0.00625 feet per second (ft/sec). For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from Rock Slough diversions. Furthermore, the actual effect is likely to be much lower than 0.00625 ft/sec because the water diverted at the Rock Slough Intake does not all come from the San Joaquin River west of Jersey Point.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, the combined effect of all three intakes is examined. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Winter-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant

particles such as phytoplankton. To examine the effect on neutrally buoyant particles, the distance that a particle would travel due to the maximum permitted Rock Slough diversions over the course of a day is calculated. A change in velocity of 0.00625 ft/sec could move a neutrally buoyant particle approximately 540 ft over the course of the day (0.00625 ft/sec * 86,400 sec/day). For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is not significant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 4 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Alternative 4 includes the North Bay Aqueduct (NBA) intake in the North Delta and operation of the Barker Slough Pumping Plant. Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant (monitoring data is available at https://www.wildlife.ca.gov/Regions/3)). There should be no discernable effect to the Winter-Run Chinook Salmon due to the operations of the Barker Slough Pumping Facility. This is due to the infrequent presence of Winter-Run Chinook Salmon in the monitoring surveys indicating a low risk of entrainment. Further, Barker Slough Pumping Facility fish screens are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment while greatly minimizing any impingement of fish against the screen.

Potential changes to aquatic resources due to water transfers

Under Alternative 4, Reclamation is extending the water transfer window until November, from the current July through September window. This extension could result in increased flows entering the Delta and increased pumping at Jones and Banks Pumping Plants.

Egg, alevin, and fry life stages of Winter-Run Chinook Salmon do not occur in the Delta, and therefore would not be affected by this action. Winter-Run Chinook Salmon juveniles enter the Delta starting in December, and therefore would be unlikely to be exposed to increased pumping of water transfers through November. Adults returning from the ocean could possibly be in the Delta in July; however, they are strong swimmers, large fish that can avoid predators, and are unlikely to have impacts associated with direct entrainment of the pumping plants.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Winter-Run Chinook Salmon are present in the Delta between December and May with a peak in March and April (Reclamation 2019). The application of aquatic herbicide to the waters of CCF will occur during the summer months of July and August. Thus, the probability of exposing Winter-Run Chinook Salmon to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the water temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June.

Mechanical harvesting would occur on an as-needed basis and, therefore, Winter-Run Chinook Salmon could be exposed to this action, if entrained into the CCF.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

A small proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility. Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements based on lack of observed salvage during the August to October in-water work window (see Figures F.2.7, F.2.8, and F.2.9 in Appendix F of the ROC LTO BA). However, a few early migrants could occur during the in-water work window based on occurrence in the north Delta (see Figures WR_Seines and WR_Sherwood in Appendix F of the ROC LTO BA).

To the extent that the construction affects the ability of juvenile Winter-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Figure 5.6-44), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Chinook Salmon entrained into CCF. It is important to note that only small proportions of Winter-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014).

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May to meet salinity standards set by the State Water Resources Control Board and Suisun Marsh Preservation Agreement provides water quality benefits to Winter-Run Chinook Salmon habitat. This beneficial operation coincides with downstream migration of juvenile Winter-Run Chinook Salmon (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Winter-Run Chinook Salmon in Montezuma Slough thus, the proportion of the total run utilizing this route is unknown. Winter-Run Chinook Salmon typically migrate through the estuary several months before spawning, but an extended delay in the estuary may affect their ability to access their natal spawning streams. Winter-Run generally utilize high stream flow conditions to assist their upstream migration. Rapid upstream movement may be needed to take advantage of a short duration high stream flow event, particular in dry years when high flow events may be uncommon. NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.7 ft/s, so that juvenile Winter-Run Chinook Salmon would be excluded from entrainment.

The Morrow Island Distribution System (MIDS) diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, its unlikely juvenile Winter-Run Chinook Salmon will be entrained into the water distribution system, since Winter-Run Chinook have not be caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor Winter-Run Chinook Salmon.

Goodyear Slough Outfall improves water circulation in the marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Winter-Run Chinook Salmon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits juvenile Winter-Run Chinook Salmon in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat No Winter-Run Chinook Salmon are detected in the Delta between June and September. Therefore, no effects would occur as a result of the Suisun Marsh Salinity Control Gate operation.

Potential changes to aquatic resources due to changes from Clifton Court predator management

Clifton Court predator management efforts could reduce predation on listed fishes following entrainment into CCF, reducing pre-screen loss.

Potential changes to aquatic resources due to the San Joaquin Basin Steelhead Telemetry Study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

Potential changes to aquatic resources from monitoring

A number of monitoring activities described in Appendix C - Real Time Water Operations Charter, in section Routine Operations and Maintenance on CVP Activities would have the potential to capture Winter-Run Chinook Salmon. Not all the existing IEP monitoring programs that target pelagic fish identify Chinook Salmon race. Of the programs that target and identify Winter-Run Chinook Salmon, collective catches are less than 1% of the Winter-Run JPE (Reclamation 2019). Because such a small percentage of the total JPE is captured in the monitoring programs, the effects of the monitoring programs are not likely to have effects to the Winter-Run population. These monitoring programs are important for understanding entry and residence time of Winter-Run Chinook Salmon into the Delta and San Francisco Estuary.

O.3.9.8.4 Central Valley Spring-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Reclamation and DWR propose to operate the C.W. Bill Jones Pumping Plant and the Harvey O. Banks Pumping Plant. These pumping plants affect the hydrodynamics of the south and central Delta resulting in effects to Spring-Run Chinook Salmon entrainment, routing and through Delta survival. Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to negatively impact juvenile Chinook Salmon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, 2) “far-field” mortality resulting from altered hydrodynamics. See Winter-Run Chinook Salmon effects section for more detail concerning “far-field” and “near-field.”

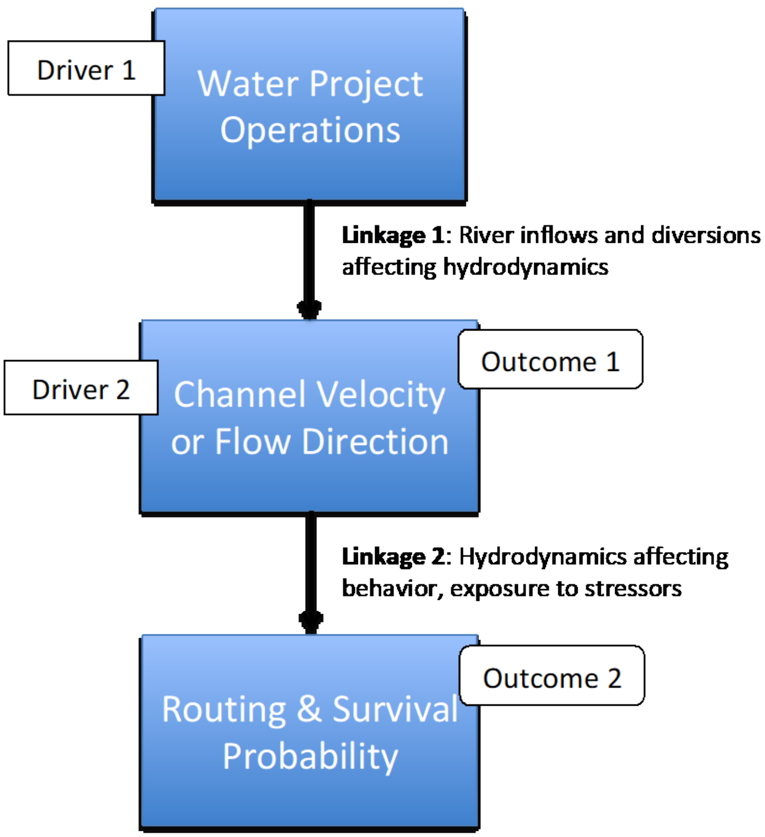

Figure O.3-149. Conceptual model for far-field effects of water project operations on juvenile salmonids in the Delta. This CM is a simplified version of the information provided by the CAMT SST.

Entrainment

Among 6.8 million tagged natural origin and 2.8 million tagged hatchery origin Spring-Run Chinook Salmon juveniles, entrainment loss averaged less than 0.0005% (Zeug and Cavallo 2014). Although data for juvenile Spring-Run Chinook Salmon originating from the San Joaquin River are limited, Zeug and Cavallo (2014) analyzed salvage of San Joaquin River-origin Fall-Run juvenile Chinook Salmon that are found in the Delta at a similar time as Spring-Run Chinook Salmon. Salvage of Fall-Run Chinook Salmon originating from the San Joaquin River averaged 1.4% and increased with export rate at the CVP and

SWP (Zeug and Cavallo 2014). However, there were few observations at export rates greater than 3,000 cfs. Average mortality at the facilities represents < 5% total juvenile mortality for San Joaquin River-origin populations but can range as high as 17.5% (Zeug and Cavallo 2014).

In the December through February period, Alternative 4 proposes an average total export rate slightly higher than No Action Alternative (119 cfs; Figure O1-1 in Appendix O, Attachment 1) and will, therefore, have a slightly higher entrainment risk. Total exports proposed for Alternative 4 in March-June (1,004 cfs lower than No Action Alternative; Figure O1-2), when juvenile Spring-Run Chinook Salmon are most abundant in the Delta, will decrease entrainment risk relative to No Action Alternative. Recent acoustic studies of juvenile Fall-Run Chinook Salmon in the San Joaquin River revealed that when the Head of Old River Barrier is out, >60% of fish detected at Chipps Island came through CVP, indicating that salvage is a higher survival route than volitional migration.

Routing

As stated in the Sacramento Winter-Run Chinook effects section, routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Juvenile Spring-Run Chinook Salmon are present in the Delta between November and early June with a peak in April (Reclamation 2019). In the December to February period, velocity overlap between Alternative 4 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 92%, 76%, 63%, 71%, and 58% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-53 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 4 in all water year types indicating routing into the interior Delta would be lower relative to No Action Alternative (Perry et al. 2015; Figure O1-57 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 4 was more than 91%, 69%, 48%, 46%, and 62% % in critical, dry, below normal, above normal, and wet years, respectively (Figure O1-54).

Spring-Run Chinook Salmon originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can be exposed to hydrodynamic project effects that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 4 and the No Action Alternative (Figure O1-55 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 4 to the No Action Alternative in the March to May period (Figure O1-56 in Appendix O, Attachment 1).

Juvenile Spring-Run Chinook Salmon are present in the Delta between November and early June with a peak in April (Reclamation 2019). Early studies using coded wire tags indicated that survival of San Joaquin River-origin juvenile Chinook Salmon was lower in the Old River Route relative to the San Joaquin main stem (Newman 2008). This finding led to strategies designed to keep larger proportions of fish in the San Joaquin River main stem including the Head of Old River rock barrier and non-physical barriers. Recent studies using acoustic technology have indicated that differences in survival among the two routes are not significant (Buchanan et al. 2013; Buchanan et al. 2018). Thus, fish that enter Old River are unlikely to experience reduced survival.

Spring–run Chinook Salmon originating from the San Joaquin River that remain in the San Joaquin River main stem at the Head of Old River are exposed to additional junctions that lead into the interior Delta including; Turner Cut, Columbia Cut, Middle River, Old River, Fisherman's Cut and False River. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junctions with San Joaquin Rivers between Alternative 4 and the No Action Alternative (Figures O1-55 in Appendix O, Attachment 1). Similar results were obtained when comparing Alternative 4 to No Action Alternative in the March to May period (Figures O1-56 in Appendix O, Attachment 1).

In the December through February period, velocity overlap between Alternative 4 and No Action Alternative in the channel upstream of the Head of Old River was 95.4%, 91.9%, 90.2%, 53.4%, and 72.9% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-55 in Appendix O, Attachment 1). In the March to May period, velocity overlap was 88.4%, 70.5%, 65.6%, 52.5%, and 67.5% in critical, dry, below normal, above normal, and wet years, respectively (Figures O1-56 in Appendix O, Attachment 1).

Through-Delta Survival

To examine potential effects of Alternative 4, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this "transitional" region. During the December to February period at Walnut Grove, velocity distributions for Alternative 4 relative to No Action Alternative were most different in wet years (70.5%) with higher velocities in Alternative 4. Velocities were also greater for Alternative 4 relative to No Action Alternative in below normal and above normal years although overlap was greater (>80%; Figure O1-57 in Appendix O, Attachment 1). In critically dry and dry years, velocity distributions were more similar (>84%; Figure O1-57 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, velocities under Alternative 4 were higher than No Action Alternative in wet, above normal, below normal, and dry years and similar in critically dry years (Figure O1-58 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 4 and No Action Alternative was most different in below normal (61.5%) and above normal water years (65.4%) with higher mean velocities in Alternative 4 (Figure O1-59 in Appendix O, Attachment 1). Velocity overlap was higher (>78%) in critically dry, dry, and wet water years with similar velocities under Alternative 4 (Figure O1-59 in Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 4 and No Action Alternative scenarios was most different in below normal (68.4%) and above normal water years (70.7%) with higher mean velocities in Alternative 4 (Figure O1-60 in Appendix O, Attachment 1). Velocity overlap was higher (>81%) in critically dry, dry, and wet water years with similar velocities under Alternative 4 (Figure O1-60 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 4, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the "transitional" region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 4 relative to No Action Alternative exhibited high overlap in all water year types (≥84.2%; Figure O1-61 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 4 and No Action Alternative in critically dry, dry, and below normal water years (≥77%) and moderate in above normal and wet years (>53%; Figure O1-62 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 4 and No Action Alternative (≥83%; Figure O1-63 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-63). At the Head of Middle River in the March –May period, overlap between Alternative 4 and No Action Alternative was moderate in most water year types (54-75%) and high in critically dry years 93.5% (Figure O1-64 in Appendix O, Attachment 1). Velocities were similar or slightly higher under Alternative 4 than No Action Alternative (Figure O1-64).

Potential changes to aquatic resources OMR Management

See section on seasonal operation above which integrates OMR management

Potential changes to aquatic resources due to Delta Cross Channel operations

The Delta Cross Channel may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. Significant amounts of flow and many juvenile Spring-Run Chinook Salmon enter the DCC (when the gates are open) and Georgiana Slough, especially during increased Delta pumping. Mortality of juvenile Salmon entering the central Delta is higher than for those continuing downstream in the Sacramento River. Juvenile Chinook Salmon which that entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010) The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Spring-Run Chinook Salmon in the Sacramento River past Knights Landing, which is upstream of the DCC, occurs from March-April (Reclamation 2019). Therefore, the DCC is closed to protect the majority of the juvenile Spring-Run migration period in the Sacramento River and reduce the proportion of fish exposed to an open DCC.

Potential changes to aquatic resources due to the Temporary Barriers Project

The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30.

The proportion of juvenile Spring-Run Chinook Salmon exposed to the agricultural barriers (Temporary Barrier Program, TBP) depends on their annual timing of installation and removal. Due to their location, primarily migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Spring-Run Chinook Salmon in the Delta is March and April (Reclamation 2019). If the agricultural barriers are operating as early as April 15 then they have the potential to expose a large proportion of the juvenile Spring-Run Chinook Salmon migrating down the San Joaquin River. When the Head of Old River barrier is not in place, acoustically tagged juvenile Chinook Salmon have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). Flap gates tied up on agricultural barriers from May 16 to May 31 would help to reduce the negative effect of the barriers during this period. However, juveniles migrating before or after this period could be exposed to the agricultural barriers with flaps down which apparently decreases passage success and survival (DWR 2018).

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 4 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD's operation, including operation of the Rock Slough Intake, for Alternative 3 remain unchanged from the current operations.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory route for Central Valley Spring-Run Chinook Salmon (NMFS 2017c), approximately 18 miles from the Sacramento River and 10 miles from the San Joaquin River via the shortest routes. Designated critical habitat for Spring-Run Chinook Salmon does not occur within Rock Slough, but is present further to the north in the Delta (NMFS 2017c, 2014). Salmonids are expected to avoid the area of the Rock Slough Intake during certain times of the year based on historical water temperatures, which range from lows of about 45°F in winter (December and January) to over 70°F beginning in May and continuing to October (Reclamation 2016).

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Central Valley Spring-Run Chinook Salmon presence near the Rock Slough Intake. Since 1994, fish monitoring has been conducted by CDFW and CCWD consistent with the separate biological opinions and permits that govern CCWD's operations. From 1994 through 1999, CDFW conducted fish monitoring at the Rock Slough Intake and in the Contra Costa Canal up to the first pumping plant. Over this 6-year period, CDFW captured a total of 108 juvenile Central Valley Spring-Run from March through May (CDFG 2002c; NMFS 2017c). From 1999 to 2009, the 11 years prior to construction of the RSFS, CCWD's Fish Monitoring Program collected a total of 11 juvenile Central Valley Spring-Run from March through May at the Rock Slough Headworks (Reclamation 2016; NMFS 2017c) and 4 juvenile Central Valley Spring-Run at Pumping Plant #1 (CCWD 2019). No adult Spring-Run were collected in the vicinity of the Rock Slough Intake from 1994 through 2009 (CDFG 2002c; Reclamation 2016; NMFS 2017c). No juvenile or adult Central Valley Spring-Run have been collected in CCWD's Fish Monitoring Program at the Rock Slough Intake since 2008.

Since construction of the RSFS, operation of the hydraulic rake cleaning system has been shown to trap and kill adult Chinook Salmon and other non-listed fish (Reclamation 2016). From 2011-2018, 47 Salmon were recovered at the RSFS (Reclamation 2016, Appendix A; Tenera Environmental 2018a), but none of the captured fish were identified as Spring-Run Chinook Salmon (NMFS 2017c).

CCWD's Fish Monitoring Program also samples behind the fish screens at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never collected Spring-Run Chinook Salmon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

CCWD's operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD's operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD's operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes (i.e., 10 miles from the San Joaquin River and 18 miles from the Sacramento River), juvenile Spring-Run Chinook Salmon are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Spring-Run can be "drawn" into the south Delta under reverse flows and high CVP and SWP pumping rates.

One indicator of reverse flows is the net flow in OMR. Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect net reverse flow in OMR, and any effect that diversions at Rock Slough Intake would have in the OMR corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the OMR corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstem of the Sacramento River or the San Joaquin River and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run Chinook Salmon. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, we examine the combined effect of all three intakes. CCWD's Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD's combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD's Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Spring-Run Chinook Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run Chinook Salmon section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is insignificant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 4 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Alternative 4 includes the North Bay Aqueduct (NBA) intake in the North Delta and operation of the Barker Slough Pumping Plant. Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant (monitoring data is available at https://www.wildlife.ca.gov/Regions/3). The NBA is located within designated critical habitat for Spring-Run Chinook Salmon. There should be no discernable effect to the Spring-Run Chinook Salmon due to the operations of the Barker Slough Pumping Facility. This is due to the infrequent presence of Spring-Run Chinook Salmon in the monitoring surveys indicating a low risk of entrainment. Further, Barker Slough Pumping Facility fish screens are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment while greatly minimizing any impingement of fish against the screen.

Potential changes to aquatic resources due to water transfers

Under Alternative 4, Reclamation is expanding the transfer window to November from the current July to September. Expanding the transfer window could lead to increased pumping at Jones and Banks Pumping Plants, when capacity is available. The Figures below show when capacity is available under Alternative 1 and the No Action Alternative, in terms of exceedances, years in the model period of record, and average by water year types. These values are total available and are not filtered for the pattern on which water might be acquired for transfer. The pattern of acquisition could decrease these values, as well as reoperation of storage that might be required, or the water cost of meeting D-1641. Prior estimates indicate that approximately 50% of the capacity in the figures below would be useful for water transfers given these timing and upstream considerations. In addition, a 20-30% surcharge on acquisition might be necessary to accommodate the salinity related inefficiencies that arise in operations. Based on the figures below and these additional estimates, expanding the water transfer window could result in an additional approximately 50 TAF of pumping in most year types. As more stored water is available from CVP and SWP reservoirs to pump in wetter year types, most of the available capacity for transfers is in drier year types (Figures O.3-150 through O.3-151).

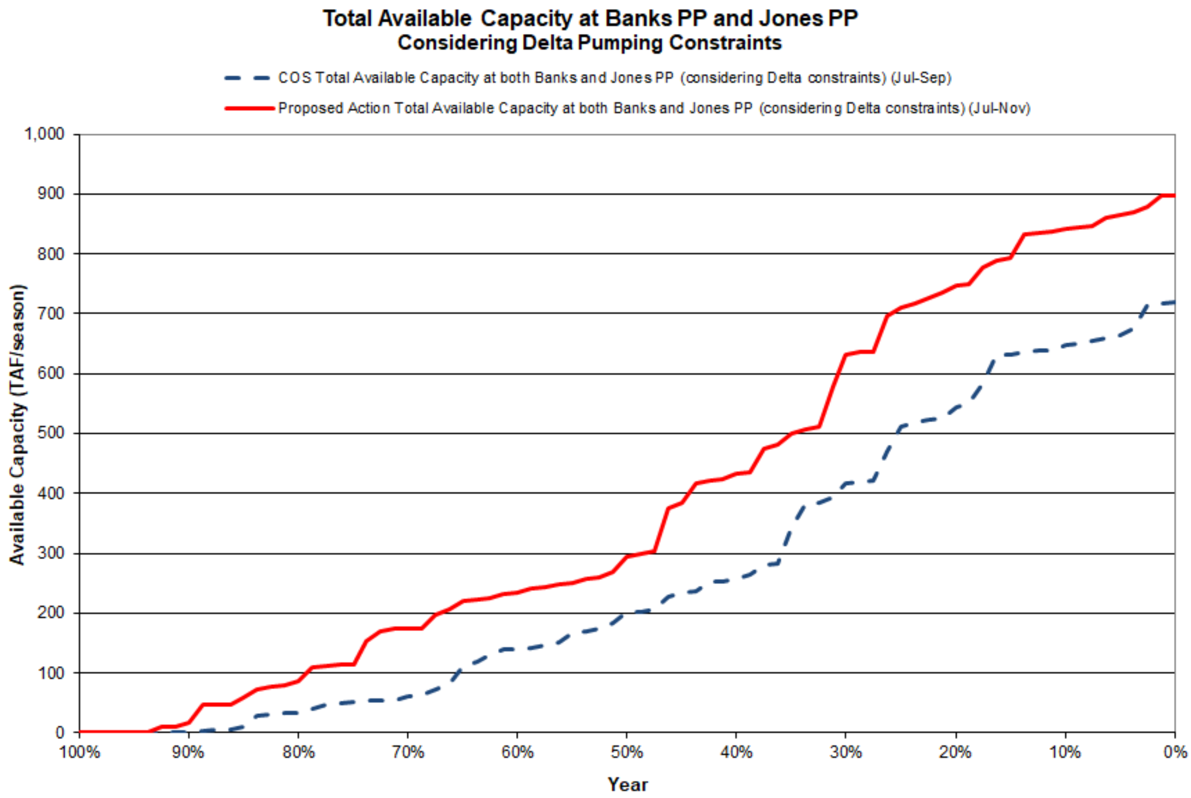

Figure O.3-150. Exceedance of Available Capacity for Transfers at Jones and Banks under the Alternative 1 and No Action Alternative

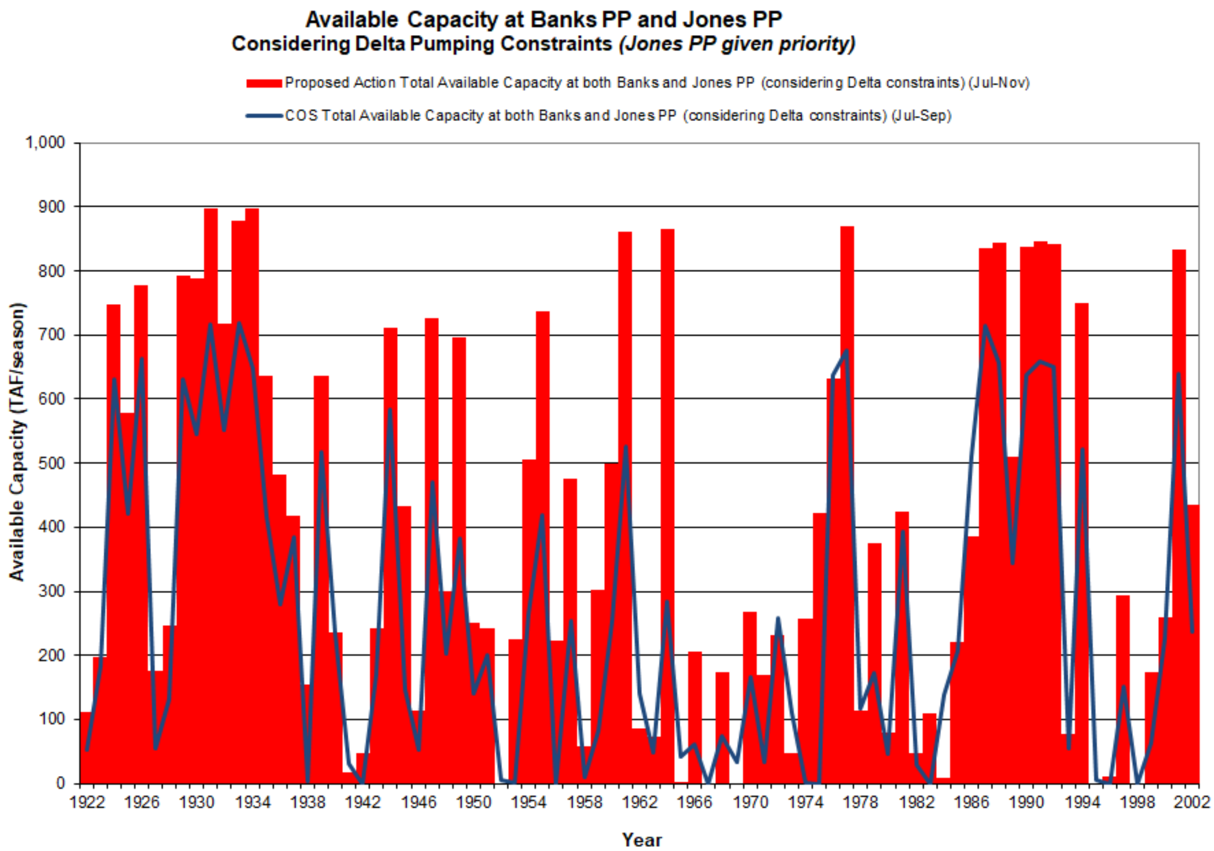

Figure O.3-151. Modeled Annual Maximum Available Capacity for Transfers under Alternative 1 and No Action Alternative, CalSim Period of Record (1922–2003)

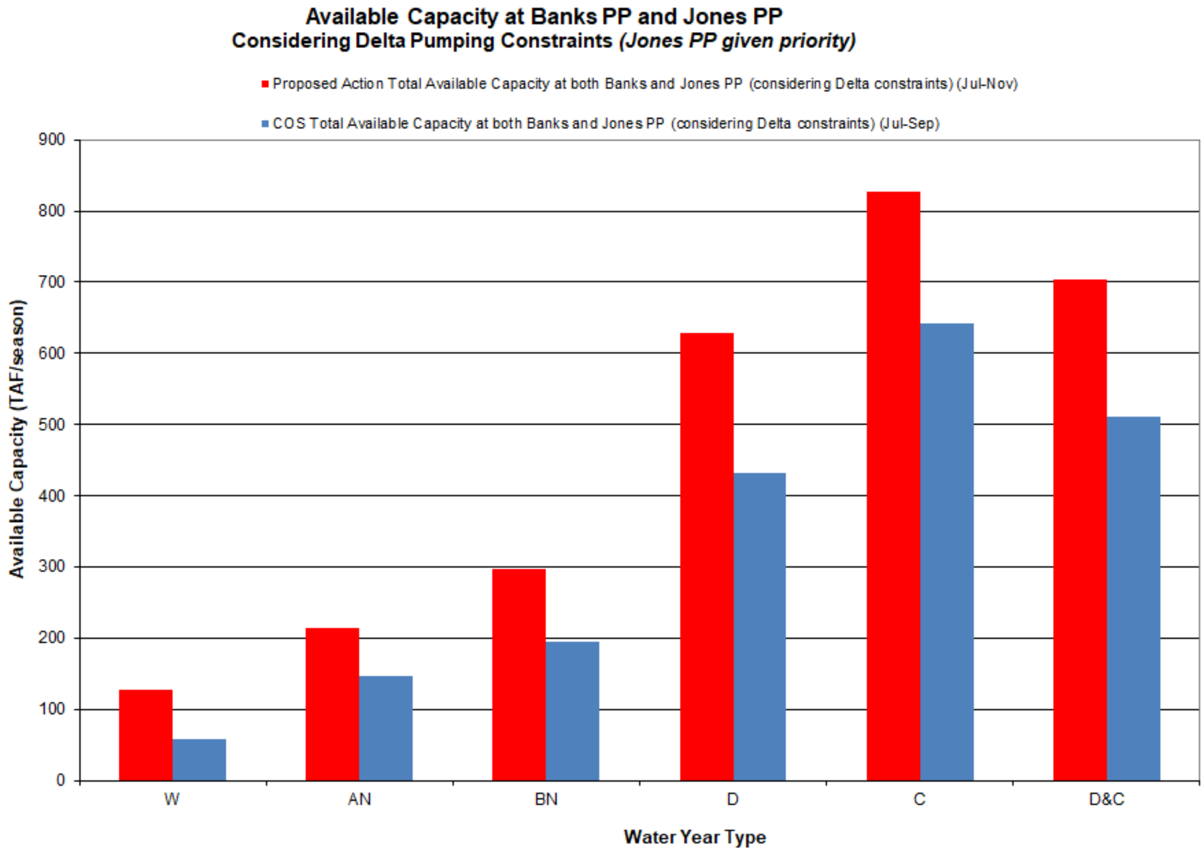

Figure O.3-152. Water Year Type average available capacity at Jones and Banks Pumping Plants

Egg, alevin, fry, and adult life stages of Spring-Run Chinook Salmon would not be exposed to the effects of increased water transfers as they do not occur in the Delta during July through November. Juvenile Central Valley Steelhead are detected at Chipps Island between December and July with the highest abundance in March to May (Reclamation 2019). Thus, only the very early or late migrants could potential be exposed to water transfers that occur during this time. These early or late migrant juvenile Spring-Run Chinook Salmon could be exposed to increased effects of entrainment, routing, and decreased Delta survival (see OMR management section) as a result of the expanded water transfer window. Increased flows during conveyance in the Sacramento River could provide small survival benefits to migrating juveniles (Perry et al. 2018).

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Spring-Run are present in the Delta between mid-November and early June with a peak in April (Reclamation 2019). The application of aquatic herbicide to the waters of Clifton Court Forebay will occur during the summer months of July and August. Thus, the probability of exposing Spring-Run Chinook Salmon to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

A number of programmatic actions are proposed to improve salvage efficiency of TFCF, including installing a carbon dioxide injection device to allow remote controlled anesthetization of predators in the secondary channels of the Tracy Fish Facility. These actions could potentially benefit juvenile Spring-Run Chinook Salmon through greater salvage efficiency.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see figures in Appendix F of the ROC LTO BA: WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race). Risks to these few individuals would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*), the selected in-water work window, and the small scale of the in-water construction. For juvenile Spring-Run Chinook Salmon that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Predator control efforts at Skinner Fish Facility under Alternative 4 to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May to meet salinity standards set by the State Water Resources Control Board and Suisun Marsh Preservation Agreement provides water quality benefits to Spring-Run Chinook Salmon habitat. This beneficial operation coincides with downstream migration of juvenile Spring-Run Chinook Salmon (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Spring-Run Chinook Salmon in Montezuma Slough thus, the proportion of the total run utilizing this route is unknown. Spring-Run Chinook Salmon typically migrate through the estuary several months before spawning, but an extended delay in the estuary may affect their ability to access their natal spawning streams. Spring-Run generally utilize high stream flow conditions during the spring snowmelt to assist their upstream migration. Rapid upstream movement may be needed to take advantage of a short duration high stream flow event, particularly in dry years when high flow events may be uncommon. If the destination of a pre-spawning adult Salmon is among the smaller tributaries of the Central Valley, it may be important for migration to be unimpeded, since access to a spawning area could diminish with receding flows. However, NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.7 ft/s, so that juvenile Spring-Run Chinook Salmon would be excluded from entrainment.

The Morrow Island Distribution System (MIDS) diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, its unlikely juvenile Central Valley Spring-Run Chinook Salmon will be entrained into the water distribution system, since Spring-Run Chinook have not been caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor Spring-Run Chinook Salmon.

Goodyear Slough Outfall improves water circulation in the marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Spring-Run Chinook Salmon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits juvenile Spring-Run Chinook Salmon in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat No Spring-Run Chinook Salmon are detected in the Delta between June and September. Therefore, no effects would occur as a result of the Suisun Marsh Salinity Control Gate operation.

Potential changes to aquatic resources due to changes from Clifton Court predator management

Predator control efforts at Clifton Court Forebay under Alternative 4 could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts during the summer in-water work window.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

Potential changes to aquatic resources from monitoring

Less than 2% of the estimated Spring-Run Chinook Salmon population, as indexed by the Red Bluff Rotary Screw Trap data, is collectively captured by the salmonid monitoring programs that support CVP operations (Reclamation 2019). Because such a small percentage of the estimated Spring-Run Chinook Salmon juvenile production is captured in the monitoring programs, the effects of the monitoring programs are not likely to have effects to the Spring-Run population.

O.3.9.8.5 Central Valley Fall-Run Chinook Salmon

Potential changes to aquatic resources due to seasonal operations

Hydrodynamic changes associated with river inflows and South Delta exports have been hypothesized to adversely affect juvenile Chinook Salmon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, 2) “far-field” mortality resulting from altered hydrodynamics. Near-field or entrainment effects of proposed seasonal operations can be most appropriately assessed by examining patterns of proportional population entrainment available from decades of coded wire tag studies (e.g., Zeug and Cavallo 2014). A foundation for assessing far-field effects has been provided by work of the Collaborative Adaptive Management Team’s (CAMT) Salmonid Scoping Team (SST). The SST completed a thorough review of this subject and defined a driver- linkage-outcome (DLO) framework for specifying how water project operations (the "driver") can influence juvenile salmonid behavior (the "linkage") and potentially cause changes in survival or routing (the "outcome"). The SST concluded altered "Channel Velocity" and altered "Flow Direction" were the only two hydrodynamic mechanisms by which exports and river inflows could affect juvenile salmonids in the Delta. Figure O.3-153 provides a simplified conceptual model of the DLO defined by the CAMT SST.

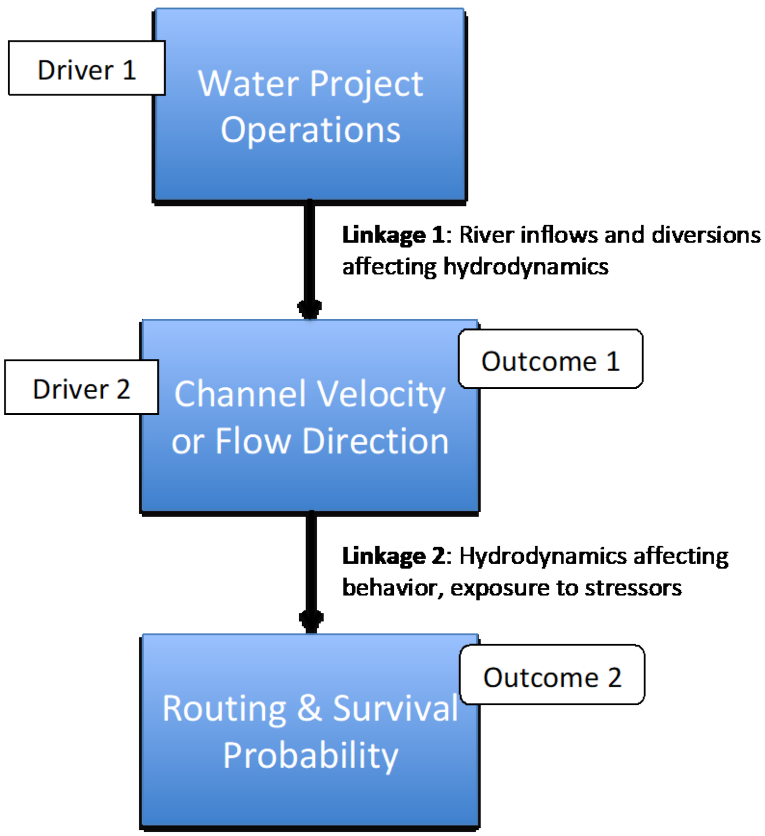

Figure O3-153. Conceptual model for far-field effects of water project operations on juvenile salmonids in the Delta. This CM is a simplified version of the information provided by the CAMT SST.

Though many juvenile salmonid tagging studies have been conducted in the Delta, the focus has primarily been on estimating reach survival and routing- not assessing export-related hydrodynamic mechanisms defined by the SST's DLO. In fact, most tagging studies have targeted areas of the Delta where "Channel Velocity" and "Flow Direction" may not be appreciably affected by exports (e.g., Newman and Brandes 2010; Perry et al. 2010; Perry et al. 2012; Perry et al. 2015; Michel et al. 2013).

In order to assess the potential for water project operations to influence survival and routing, we analyzed Delta hydrodynamic conditions by utilizing outputs from DSM2 Hydro modeling. Our analysis of DSM2 output is based on our previous work creating map-based visualizations of spatial hydrodynamic patterns at the scale of the Delta. The map-based approach allows us to identify a 'footprint' of the hydrodynamic differences between scenarios. The maps are based on a comparative metric, proportion overlap (more below), to capture channel-level hydrodynamic details as a single number for color-scaled mapping of

Delta channels. Our previous work made clear that spatial patterns were more easily discerned by mapping comparative metrics than by mapping descriptive metrics in multiple panels.

The objective of the comparative metric is to summarize the water velocity time series for each channel and scenario such the channel-level comparison is captured in a single number. For the proportion overlap metric, kernel density estimates are calculated on each time series. The kernel density estimates represent a non-parametric smoothing of the empirical distribution of time series values. The proportion overlap of two kernel density estimates is calculated with the following steps: 1) calculate the total area under the curve (AUC_t) as the sum of the AUC for each density estimate, 2) calculate the AUC of the overlapping portions (AUC_o) of the two density distributions being compared, and 3) calculate the overlapping proportion of the density distributions as AUC_o/AUC_t. Proportion overlap is naturally bound by zero and one; a value of zero indicates no overlap and a value of one indicates complete overlap. Lower values of proportion overlap identify channels demonstrating larger differences in a scenario comparison.

The proportion overlap metric is best applied over relatively short time periods because seasonal and annual variation in water velocity can overwhelm differences between scenarios. Thus, we calculated proportion overlap for every DSM2 channel for two seasons (Dec-Feb, May-Mar) in each water year (1922–2003). We excluded DSM2 output from water year 1921 to allow for an extensive burn-in period. We calculated proportion overlap based on hourly DSM2 output. Because each season was roughly 90 days, each comparison involved roughly 4,300 DSM2 values (2 scenarios * 24 hours * 90 days) for each channel.

Because we calculated proportion overlap for each channel in each water year, we summarized the proportion overlap values prior to mapping (i.e., not feasible to map proportion overlap for every comparison in every water year). To summarize, we found the minimum proportion overlap for each channel for each water year type for each comparison. The minimum values represent the maximum expected effect. Note that the year with the minimum proportion overlap for one channel might not be the same year as for another channel.

Entrainment

Zeug and Cavallo (2014) analyzed > 1000 release groups representing, more than 28 million coded wire tagged juvenile fish including winter, late fall and Fall-Run Chinook Salmon. This data is extremely useful because it represents large release groups of tagged smolts where the number of fish representing each release group lost to entrainment at the export facilities has been estimated. Estimating loss from "raw" salvage is problematic because the actual stock or basin of origin is often unknown (e.g., poor performance of length-at-date curves). Furthermore, with "raw" salvage, the number of smolts produced and potentially exposed to entrainment is unknown. The CWT salvage data analyzed by Zeug and Cavallo (2014) overcomes these deficiencies and provides the most appropriate basis for defining stock-specific categories of entrainment risk.

The average proportion Sacramento River-origin Fall-Run Chinook salvaged over a 15-year period was 0.0001 and the proportion of mortality accounted for by entrainment averaged 0.0003 (Zeug and Cavallo 2014). Salvage increased with increasing exports, but loss never exceeded 1% regardless of export rate. Late Fall-Run juveniles were salvaged at a higher rate than any other race (0.02% of each release group) and entrainment related mortality accounted for almost 1% of total mortality on average (Zeug and Cavallo 2014). Proportional loss of Late-Fall remained low until exports exceeded ~9,000 cfs when proportional loss could approach 8% (Zeug and Cavallo 2014). In the December through February period when Late Fall-Run are most abundant, Alternative 4 proposes an average total export rate slightly higher than No Action Alternative (119 cfs; Figure O1-1) and will therefore have a slightly higher entrainment risk. Total exports proposed for Alternative 4 in March-June (554 cfs lower than No Action Alternative; Figure O1-2) when juvenile Fall-Run are most abundant in the Delta, will decrease entrainment risk relative to No Action Alternative.

Routing

Routing of juvenile Chinook Salmon into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 4 were evaluated using DSM2 as described above. Juvenile Fall-Run Chinook Salmon abundance in the Delta is greatest between February and May and Late Fall-Run are present in the Delta between November and July with peaks in January through February and April through May (Table FR_1, LFR_1). In the December through February period, velocity overlap between Alternative 4 and No Action Alternative in the Sacramento River main stem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 92%, 76%, 63%, 71%, and 8% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-53 in Appendix O, Attachment 1). During the December through February period, velocities were higher under Alternative 4 in all water year types indicating routing into the interior Delta would be lower relative to No Action Alternative (Perry et al. 2015; Figure O1-57 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 4 was more than 91%, 69%, 48%, 46%, and 62% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-54).

Fall-Run and Late Fall-Run juveniles originating from the Sacramento River that enter the interior Delta via Georgiana Slough and the Delta Cross Channel can be exposed to hydrodynamic project effects that could affect routing. Once these fish arrive at the junction of the Mokelumne River and the San Joaquin River, they can move south toward the export facilities or west toward the ocean. In the December through February period analysis of DSM2 data indicates that there is little change to velocities in the region of the junction of the Mokelumne and San Joaquin Rivers between Alternative 4 and the No Action Alternative (Figure O1-55). Similar results were obtained when comparing Alternative 4 to the No Action Alternative in the March to May period (Figure O1-56).

Through-Delta Survival

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of the proposed project, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, velocity distributions for Alternative 4 relative to No Action Alternative were most different in wet years (70.5%) with higher velocities in Alternative 4. Velocities were also greater for Alternative 4 relative to No Action Alternative in dry, below normal, and above normal years although overlap was greater (>80%; Figure O1-57 in Appendix O, Attachment 1). In critically dry years, velocity distributions were more similar (>95%; Figure O1-57 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, velocities under Alternative 4 were similar or higher than No Action Alternative in all water year types (Figure O1-58 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 4 and No Action Alternative was lowest in below normal (61.5%) and above normal (65.4%) years with higher mean velocities under Alternative 4 (Figure O1-59 in Appendix O, Attachment 1). In critically dry, dry, and wet water years, overlap was higher (>78%) with similar velocities under Alternative 4 (Figure O1-59 in

Appendix O, Attachment 1). At Steamboat Slough in the March through May period, overlap between Alternative 4 and No Action Alternative was lowest in below normal (68.4%) and above normal (70.7%) years with higher mean velocities under Alternative 4 (Figure O1-60 in Appendix O, Attachment 1). In critically dry, dry, and wet water years, overlap was higher (>81%) with similar velocities under Alternative 4 (Figure O1-60 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 4, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the "transitional" region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 4 relative to No Action Alternative exhibited high overlap in all water year types (≥84.2%; Figure O1-61 in Appendix O, Attachment 1). At the Head of Middle River during the December through February period, overlap was high between Alternative 4 and No Action Alternative in critically dry, dry, and below normal water years (≥88%) and moderate in wet and above normal years (53% to 75%; Figure O1-62 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 4 and No Action Alternative (>83%; Figure O1-63 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-63). At the Head of Middle River in the March –May period, overlap between Alternative 4 and No Action Alternative was moderate in most water year types (55-75%) and higher in critically dry years >93% (Figure O1-64 in Appendix O, Attachment 1). Velocities were generally lower under Alternative 4 than No Action Alternative (Figure O1-64 in Appendix O, Attachment 1).

Potential changes to aquatic resources OMR Management

See section on seasonal operations which includes OMR management

Potential changes to aquatic resources due to Delta Cross Channel operations

The Delta Cross Channel may be closed for up to 45 days from November through January for fishery protection purposes. From February 1 through May 20, the gates are closed for fishery protection purposes. The gates may also be closed for 14 days from May 21 through June 15 for fishery protection purposes. The peak migration of juvenile Fall-Run Chinook Salmon in the Sacramento River past West Sacramento, which is near the DCC, occurs from February through May (Table FR_1). Therefore, the DCC is closed for the majority of the juvenile Fall-Run migration period in the Sacramento River and as such the proportion of fish exposed to an open DCC would be low. Juvenile Fall-Run Chinook Salmon that are entrained into an open DCC and transported to the interior Delta have reduced survival (Perry et al. 2010).

Potential changes to aquatic resources due to the Temporary Barriers Project

The Temporary Barriers Project (TBP) consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions and one rock barrier to improve San Joaquin River salmonid migration in the south Delta. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, Grant Line Canal near Tracy Boulevard Bridge, and the head of Old River. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30. The head of Old River Barrier is only installed from September 16 to November 30 to improve flow and dissolved oxygen conditions in the San Joaquin River for the immigration of adult Fall-Run Chinook Salmon.

The proportion of juvenile Fall-Run exposed to the TBP depends on their annual timing of installation and removal. Due to their location, primarily migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Fall-Run in the Delta at Mossdale is February through May (Table FR_1). The Head of Old River Barrier would have no effect on juvenile Fall-Run if installed from September 16 to November 30 as juvenile Fall-Run are largely absent from this section of the San Joaquin River during this time period (FR_1). If the agricultural barriers are operating as early as April 15 then they have the potential to expose a large proportion of the juvenile Fall-Run migrating down the San Joaquin River. When the Head of Old River barrier is not in place, acoustically tagged juvenile Chinook Salmon have demonstrated a high probability of selecting the Old River route (Buchanan 2018), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). Flap gates tied up on agricultural barriers from May 16 to May 31 would help to reduce the negative effect of the barriers during this period. However, juveniles migrating before or after this period could be exposed to the agricultural barriers with flaps down which apparently decreases passage success and survival (DWR 2018). Therefore, the potential negative effects of the agricultural barriers depend on when they are installed and whether the flap gates are down or tied up but overall would be medium to high.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD’s operations in Alternative 4 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD’s operations, including operation of the Rock Slough Intake, under Alternative 3 would remain unchanged from the current operations.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Fall-Run/Late Fall-Run Chinook Salmon presence near the Rock Slough Intake. From 1999 to 2011, the 11 years prior to construction of the RSFS, CCWD’s Fish Monitoring Program collected 23 juvenile Fall-Run/Late Fall-Run Chinook Salmon at the Rock Slough Headworks and Contra Costa Pumping Plant #1. Since construction of the Rock Slough Fish Screen in 2012, no Fall-Run/Late Fall-Run Chinook Salmon have been collected behind the fish screen. CCWD’s Fish Monitoring Program also samples at CCWD’s other south Delta intakes. Since the intakes have been in operation, CCWD’s Fish Monitoring Program has never collected Fall-Run/Late Fall-Run Chinook Salmon at CCWD’s Old River Intake or Middle River Intake (CCWD 2019).

CCWD’s operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD’s operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of CCWD’s operations on Delta hydrodynamics by determining the effect that CCWD pumping at

maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Central Valley Fall-Run/Late Fall-Run are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile Salmon can be “drawn” into the south Delta under reverse flows and high CVP and SWP pumping rates.

One indicator of reverse flows is the net flow in Old and Middle Rivers (OMR). Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect net reverse flow in Old and Middle Rivers (OMR), and any effect that diversions at Rock Slough Intake would have in the Old and Middle River corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the Old and Middle River corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstems of the Sacramento River or the San Joaquin River and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, we examine the combined effect of all three intakes. CCWD’s Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD’s combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD’s Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Central Valley Fall-Run/Late Fall-Run Salmon and are not likely to affect the movement of juvenile salmonids.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is not significant in comparison to the tidal excursion and mixing at this location.

In summary, CCWD's operations under Alternative 4 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Listed salmonids may be present in the waterways adjacent to the Barker Slough Pumping Plant, however several years of monitoring have failed to consistently capture any salmonids during the winter Delta Smelt surveys (1996 to 2004) in Lindsey Slough or Barker Slough. Captures of Chinook Salmon have usually occurred in the months of February and March and typically are only a single fish per net haul (http://www.delta.dfg.ca.goc/data/nba). Most Chinook Salmon captured have come from Miner Slough, which is a direct distributary from the Sacramento River via Steamboat and Sutter Sloughs. Few if any San Joaquin River-origin Fall-Run Chinook Salmon are expected to be exposed to the North Bay aqueduct because it is not on the migration route of this species.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few if any juvenile Fall-Run Chinook Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program. Juvenile Fall-Run are present in the Delta between mid-November and early June with a peak in April (Table_WR1). The application of aquatic herbicide to the waters of Clifton Court Forebay will occur during the summer months of July and August. Thus, the probability of exposing Spring-Run to the herbicide is very low. Based on typical water temperatures in the vicinity of the salvage facilities during this period, the temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June. Mechanical harvesting would occur on an as-needed basis and therefore listed salmonids could be exposed to this action, if entrained into the Forebay.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

Although actions at the Tracy facility could positively affect juvenile Fall-Run Chinook Salmon through greater salvage efficiency, only small proportions of Fall-Run Chinook Salmon are lost at the CVP (Zeug and Cavallo 2014).

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Chinook Salmon entrained into Clifton Court Forebay. However, given that only small proportions of Fall-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014), the population-level positive effect of this action would be low. Larger proportions of Late Fall-Run Chinook Salmon are lost at the facilities and this action would have a larger effect for this run.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May coincides with downstream migration of juvenile Fall-Run Chinook Salmon (Table FR_1). NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

As described by NMFS (2009: 437-438), the Roaring River Distribution System (RRDS)'s water intake (eight 60-inch-diameter culverts) is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.2 ft/s (for Delta Smelt protection), so that juvenile Fall-Run Chinook Salmon would be excluded from entrainment.

NMFS (2009: 438) considered it unlikely that juvenile Winter-Run Chinook Salmon, would be entrained by the three unscreened 48-inch culverts that form the Morrow Island Distribution System (MIDS) water intake, as a result of their larger size and better swimming ability relative to the size of Fall-Run Chinook Salmon observed to have been entrained (<45 mm), and also because the location of the MIDS intake on Goodyear Slough is not on a migratory corridor for listed juvenile salmonids. Although Fall-Run have been entrained at this facility, only a small proportion of total migrants are likely to encounter it.

NMFS (2009: 438) concluded that it would be unlikely that Chinook Salmon would encounter or be negatively affected by the Goodyear Slough outfall given its location and design, which is intended to improve water circulation in Suisun Marsh and therefore was felt by NMFS (2009: 438) to likely be of benefit to juvenile salmonids by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat

Juvenile Fall-Run Chinook Salmon are abundant in the Delta in December and January and April and May (Reclamation 2019). Late Fall-Run are most abundant from January through April. Small fractions of each run could be exposed to Fall Delta Smelt habitat actions. For fish that are exposed, increased turbidity may reduce susceptibility to predation and increase through-Delta survival.

Potential changes to aquatic resources due to changes from Clifton Court predator management

Pre-screen survival of juvenile Chinook Salmon has been shown to be low (Gingras 1997) and predation is thought to be a major source of mortality. Analyses by Zeug and Cavallo (2014) indicate that only small proportions of Sacramento River-origin Fall-Run Chinook Salmon arrive at the facilities. However, moderate proportions of San Joaquin River-origin Fall-Run arrive at the facilities. For fish that are entrained into Clifton Court Forebay, predator control may increase pre-screen survival. The overall effect of the action is low for Sacramento River-Origin fish and moderate for San Joaquin River and Mokelumne River-origin fish

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

No effect

O.3.9.8.6 Central Valley Steelhead

Potential changes to aquatic resources due to seasonal operations

Entrainment

ICF (2018) analyzed salvage of Central Valley Steelhead at the CVP and SWP between 2003 and 2017 and found that salvage increased with export rate and decreased with San Joaquin River flow. Salvage also decreased with OMR flow. However, OMR is a metric comprised of both exports and San Joaquin River flow which complicates attempts to understand individual effects.

In the December through February period, Alternative 4 proposes an average total export rate slightly higher than the No Action Alternative (119 cfs; Figure O1-1 in Appendix O, Attachment 1) and will therefore have slightly higher entrainment risk. Total exports proposed for Alternative 4 in March-June (554 cfs lower than No Action Alternative; Figure O1-2 in Appendix O, Attachment 1) when juvenile Central Valley Steelhead are most abundant in the Delta at Chipps Island (Reclamation 2019), will decrease entrainment risk relative to No Action Alternative.

Routing

Routing of juvenile Central Valley Steelhead into alternative migration routes is closely related to hydrodynamics (Perry et al. 2015; Cavallo et al. 2015; Steel et al. 2012). Changes to hydrodynamics in Delta channels resulting from Alternative 4 were evaluated using DSM2. Juvenile Central Valley Steelhead are present in the Sacramento River at Hood upstream of the first distributary junctions between November and early June with peak abundance from February to early June (Reclamation 2019). In the December to February period, velocity overlap between Alternative 4 and No Action Alternative in the Sacramento River mainstem between the Sutter-Steamboat and DCC/Georgiana Slough Junctions, was more than 92%, 76%, 63%, 71%, and 58% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-53 in Appendix O, Attachment 1). During the December to February period, velocities were similar or higher under Alternative 4 in all water year types indicating routing into the interior Delta would be lower relative to No Action Alternative (Perry et al. 2015; Figure O1-57 in Appendix O, Attachment 1). During the March to May period, velocity overlap between No Action Alternative and Alternative 4 was more than 91%, 69%, 48%, 46%, and 62% in critically dry, dry, below normal, above normal, and wet years, respectively (Figure O1-54 in Appendix O, Attachment 1).

Through-Delta Survival

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 4, changes in velocity distributions were examined for the Sacramento River at Walnut Grove and Steamboat Slough which are both in this “transitional” region. During the December to February period at Walnut Grove, velocity distributions for Alternative 4 relative to No Action Alternative were most different in wet years (70.5%) with higher velocities in Alternative 4. Velocities were also greater for Alternative 4 relative to No Action Alternative in dry, below normal, and above normal years although overlap was greater (>80%; Figure O1-57 in Appendix O, Attachment 1). In critically dry years, velocity distributions were more similar (95%; Figure O1-57 in Appendix O, Attachment 1). At Steamboat Slough in the December to February period, velocities under Alternative 4 were higher than No Action Alternative in most water year types and similar in critically dry years (Figure O1-58 in Appendix O, Attachment 1).

In the March through May period at Walnut Grove, velocity overlap between Alternative 4 and No Action Alternative was >78% in critically dry, dry, and wet water types with similar velocities under Alternative 4 (Figure O1-59 in Appendix O, Attachment 1). Overlap was most different in below normal (61.5%) and above normal (65.4%) years with higher mean velocities under Alternative 4 (Figure O1-59). At Steamboat Slough in the March through May period, overlap was most different in below normal (68.4%) and above normal years (70.7%) with higher mean velocities under Alternative 4 (Figure O1-60 in Appendix O, Attachment 1). Velocity overlap between Alternative 4 and No Action Alternative scenarios was >81% in critically dry, dry, and wet years with similar velocities under Alternative 4 (Figure O1-60 in Appendix O, Attachment 1).

A recent study by Perry et al. (2018) found that the effect of flow on survival is not uniform throughout the Delta. Relationships between flow and survival were significant only in reaches where flow changes from bi-directional to unidirectional when discharge increases. To examine potential effects of Alternative 4, changes in velocity distributions were examined for the San Joaquin River at Highway 4 and the Head of Middle River which are both in the "transitional" region of the San Joaquin River. During the December to February period at the San Joaquin River at Highway 4, velocity distributions for Alternative 4 relative to No Action Alternative exhibited high overlap in all water year types (>84%; Figure O1-61 in Appendix O, Attachment 1). At the Head of Middle River during the December to February period, overlap was high between Alternative 4 and No Action Alternative in critically dry, dry, and below normal water years (>88%) and moderate in wet and above normal years (53% to 75%; Figure O1-62 in Appendix O, Attachment 1).

In the March to May period in the San Joaquin River at Highway 4, velocity overlap was high between Alternative 4 and No Action Alternative (>83%; Figure O1-63 in Appendix O, Attachment 1). Velocities were similar in all water year types (Figure O1-63). At the Head of Middle River in the March –May period, overlap between Alternative 4 and No Action Alternative was moderate in most water year types (54% to 75%) and higher in critically dry years (93.5%; Figure O1-48 in Appendix O, Attachment 1). Velocities were similar or slightly higher under Alternative 4 than No Action Alternative (Figure O1-64).

Potential changes to aquatic resources OMR Management

See section on Seasonal Operations which includes OMR management

Potential changes to aquatic resources due to Delta Cross Channel operations

Significant flow and many juvenile Central Valley Steelhead enter the central Delta when the DCC gates are open. Mortality of juvenile Central Valley Steelhead entering the central Delta is higher than for those continuing downstream in the Sacramento River. The peak migration of juvenile Central Valley Steelhead in the Sacramento River past Knights Landing, which is upstream of the DCC, occurs from January through February (Reclamation 2019). Therefore under Alternative 4, the continued operation of the DCC to protect the majority of the juvenile Central Valley Steelhead during their migration period in the Sacramento River would reduce the proportion of fish exposed to an open DCC and result in beneficial impacts to this life stage when compared to the No Action Alternative.

Potential changes to aquatic resources due to the Temporary Barriers Project

The Temporary Barriers Project (TBP) consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions and one rock barrier to improve San Joaquin River salmonid migration in the south Delta. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, Grant Line Canal near Tracy Boulevard Bridge, and the head of Old River. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near

Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30. The Head of Old River Barrier is only installed from September 16 to November 30 to improve flow and dissolved oxygen conditions in the San Joaquin River for the immigration of adult Fall-Run Chinook Salmon.

The proportion of juvenile Central Valley Steelhead exposed to the TBP depends on their annual timing of installation and removal. Due to their location, primarily juvenile Central Valley Steelhead migrants originating from the San Joaquin River would be exposed to the TBP. The peak relative abundance of juvenile Central Valley Steelhead in the San Joaquin River in the vicinity of the TBP (Mossdale) occurs in April and May (Reclamation 2019). If the agricultural barriers are operating as early as April 15, there is potential exposure to a large proportion of the juvenile Central Valley Steelhead migrating down the San Joaquin River.

When the Head of Old River barrier is not in place, acoustically tagged juvenile Central Valley Steelhead have demonstrated a high probability of selecting the Old River route (Buchanan 2018[PC1]), which would expose them to the agricultural barriers. When the agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Central Valley Steelhead migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up, Central Valley Steelhead passage past the agricultural barrier was improved (DWR 2018). Therefore, although Alternative 4 does not include HORB, which could result in negative impacts to Central Valley Steelhead juvenile migration, the improvements to the agricultural barriers (including flap gates tied up from May 16 to May 31) would help to reduce the negative effect of the barriers on migrating juvenile Central Valley Steelhead during this period relative to No Action Alternative. However, juvenile Central Valley Steelhead migrating before or after this period could be exposed to the agricultural barriers with flaps down, which apparently decreases passage success and survival (DWR 2018). Therefore, the potential negative effects of the agricultural barriers under Alternative 4 on juvenile Central Valley Steelhead depends on when they are installed and whether the flap gates are down.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD’s operations in Alternative 4 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD’s intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD’s operations, including operation of the Rock Slough Intake, under Alternative 3 would remain unchanged from the current operations.

Fish monitoring prior to the construction of the Rock Slough Fish Screen (RSFS) indicates the timing and magnitude of Central Valley Steelhead presence near the Rock Slough Intake. From 1999 to 2011, the 11 years prior to construction of the RSFS, CCWD’s Fish Monitoring Program collected 15 juvenile Central Valley Steelhead at the Rock Slough Headworks and Pumping Plant #1. Since construction of the Rock Slough Fish Screen, no Central Valley Steelhead have been collected behind the fish screen. CCWD’s Fish Monitoring Program also samples at CCWD’s other south Delta intakes. Since the intakes have been in operation, CCWD’s Fish Monitoring Program has never collected Central Valley Steelhead at CCWD’s Old River Intake or Middle River Intake (CCWD 2019).

CCWD’s operations, including operation of the Rock Slough, Old River, and Middle River intakes and Los Vaqueros Reservoir, are simulated in the CalSim model. Thus, CalSim results discussed throughout this appendix include the effects of CCWD’s operations in combination with all other water diversions and reservoir operations. A further analysis was undertaken to isolate the maximum possible effects of

CCWD’s operations on Delta hydrodynamics by determining the effect that CCWD pumping at maximum capacity would have on Delta channel water velocity. Results of this analysis are shown below; in all cases the maximum possible effect of CCWD's operations is de minimis.

Due to the location of the Rock Slough Intake near the end of a dead-end slough, far from the main migratory routes, juvenile Central Valley Steelhead are not likely to be in the vicinity of the Rock Slough Intake. However, according to NMFS (2017), juvenile salmonids can be “drawn” into the south Delta under reverse flows and high CVP and SWP pumping rates. One indicator of reverse flows is the net flow in OMR. Rock Slough Intake is located on Rock Slough, approximately 3.5 miles west of the junction of Rock Slough and Old River, which is over 12 river miles north of the gates to the SWP Clifton Court Forebay. Given its location, the Rock Slough Intake does not affect OMR, and any effect that diversions at Rock Slough Intake under Alternative 3 would have in the OMR corridor would be to increase the northerly (positive) flow away from the Banks and Jones Pumping Plants. For juveniles that migrate down the Old and Middle River corridor that are not salvaged at TFCF or Skinner Fish Facility, any effect of Rock Slough Intake diversions would be a positive effect on OMR.

For juveniles that migrate down the mainstems of the Sacramento or San Joaquin Rivers and for juveniles that were salvaged, trucked, and released in the western Delta, the potential effect of Rock Slough diversions on the net reverse flow in San Joaquin River may be relevant. The effect of water diversions at Rock Slough Intake on the velocity in the San Joaquin River at Jersey Point is presented in the effects analysis for juvenile Winter-Run. As detailed in that section, the maximum potential effect of water diversions at Rock Slough Intake (assuming diversions at the maximum permitted capacity of 350 cfs and all water diverted by the Rock Slough Intake comes from the San Joaquin River at Jersey Point) is 0.00625 ft/sec in the San Joaquin River at Jersey Point. For comparison, the velocity threshold for design of fish screens to prevent impingement of salmonids is 0.33 ft/sec, which is 50 times the maximum possible contribution from the Rock Slough diversions.

Recognizing that CCWD owns and operates two additional intakes in the south Delta, the combined effect of all three intakes was examined. CCWD’s Old River Intake and Middle River Intake have a physical capacity of 250 cfs at each intake. If CCWD were to divert at all three intakes at the maximum capacity at the same time, total CCWD diversions would be 850 cfs. The corresponding effect on velocity in the San Joaquin River at Jersey Point would be 0.015 ft/sec. The velocity threshold used to protect salmonids from diversions in the vicinity of fish screens (0.33 ft/sec) is over 21 times greater than the maximum possible contribution from CCWD’s combined physical capacity. The water diversions at the Rock Slough Intake when combined with diversions at CCWD’s Old River Intake and Middle River Intake have a negligible effect on velocity along the migratory path for juvenile Central ValleySteelhead.

Nonetheless, even extremely small changes in velocity can affect the movement of neutrally buoyant particles such as phytoplankton. As shown in the Winter-Run section, the diversions at the Rock Slough Intake could move a neutrally buoyant particle in the San Joaquin River at Jersey Point approximately 540 ft over the course of the day. For comparison, the tidal excursion on the San Joaquin River at Jersey Point during a flood tide (i.e., the distance a particle will travel tidally upstream during a flood tide) is about 34,000 ft on average (or 6.4 miles), which is about 63 times the distance that diversions at Rock Slough could move a particle at the same location over the course of a full day. Therefore, the maximum possible contribution of diversions at Rock Slough on movement of neutrally buoyant particles such as phytoplankton is insignificant in comparison to the tidal excursion and mixing at this location. Although the diversions at Rock Slough Intake are not likely to impact juvenile Central Valley Steelhead, the aggregate effect of all water diversions in the Delta, including exports at Jones and Banks Pumping Plants can affect channel velocity.

In summary, CCWD's operations under Alternative 4 would remain consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir, and as shown above, the effect of CCWD's operations on Delta hydrodynamics is negligible.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Under Alternative 4, there would be no changes to operational criteria at the NBA's BSPP relative to current op. Juvenile Central Valley Steelhead could occur in the vicinity of the BSPP; however, the fish screens used at the facility are designed to protect juvenile salmonids per NMFS criteria and should prevent entrainment and greatly minimize impingement of fish against the screen itself (NMFS 2009). In addition, the location of the facility is well off the typical migration corridor of juvenile Central Valley Steelhead (NMFS 2009: 417). No juvenile Central Valley Steelhead have been captured during CDFW monitoring surveys from 1996 to 2004 (http://www.delta.dfg.ca.goc/data/nba).

Potential changes to aquatic resources due to water transfers

Central Valley Steelhead juveniles could be exposed to increased entrainment, predation, and decreased through-Delta survival as a result of the expanded transfer window under Alternative 4, but as the peak of the juvenile out-migration is in the spring, effects are anticipated to be minimal. No other life stages of Central Valley Steelhead would co-occur in time and space with water transfers from the Delta.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Under Alternative 4, the application of aquatic herbicide to the waters of CCF will occur during the summer months of July and August. Juvenile Central Valley Steelhead abundance in the Delta peaks between March and May (Reclamation 2019). Based on typical water temperatures in the vicinity of the salvage facilities during this period, the water temperatures would be incompatible with salmonid life history preferences, generally exceeding 70°F by mid-June. As such, it is unlikely that juvenile Central Valley Steelhead would be rearing near this location after mid-June and the potential application of aquatic herbicide would only occur well after the peak out-migration period (Reclamation 2019) and therefore Central Valley Steelhead are not expected to be exposed to herbicide application activities.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

Small proportions of Sacramento River-origin Central Valley Steelhead and moderate proportions of Mokelumne River and San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the Tracy Fish Facility. However, for fish that arrive at the facility, the proposed improvements resulting in greater salvage efficiency under Alternative 4 are likely to increase survival of juvenile Central Valley Steelhead.

As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, none to a few late migrants or early migrants have the potential to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements. Risks of decrease Central Valley Steelhead juvenile salvage during construction would be minimized through appropriate mitigation measures.

Skinner Fish Facility improvements under Alternative 4 to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from October through May under Alternative 4 coincides with downstream migration of juvenile Central Valley Steelhead (Reclamation 2019). Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. No data are available to estimate the abundance of juvenile Central Valley Steelhead thus, the proportion of the total run utilizing this route is unknown. However, NMFS (2009) determined that operation of the SWSCG is unlikely to impede migration of juvenile salmonids or produce conditions that support unusually high numbers of predators.

Under Alternative 4, the Roaring River Distribution System water diversion intake is equipped with fish screens (3/32-inch opening, or 2.4 mm) operated to maintain screen approach velocity of 0.2 ft/s (for Delta Smelt protection), excluding juvenile Central Valley Steelhead from entrainment (NMFS 2009: 437).

The MIDS diverts water from Goodyear Slough through three 48-inch diameter culverts during high tide. Although the MIDS intakes do not currently have fish screens, it is unlikely juvenile Central Valley Steelhead will be entrained into the water distribution system because Central Valley Steelhead have not been caught in past surveys. Also, the large size and better swimming ability of juvenile listed salmonids in the Delta allow these fish to avoid entrainment at MIDS. In addition, the location of the MIDS intake on Goodyear Slough further reduces the risk of entrainment. Goodyear Slough is not a migratory corridor for Central Valley Steelhead. The operation of the MIDS under Alternative 4 would not impact Central Valley Steelhead.

Goodyear Slough Outfall improves water circulation in the Suisun Marsh. This structure consists of four 48-inch diameter culverts with flap gates designed to drain water from the southern end of Goodyear Slough into Suisun Bay. On flood tides, the gates reduce the amount of tidal inflow into Goodyear Slough. Due to its location and design, Central Valley Steelhead are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall likely benefits Central Valley Steelhead in Suisun Marsh by improving water quality and increasing foraging opportunities.

Potential changes to aquatic resources due to changes from Delta Smelt fall habitat operations

Central Valley Steelhead juveniles are in the Delta in the spring. Reclamation proposes to conduct actions for Fall Delta Smelt Habitat in the fall, as adult Central Valley Steelhead are migrating upstream. Fall Delta Smelt Habitat actions are unlikely to affect adult Central Valley Steelhead.

Potential changes to aquatic resources due to changes from Clifton Court predator management

Clifton Court predator management under Alternative 4 could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

No effect

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

Potential changes to aquatic resources from monitoring

Population estimates for wild Steelhead remain outstanding in the Central Valley therefore, it is difficult to quantify the effects of the monitoring on Steelhead populations. However, most existing monitoring programs in the Central Valley and Delta/SF Estuary are not designed to capture Steelhead, which are much larger than Chinook Salmon upon river and Delta entry. Existing programs likely have poor capture efficiency for collecting and retaining Steelhead. Therefore, it is unlikely the monitoring programs have any effects to the population.

O.3.9.8.7 North American Green Sturgeon Southern DPS

Potential changes to aquatic resources due to seasonal operations

Hydrodynamic changes associated with river inflows and South Delta exports have been suggested to negatively impact southern DPS Green Sturgeon in two distinct ways: 1) “near-field” mortality associated with entrainment to the export facilities, 2) “far-field” mortality resulting from altered hydrodynamics. The SST completed a thorough review of this subject and defined a driver- linkage-outcome (DLO) framework for specifying how water project operations (the “driver”) can influence juvenile salmonid behavior (the “linkage”) and potentially cause changes in survival or routing (the “outcome”). A similar analysis is not available for southern DPS Green Sturgeon.

Entrainment

As described by NMFS (2009: 386), impacts to the migratory corridor function of juvenile and subadult Green Sturgeon critical habitat from south Delta exports are less clear than for juvenile salmonids because Green Sturgeon spend 1 to 3 years rearing in the Delta environment before transitioning to their marine life history stage. During this Delta rearing phase, Green Sturgeon are free to migrate throughout the Delta. In the conceptual model, it is hypothesized that higher rates of exports may result in higher rates of entrainment. However, estimating entrainment risk from raw salvage data is not possible due to a lack of information on the number of juvenile Green Sturgeon potentially exposed to salvage.

Juvenile southern DPS Green Sturgeon (> 5 mo) are present in the Delta all year and subadults are most abundant from June through November. In the June through September period under Alternative 4 Reclamation proposes an average total export rate slightly higher than No Action Alternative (440 cfs; Figure O1-15 in Appendix O, Attachment 1) and are unlikely to measurably increase entrainment risk. Total exports proposed for Alternative 4 in September-November (904 cfs higher than No Action Alternative; Figure O1-16 in Appendix O, Attachment 1) are unlikely to measurably increase entrainment risk relative to No Action Alternative.

Juvenile White and Green Sturgeon are infrequent at the TFCF but may occur in the facility salvage year-round. Salvage is expected to be similar and slightly higher than No Action Alternative under Alternative 4.

Routing

Juvenile Green Sturgeon (>5 mo) are present in the Delta all year and subadults are most abundant from June to November (Reclamation 2019). Juvenile Green Sturgeon swim and behave quite differently and have distinct body morphologies and habitat associations in the Delta compared to outmigrating salmonids, so it is hypothesized that juvenile Green Sturgeon have different routing-hydrology survival relationships. Per NMFS (2009: 338), Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways. It is highly uncertain how Green Sturgeon routing would change with Alternative 4.

Through-Delta Survival

Little is known about the relationship between survival of juvenile Green Sturgeon and Delta hydrology. Green Sturgeon reside in the Delta for 1 to 3 years suggesting they encounter a variety of daily, seasonal, and annual hydrological conditions. The majority of Green Sturgeon in the Delta are likely not surviving through the Delta per se, but using these habitats for rearing and foraging. Per NMFS (2009: 338), Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways. For juvenile outmigrating Green Sturgeon present in these regions, increasing negative velocities under Alternative 4 may result in lower survival. However, as described above, there is a lower probability of juvenile Green Sturgeon residing in this area.

Potential changes to aquatic resources OMR Management

See section above on Seasonal operations which includes OMR management

Potential changes to aquatic resources due to Delta Cross Channel operations

Delta Cross Channel operations under Alternative 4 are changed to allow Reclamation to predict water quality exceedances and open the DCC if D-1641 criteria are predicted to be exceeded. This results in greater opening times of the DCC.

Little is known about the migratory behavior of juvenile Green Sturgeon in the Sacramento River basin. It is likely that juvenile Green Sturgeon (larger than the 75 mm) will not enter the Delta prior to their first winter and thus would not be exposed to the open DCC gates. If juvenile Green Sturgeon are exposed to the open DCC gates, they could be entrained into the central / south Delta and exposed to biological and physical conditions in this area, including potentially greater predation. It is likely that these fish will enter the Delta sometime in the winter or spring following their hatching upriver and encounter both types of gate configurations as they enter the Delta.

Potential changes to aquatic resources due to the Temporary Barriers Project

Agricultural Barriers (Temporary Barrier Project, TBP) are included in Alternative 4 and consists of three rock barriers across south Delta channels to improve water levels for agricultural diversions. The temporary rock barriers are installed and removed at Middle River near Victoria Canal, Old River near Tracy, and Grant Line Canal near Tracy Boulevard Bridge. The TBP is operated based on San Joaquin River flow conditions. The agricultural barriers at Middle River and Old River near Tracy can begin operating as early as April 15 but the tide gates are tied open from May 16 to May 31. After May 31, the barriers in Middle River, Old River near Tracy, and Grant Line Canal are permitted to be operational until they are completely removed by November 30.

Juvenile Green Sturgeon are present in the Delta in all months of the year. However, little is known about their spatial distribution. When the south Delta agricultural barriers are operating with tidal flap gates down, a significant decline in passage and reach survival of acoustically tagged juvenile Chinook Salmon migrating past the barrier has been observed compared to when the barrier is not present (DWR 2018). When flap gates are tied up (May 16 to May 31), outmigrating Chinook Salmon passage past the agricultural barrier was improved (DWR 2018). It could be inferred that passage of outmigrating juvenile Green Sturgeon may also be improved when flap gates are tied up. Therefore, the potential negative effects of the agricultural barriers under Alternative 4 depends on when they are installed and whether the flap gates are down or tied up.

Potential changes to aquatic resources due to Contra Costa Water District operations

CCWD's operations in Alternative 4 are consistent with the operational criteria specified in separate biological opinions and permits that govern operations at CCWD's intakes and Los Vaqueros Reservoir (NMFS 1993, 2007, 2010, 2017; USFWS 1993a, 1993b, 2000, 2007, 2010, 2017; CDFG 1994, 2009a). Therefore, CCWD's operations, including operation of the Rock Slough Intake, for Alternative 3 remain unchanged from current conditions and the No Action Alternative.

The Contra Costa Canal Rock Slough Intake is located on a dead-end slough, far from the main migratory routes for southern DPS Green Sturgeon (NMFS 2017c), approximately 18 miles from the Sacramento River and 10 miles from the San Joaquin River via the shortest routes. Water temperatures in Rock Slough range from lows of about 40 degrees F in winter (December and January) to over 70 degrees F beginning in May and continuing through October (NMFS 2017c).

A review of the 24 years of fish monitoring data (1994–2018) near the Rock Slough Intake both pre- and post-construction of the Rock Slough Fish Screen (RSFS) showed that southern DPS Green Sturgeon have never been observed in Rock Slough (CDFG 2002c; Reclamation 2016; NMFS 2017c; Tenera Environmental 2018b; ICF 2018). CCWD's Fish Monitoring Program also samples at CCWD's other south Delta intakes. Since the intakes have been in operation, CCWD's Fish Monitoring Program has never observed southern DPS Green Sturgeon at CCWD's Old River Intake or Middle River Intake (CCWD 2019).

It is unlikely that juvenile, subadult, or adult Green Sturgeon would be present in Rock Slough due to the shallow depth, warm water temperatures, and low dissolved oxygenwhich make the area unsuitable habitat during most of the year. Therefore, it is unlikely that Green Sturgeon will be entrained at Rock Slough Intake and unlikely that Green Sturgeon would be impacted by CCWD operations.

Potential changes to aquatic resources due to North Bay Aqueduct operations

Overall, the modeled exports in Alternative 4 represent a significant increase in export levels and, thus, a greater risk to Green Sturgeon in the waters adjacent to the pumping facility compared to their historical vulnerability (NOAA 2009). However, Green Sturgeon are expected to be fully screened out of the facilities by the positive barrier fish screen in place at the pumping facility.

Potential changes to aquatic resources due to water transfers

As discussed under the Spring-Run Chinook Salmon water transfer section, under Alternative 4 Reclamation proposes to expand the transfer window to November. This extended transfer window could result in approximately 50 TAF of additional pumping per year in most years, with associated entrainment, routing, and through-Delta survival impacts. Please see the OMR management section for a discussion of the effects of pumping.

Juveniles older than 5 months, subadults, and adult Green Sturgeon could be exposed to the effects of increased pumping due to water transfers. Although southern DPS Green Sturgeon are present in the Delta in all months of the year, Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways (NMFS 2009:338). Therefore, there are no negative impacts of increased pumping at Jones and Banks Pumping Plants due to water transfers under Alternative 4.

Juvenile southern DPS Green Sturgeon are present in the Delta in every month of the year (Reclamation 2019). Thus, some portion of the population would be exposed to this action. Increases in Delta inflow during water transfers may have benefits for juvenile Green Sturgeon. However, there is no information on relationships between flow and juvenile Green Sturgeon ecology.

Potential changes to aquatic resources from Clifton Court aquatic weed removal

Few southern DPS juvenile Green Sturgeon Salmon would be expected to be exposed to the Clifton Court Forebay Aquatic Weed Control Program as part of Alternative 4. Although southern DPS juvenile Green Sturgeon are present in the Delta in all months of the year, Green Sturgeon are likely to be found in the main channels of the Delta and the larger interconnecting sloughs and waterways, with western Delta waterways having a higher likelihood of presence than eastern Delta waterways (NMFS 2009:338). The application of aquatic herbicide to the waters of Clifton Court Forebay will occur during the summer months of July and August. Thus, the likelihood of exposing juvenile Green Sturgeon to the herbicide is very low. Mechanical harvesting would occur on an as-needed basis and, therefore, juvenile Green Sturgeon could be exposed to this action, if entrained into the Forebay.

As discussed in Appendix D, treatment of harmful algal blooms with peroxide-based algaecide is proposed to occur as needed, year-round, but there are no anticipated impacts to fish because the oxidation reaction occurs immediately upon contact with the water, destroying algal cell membranes and chlorophyll, with hydrogen peroxide and oxygen as byproducts.

Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements

Upgrades to the TFCF under Alternative 4 will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish, and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

Upgrades to the TFCF will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

As previously described, juvenile Green Sturgeon can occur in the Delta year-round (Reclamation 2019) and, therefore, have the potential to be exposed to the effects of construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements. If construction affects the efficiency of Green Sturgeon salvage (which is an element of entrainment risk; Reclamation 2019), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*).

Skinner Fish Facility improvements under Alternative 4, which involve predator control efforts, can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently. Thus, Alternative 4 is not likely to negatively impact juvenile Green Sturgeon.

Potential changes to aquatic resources due to changes from Suisun Marsh facilities

Operation of the SMSCG from June through September under Alternative 4 coincides with a portion of the downstream migration of juvenile southern DPS Green Sturgeon, as well as adult southern DPS Green Sturgeon. Montezuma Slough provides an alternative route to their primary migration corridor through Suisun Bay. During full gate operation, the flashboards are installed and the radial gates open and close twice each tidal day. Green Sturgeon are thought to successfully pass through either the boat lock or through the gates during periods when the gates are open. NMFS (2009) determined that operation of the SWSCG is unlikely to produce conditions that support unusually high numbers of predators, change habitat suitability or availability for rearing or migration of juvenile and adult Green Sturgeon. Green Sturgeon are strong swimmers and therefore the operation of the Suisun Marsh Salinity Control Gate will have no impact on adults or juvenile Green Sturgeon.

The low screen velocity at the intake culverts combined with a small screen mesh size are expected to successfully prevent Green Sturgeon from being entrained into the RRDS under Alternative 4. (NOAA 2009).

The MIDS intakes under Alternative 4 do not currently have fish screens, and juvenile Green Sturgeon are more prone to entrainment than other species such as White Sturgeon (Poletto et al. 2014). However, fisheries monitoring performed in 2004-05 and 2005-06 identified entrainment of 20 fish species, none of which were Green Sturgeon (NOAA 2009). Presence of Green Sturgeon in the area of the MIDS intake is not well studied or documented, but it if Green Sturgeon are present, they may potentially avoid entrainment as they do not typically swim along the surface where the diversion is located.

Due to its location and design, Green Sturgeon are not likely to encounter this structure or be negatively affected by its operation. Improved water circulation by the operation of the Goodyear Slough Outfall under Alternative 4 likely benefits juvenile Green Sturgeon in Suisun Marsh by improving water quality and increasing foraging opportunities (NOAA 2009).

Potential changes to aquatic resources due to changes from Clifton Court predator management

Predator control efforts under Alternative 4 can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently.

Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study

Potential changes to aquatic resources due to reintroduction changes from the fish conservation and culture laboratory

Potential changes to aquatic resources from monitoring

No effect

Population estimates for Green Sturgeon also remain outstanding in the Central Valley. Similar to Steelhead, the existing monitoring programs very rarely catch Green Sturgeon because most monitoring programs are not designed to capture them. Similar to Steelhead, it is unlikely the monitoring programs have an effect to the population.

O.3.9.9 *Nearshore Pacific Ocean on the California Coast*

O.3.9.9.1 Southern Resident Killer Whale

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

Under Alternative 4, water operations would include increases in flow as a result of unimpaired flow percentage requirements. Potential effects to Chinook Salmon, which as described in Section O.3.2.9 *Nearshore Pacific Ocean of the California Coast* are important prey to Southern Resident Killer Whale, are analyzed above in Sections O.3.6.1.1 *Trinity River*, O.3.6.1.2 *Sacramento River*, O.3.6.1.3 *Clear Creek*, O.3.6.1.4 *Feather River*, O.3.6.1.5 *American River*, O.3.6.1.6 *Stanislaus River*, O.3.6.1.7 *San Joaquin River*, and O.3.6.1.8 *Bay Delta*. These analyses suggest that Alternative 4 may result in some potential positive and negative effects to Central Valley Chinook Salmon stocks relative to the No Action Alternative. There is uncertainty in the extent to which any such changes would affect Southern Resident Killer Whale given that effects are potentially limited by the medium importance of Central Valley Chinook Salmon stocks to Southern Resident Killer Whale diet and the relatively high representation of hatchery-origin juvenile Chinook Salmon, many of which are released downstream of the Delta (Reclamation 2019).

O.3.10 Alternative 4 – Program-Level Effects

O.3.10.1 *Sacramento River*

Potential changes to aquatic resources from Battle Creek restoration

Acceleration of the Battle Creek restoration program will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from lower intakes near Wilkins Slough

Lowering intakes of diversions near Wilkins Slough will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from Shasta TCD Improvements

Improvement of the Shasta TCD will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from operation of the Livingston-Stone National Fish hatchery (Winter-Run Chinook Salmon)

Increased production of Winter-Run Chinook Salmon at the Livingston-Stone National Fish Hatchery will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the

No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from small screen program

Increased installation and improvements to screens on small diversions in the Sacramento River will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from spawning habitat restoration

Increased spawning habitat restoration will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources from rearing habitat restoration

Increased rearing habitat restoration will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources with respect to potential effects of this measure.

Potential changes to aquatic resources due to adult rescue activities

Additional adult rescue (beyond what CDFW is currently doing, as noted for Alternative 1) will not occur under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 and the No Action Alternative are likely to have similar effects on aquatic resources.

Potential changes to aquatic resources due to trap and haul activities

The juvenile trap and haul strategy is not being implemented under either Alternative 4 or the No Action Alternative. Therefore, Alternative 4 is likely to have similar effects on aquatic resources as the No Action Alternative.

O.3.10.2 *Bay-Delta*

O.3.10.2.1 <u>Delta Smelt</u>

Potential changes to Delta Smelt from tidal habitat restoration

The effects of completion of 8,000 acres of tidal habitat restoration under Alternative 4 generally would be expected to be similar to those described for Alternative 1, although given that Delta outflow is greater in spring/summer than under the No Action Alternative, restoration may add to potential positive operations effects, rather than offsetting negative operations effects.

O.3.10.2.2 <u>Longfin Smelt</u>

Potential changes to Longfin Smelt from tidal habitat restoration

The effects of completion of 8,000 acres of tidal habitat restoration under Alternative 4 generally would be expected to be similar to those described for Alternative 1, although given that Delta outflow is greater in spring than under the No Action Alternative, restoration may add to potential positive operations effects, rather than offsetting negative operations effects.

O.3.10.2.3 Sacramento Winter-Run Chinook Salmon

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

This action would hydrologically connect the Sacramento River with the Sacramento Deepwater Ship Channel (SDWSC) via the Stone Lock facility from mid-spring to late fall. Juvenile Winter-Run Chinook Salmon may be exposed to the Sacramento Deepwater Ship Channel (SDWSC) component of Alternative 4. This action would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018) to provide food web benefits to Delta Smelt. Juvenile Winter-Run Chinook Salmon abundance downstream of Stone Lock at Sherwood Harbor is highest in February and March, declines in April, and is moderate in November (Reclamation 2019). Juvenile Winter-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be routed into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, if survival rates are similar, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit associated with Alternative 4. A hydrologically connected SDWSC could potentially attract adult Winter-Run Chinook Salmon. If the connection is maintained there would likely not be impacts to adults. However, if the connection is not maintained there could be migratory delays and stranding.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and therefore would have limited effects on Winter-Run Chinook Salmon, who are in the Delta between December and May for juveniles, and December to July for adults.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 4, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Winter-Run Chinook Salmon, who are in the Delta between December and May for juveniles, and December to July for adults.

Potential changes to aquatic resources due to tidal habitat restoration

Although migration through the Delta represents a short period, a large proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to 8,000 acres of tidal habitat restoration in the Delta. Tidal habitat restoration is expected to benefit juvenile Winter-Run Chinook Salmon in several aspects represented by the Winter-Run Chinook Salmon conceptual model including increased food availability and quality and refuge habitat from predators (Reclamation 2019). These benefits can manifest in higher growth rates and increased survival through the Delta. Reclamation and DWR will consult on future tidal habitat restoration with USFWS and NMFS on potential effects to fish from construction-related effects.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Winter-Run Chinook Salmon. Although Alternative 4 would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Winter-Run Chinook Salmon. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016). Winter-Run Chinook Salmon juveniles in the Bay-Delta are unlikely to be exposed to the effects of construction at predator hot spot removal locations in the Sacramento River, as the in-water work window is in the summer / fall when Winter-Run Chinook Salmon juveniles are generally in the upper river.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Winter-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. Few Winter-Run Chinook Salmon are expected to be exposed to improvements to the Delta Cross Channel. Seasonal closure periods would still be in place to protect migrating salmonids. Potential diurnal operation during closure periods could increase exposure of Winter-Run Chinook Salmon juveniles to entrainment into the interior Delta. Improved biological and physical monitoring associated with improvements would likely minimize potentially increased routing into the interior Delta and subsequent entrainment. Greater operational flexibility and increased gate reliability resulting from improvements would reduce the risk of gate failure that could result in higher rates of entrainment.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

A small proportion of juvenile Winter-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility. Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

Few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements based on lack of observed salvage during the August to October in-water work window (see Figures F.2.7, F.2.8, and F.2.9 in Appendix F of the ROC LTO BA). However, a few early migrants could occur during the in-water work window based on occurrence in the north Delta (see Figures WR_Seines and WR_Sherwood in Appendix F of the ROC LTO BA).

To the extent that the construction affects the ability of juvenile Winter-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Figure 5.6-44), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Chinook Salmon entrained into

CCF. It is important to note that only small proportions of Winter-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014).

Potential changes to aquatic resources due to changes to the small screen program

There may be some overlap Winter-Run Chinook Salmon with the main late spring-fall irrigation period for small diversions. Diversion screening could reduce entrainment of late migrating individuals. It is important to note that only a small proportion of the population would be exposed.

Few if any juvenile Winter-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Winter-Run Chinook Salmon primarily migrate from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

The operation of the Delta Fish Species Conservation Hatchery would not provide benefits to any life stage of Winter-Run Chinook Salmon. Potential negative effects of the Delta Fish Species Conservation Hatchery include inadvertent propagation and spread of invasive or nuisance species, which could affect juvenile Winter-Run Chinook Salmon through changes in food web structure, for example, in the case of invasive quagga and zebra mussels (Fera et al. 2017). Additional impacts could include reduced water quality resulting from hatchery discharge. Potential negative effects from discharged water are expected to be minimal due to the water treatment and the very small size of the discharge compared to flows in the Sacramento River near the hatchery location. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Winter-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Bay-Delta, few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of early migrants to in-water and shoreline construction of the hatchery intake and outfall, as illustrated by timing of occurrence in Sacramento seines and trawls (see Figures F.2.4 and F.2.5 in Appendix F of the ROC LTO BA). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of construction of the Delta Fish Species Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

O.3.10.2.4 Central Valley Spring-Run Chinook Salmon

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

This action would hydrologically connect the Sacramento River with the Sacramento Deepwater Ship Channel (SDWSC) via the Stone Lock facility from mid-spring to late fall. Juvenile Spring-Run Chinook Salmon abundance in the Delta is moderate in March and peaks in April (Reclamation 2019). Juvenile Spring-Run Chinook Salmon passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially enter the SDWSC. There are potential benefits to Spring-Run Chinook Salmon from this action. Fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar. However, estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. Also, there is potential for decreased migration time to the ocean and exposure to larger food sources of Liberty Island, but this is currently uncertain.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and therefore would have limited effects on Spring-Run Chinook Salmon, who are in the Delta January through February for adults, and November through June for juveniles, with a peak of juvenile migration from March to April.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 4, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Spring-Run Chinook Salmon, who are in the Delta January through February for adults, and November through June for juveniles, with a peak of juvenile migration from March to April.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Spring-Run Chinook Salmon are expected to benefit from continuing to construct the 8,000 acres of tidal habitat restoration in the Delta under Alternative 4. Benefits include increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of yearling migrants that enter the Delta in the fall. Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes the following: temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance, indirect impairment of aquatic ecosystem productivity, loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams.

Many of these are elements highlighted in the SAIL conceptual model (Figure 5.6-4). The risk from these potential effects would be minimized through application of mitigation measures MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12 and MM-AQUA-17. (Appendix E, *Mitigation Measures*).

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 4 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Spring-Run Chinook Salmon. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Spring-Run Chinook. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016).

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Greater operational flexibility and increased gate reliability resulting from improvements to the Delta Cross Channel under Alternative 4 would reduce the risk of gate failure that could result in higher rates of entrainment of Spring-Run Chinook Salmon, if left open. Few Spring-Run Chinook Salmon are expected to be exposed to in-water construction related improvements to the Delta Cross Channel due to observance of species protective work windows. Seasonal closure periods would still be in place to protect Spring-Run Chinook Salmon. The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Spring-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. However, improved biological and physical monitoring associated with improvements would likely minimize potentially increased entrainment.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

A number of programmatic actions are proposed to improve salvage efficiency of TFCF, including installing a carbon dioxide injection device to allow remote controlled anesthetization of predators in the secondary channels of the Tracy Fish Facility. These actions could potentially benefit juvenile Spring-Run Chinook Salmon through greater salvage efficiency.

Few if any juvenile Spring-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see figures in Appendix F of the ROC LTO BA*:* WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race). Risks to these few individuals would be minimized through appropriate mitigation measures for aquatic resources (Appendix E, *Mitigation Measures*), the selected in-water work window, and the small scale of the in-water construction. For juvenile Spring-Run Chinook Salmon that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Predator control efforts at Skinner Fish Facility under Alternative 4 to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Spring-Run Chinook Salmon entrained into Clifton Court Forebay. Spring-Run Chinook Salmon are unlikely to be in the area during predator control efforts.

Potential changes to aquatic resources due to changes to the small screen program

Few if any juvenile Spring-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Sacramento River Spring-Run Chinook Salmon primarily from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

The operation of the Delta Fish Species Conservation Hatchery would not provide benefits to any life stage of Winter-Run Chinook Salmon. Potential negative effects of the Delta Fish Species Conservation Hatchery include inadvertent propagation and spread of invasive or nuisance species, which could affect juvenile Winter-Run Chinook Salmon through changes in food web structure, for example, in the case of invasive quagga and zebra mussels (Fera et al. 2017). Additional impacts could include reduced water quality resulting from hatchery discharge. Potential negative effects from discharged water are expected to be minimal due to the water treatment and the very small size of the discharge compared to flows in the Sacramento River near the hatchery location. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Winter-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Bay-Delta, few if any juvenile Winter-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be some exposure of early migrants to in-water and shoreline construction of the hatchery intake and outfall, as illustrated by timing of occurrence in Sacramento seines and trawls (see Figures F.2.4 and F.2.5 in Appendix F of the ROC LTO BA). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction.

Winter-Run Chinook Salmon adults would not be expected to be exposed to the effects of construction of construction of the Delta Fish Species Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019).

O.3.10.2.5 <u>Central Valley Fall-Run Chinook Salmon</u>

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

Moderate to high proportions of juvenile Fall-Run Chinook Salmon are expected to be exposed to the Sacramento Deepwater Ship Channel (SDWSC) action. This action would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018). Juvenile Fall-Run abundance in the Delta is moderate in peaks in April and May (Table FR_1). Juvenile Fall-Run passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be entrained into the SDWSC. Estimates of salmonid survival in the

SDWSC are not available to compare with rates in the Sacramento River route. However, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar. The effect of this action on juvenile Fall-Run Chinook Salmon is moderate.

No San Joaquin River-origin Fall-Run are expected to be exposed to the Sacramento Deepwater Ship Channel.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

This action is proposed to occur in July or September which is largely outside of the migration period for juvenile Fall-Run and Late Fall-Run Chinook Salmon in the Delta (Table _FR1, Table LFR1). For fish that are exposed, increased food production could potentially enhance growth. The effect of this action is expected to be low.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

This action is proposed to occur in July or September which is largely outside of the migration period for juvenile Fall-Run and Late Fall-Run Chinook Salmon in the Delta (Table _FR1, Table LFR1). For fish that are exposed, increased food production could potentially enhance growth. The effect of this action is expected to be low.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Fall-Run and Late Fall-Run Chinook Salmon are expected to be exposed to 8,000 acres of tidal habitat restoration in the Delta. Tidal habitat restoration is expected to benefit juvenile Chinook Salmon in several aspects represented by the Winter-Run conceptual model (Figure WR_CM4) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta. Migration through the Delta represents a short period in the migration of juvenile Fall-Run and Late Fall-Run Chinook Salmon. Thus, the total effect of this action is moderate.

Few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance (e.g., gill damage and reduced ability to take in oxygen, increasing metabolic cost), indirect impairment of aquatic ecosystem productivity (e.g., reduction in benthic macroinvertebrate production and availability), loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. Many of these are elements highlighted in the SAIL conceptual model (Reclamation 2019). The risk from these potential effects would be minimized through application of MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14 (Appendix E, *Mitigation Measures*).

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal is primarily focused on providing positive effects to downstream-migrating juvenile salmonids including Fall-Run and Late Fall-Run Chinook Salmon. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of juvenile Spring-Run Chinook. All hotspots are limited in scale relative to overall available habitat and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016).

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Greater operational flexibility and increased gate reliability resulting from improvements to the Delta Cross Channel under Alternative 4 would reduce the risk of gate failure that could result in higher rates of entrainment of Fall-Run and Late Fall-Run Chinook Salmon, if left open. Few Fall-Run or Late fall-Run Chinook Salmon are expected to be exposed to in-water construction related improvements to the Delta Cross Channel due to observance of species protective work windows. Seasonal closure periods would still be in place to protect Chinook Salmon. The DCC is an older structure which requires manual operation and increased use could result in locks braking in either open or closed positions. Migrating Fall-Run and Late fall-Run Chinook Salmon would benefit from faster operations that prevent straying into the central Delta and catastrophic failure of the facility. However, improved biological and physical monitoring associated with improvements would likely minimize potentially increased entrainment.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

A small proportion of juvenile Fall-Run Chinook Salmon are expected to be exposed to the Tracy Fish Facility (Zeug and Cavallo 2014). However, for fish that arrive at the facility, the proposed improvements are likely to increase survival through the facility.

Few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements, based on lack of observed salvage during the August to October in-water work window (see Figures WR_salvage_unclipped_date, WR_salvage_clipped_date, and WR_salvage_clipped_CWT_race in Appendix F of the ROC LTO BA). To the extent that the construction affects the ability of juvenile Fall-Run, and Late Fall-Run Chinook Salmon to be efficiently salvaged (as part of the entrainment risk habitat attribute in the SAIL conceptual model; Figure WR_CM4), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures (Appendix E, *Mitigation Measures*). Given the low potential exposure because of the in-water work window, the application of mitigation measures, and the small scale of the in-water construction, it is concluded that the negative population-level effects of Tracy Fish Facility Improvements construction would be low on this life stage.

Skinner Fish Facility improvements from predator control efforts to reduce predation on listed fishes following entrainment into Clifton Court Forebay could reduce pre-screen loss of juvenile Chinook Salmon entrined into Clifton Cout Forebay. However, given that only small proportions of Fall-Run Chinook Salmon are lost at the SWP (Zeug and Cavallo 2014), the population-level positive effect of this action would be low. Larger proportions of Late Fall-Run Chinook Salmon are lost at the facilities and this action would have a larger effect for this run.

Potential changes to aquatic resources due to changes to the small screen program

Although there may be moderate overlap Fall-Late Fall-Run Chinook Salmon with the main late spring-fall irrigation period for small diversions, and small diversion screening could reduce entrainment of late migrating individuals, the potential population-level positive effect would be low because only a small proportion of the population would be exposed.

Few if any juvenile Fall- /Late Fall-Run Chinook Salmon rearing and outmigrating in the Bay-Delta are expected to be exposed to the effects of construction of screens on water diversion intakes. Juvenile Sacramento River Fall- /Late Fall-Run Chinook Salmon primarily migrate from November through early May (NMFS 2014c), largely outside of the timing of in-water construction (July 15 to October 15). In addition, the work area for these projects is small, limiting exposure to construction.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

Potential effects of the Delta Fishes Conservation Hatchery include inadvertent propagation and release of nuisance species and reduced water quality resulting from hatchery discharge. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Fall-Run Chinook Salmon would be restricted to a small spatial area within the primary migration route. The overall impact of the operation of this facility is low.

As with the other proposed construction activities in the Bay-Delta, few juvenile Fall-Run or Late Fall-Run Chinook Salmon would be expected to be exposed to the effects of construction of the Delta Fishes Conservation Hatchery based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Table FR_1, LFR_1). The relatively few individuals occurring near the construction site could be subject to effects similar to those previously described for habitat restoration (e.g., temporary loss of habitat leading to predation, degraded water quality, reduced foraging ability caused by reduced visibility, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas). The risk from these potential effects would be minimized through application of mitigation measures (Appendix E, *Mitigation Measures*). There is low potential exposure because of the in-water work window, the application of mitigation measures will reduce effects, and the in-water construction is of a small scale.

O.3.10.2.6 Central Valley Steelhead

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

Moderate to high proportions of Central Valley Steelhead are expected to be exposed to the Sacramento Deepwater Ship Channel (SDWSC) conservation measure under Alternative 4. This conservation measure would hydrologically connect the Sacramento River with the SDWSC via the Stone Lock facility from mid-spring to late fall (Wood Rodgers 2018), allowing food to enter the Delta and an alternate migration pathway. Juvenile Central Valley Steelhead abundance in the Delta peaks in February through May (Reclamation 2019). Juvenile Central Valley Steelhead passing the Stone Lock facility when there is a hydrologic connection between the waterways could potentially be entrained into the SDWSC. Estimates of salmonid survival in the SDWSC are not available to compare with rates in the Sacramento River route. However, fish entering the SDWSC would not be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar.

No Central Valley Steelhead are expected to be exposed to the Sacramento Deepwater Ship Channel construction, as the in-water work window does not overlap with their occurrence in the Delta.

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta food subsidies by routing Colusa Basin drain water to the Cache Slough area through the Yolo Bypass would occur in summer/fall and does not overlap in time or space with juvenile Central Valley Steelhead occurrence in the Delta. There would not be any effect to Central Valley Steelhead adults.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Under Alternative 4, provision of Suisun Marsh food subsidies through coordination of managed wetland flood and drain operations in Suisun Marsh and draining of RRDS to Grizzly Bay/Suisun Bay in conjunction with reoperation of the SMSCG would occur in summer/fall and therefore would have limited effects on Central Valley Steelhead juveniles, who are in the Delta between December and July. The action is not expected to have any effect on Central Valley Steelhead adults.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile Central Valley Steelhead are expected to benefit from 8,000 acres of tidal habitat restoration in the Delta under Alternative 4. Tidal habitat restoration is expected to benefit juvenile Central Valley Steelhead in several aspects represented by the Winter-Run Chinook Salmon conceptual model (Figure 5.6-4) including, increased food availability and quality and refuge habitat from predators. These benefits can manifest in higher growth rates and increased survival through the Delta; however, the Delta only represents a small fraction of the total migration route.

Few if any juvenile Central Valley Steelhead would be expected to be exposed to the effects of construction of 8,000 acres of tidal habitat restoration, based on the timing of in-water construction (August to October) and the typical seasonal occurrence of this life stage in the Delta (Reclamation 2019). There may be exposure of a few late migrants, as illustrated by timing of occurrence in Chipps mid-water trawls (Reclamation 2019). Individuals being exposed to construction could experience risk of potential effects similar to those suggested in recent restoration projects such as the Lower Yolo Restoration Project (NMFS 2014c). This includes temporary loss of aquatic and riparian habitat leading to increased predation, increased water temperature, and reduced food availability; degraded water quality from contaminant discharge by heavy equipment and soils, and increased discharges of suspended solids and turbidity, leading to direct toxicological impacts on fish health/performance (e.g., gill damage and reduced ability to take in oxygen, increasing metabolic cost), indirect impairment of aquatic ecosystem productivity (e.g., reduction in benthic macroinvertebrate production and availability), loss of aquatic vegetation providing physical shelter, and reduced foraging ability caused by decreased visibility; impediments and delay in migration caused by elevated noise levels from machinery; and direct injury or mortality from in-water equipment strikes or isolation/stranding within dewatered cofferdams. The risk from these potential effects would be minimized through application of MM-AQUA-1, MM-AQUA-2, MM-AQUA-4 through MM-AQUA-12, and MM-AQUA-14.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 4 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids, including Central Valley Steelhead. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the primary migratory routes of Central Valley Steelhead. All hotspots are limited in scale relative to overall available habitat, and previous research has not found a consistent positive effect of predator removal on juvenile salmon survival (Cavallo et al. 2012; Michel et al. 2017; Sabal et al. 2016). However, implementation of this action would likely improve conditions for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Completion of DCC gate improvements would benefit Central Valley Steelhead of all life stages within the CVP watershed systems. The peak migration of juvenile Central Valley Steelhead in the Sacramento River past Hood, which is near the DCC, occurs from February through mid-June (Reclamation 2019). No San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the DCC. As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, few late migrants or early migrants have the potential to be exposed to potential construction from improvements to the DCC under Alternative 4.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

Small proportions of Sacramento River-origin Central Valley Steelhead and moderate proportions of Mokelumne River and San Joaquin River-origin Central Valley Steelhead are expected to be exposed to the Tracy Fish Facility. However, for fish that arrive at the facility, the proposed improvements resulting in greater salvage efficiency under Alternative 4 are likely to increase survival of juvenile Central Valley Steelhead.

As previously described, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) and, therefore, none to a few late migrants or early migrants have the potential to be exposed to the effects of construction of the carbon dioxide injection device proposed for the Tracy Fish Facility Improvements. Risks of decrease Central Valley Steelhead juvenile salvage during construction would be minimized through appropriate mitigation measures.

Skinner Fish Facility improvements under Alternative 4 to reduce predation on listed fishes following entrainment into CCF could reduce pre-screen loss of juvenile Central Valley Steelhead entrained into CCF; therefore, providing a benefit for all life stages of Central Valley Steelhead.

Potential changes to aquatic resources due to changes to the small screen program

Fish screens under Alternative 4 would also benefit this life stage in the same ways described above. Juvenile Central Valley Steelhead outmigrating in the Bay-Delta may be exposed to the effects of construction of screens since they migrate downstream during most months of the year, with a peak emigration period in the spring and a smaller peak in the fall (Hallock et al. 1961). Juvenile Central Valley Steelhead may be found in the work area of these projects; however, mitigation measures would minimize impacts.

Potential changes to aquatic resources from the Delta fish species conservation hatchery

Potential effects of the Delta Fishes Conservation Hatchery include inadvertent propagation and release of nuisance species and reduced water quality resulting from hatchery discharge. Mitigation and minimization measures detailed in the EIR/EIS for the facility (Horizon Water and Environment 2017) indicate that potential impacts are less than significant. Potential exposure of juvenile Central Valley Steelhead would be restricted to a small spatial area within the primary migration route.

As with the other proposed construction activities in the Delta under Alternative 4, juvenile Central Valley Steelhead are largely absent from the Delta between August and November (Reclamation 2019) which means that none to a few late or early migrants of this life stage could be exposed to Delta Fishes

Conservation Hatchery construction. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risk from these potential effects would be minimized through application of mitigation measures (Appendix E, *Mitigation Measures*).

O.3.10.2.7 North American Green Sturgeon Southern DPS

Potential changes to aquatic resources from the Sacramento Deepwater Ship Channel food study

As described above, juvenile Green Sturgeon may potentially be entrained into the DWSC. Fish entering the SDWSC would not, however, be exposed to entrainment into the interior Delta through the DCC or Georgiana Slough which would provide a benefit if survival rates are similar between the SDWSC and the Sacramento main stem

Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin Drain study

Provision of north Delta or Suisun Marsh food subsidies by routing drain water would occur in summer/fall and therefore could provide food benefits to Green Sturgeon juveniles, who are in the Delta in the fall.

Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food subsidies study

Provision of north Delta or Suisun Marsh food subsidies by routing drain water would occur in summer/fall and therefore could provide food benefits to Green Sturgeon juveniles, who are in the Delta in the fall.

Potential changes to aquatic resources due to tidal habitat restoration

A large proportion of juvenile southern DPS Green Sturgeon are expected to be exposed to continuing to implement the 8,000 acres of tidal habitat restoration in the Delta under Alternative 4. Tidal habitat restoration is expected to benefit juvenile Green Sturgeon in several aspects represented by the Green Sturgeon juvenile conceptual model including, increased food availability and quality and refuge habitat from predators (Reclamation 2019). These benefits can manifest in higher growth rates and increased survival through the Delta.

Potential changes to aquatic resources from the predator hot spot removal program

Predator hot spot removal under Alternative 4 is primarily focused on providing positive effects to downstream-migrating juvenile salmonids. It is currently unknown if predation on juvenile Green Sturgeon in the Delta is limiting their productivity. Although the action would not be limited to existing identified hot spots (e.g., those identified by Grossman et al. 2013), the existing hotspots that may be representative of where removal efforts may be most concentrated are in the rearing and migratory corridors of juvenile Green Sturgeon.

Potential changes to aquatic resources from Delta Cross Channel gate improvements

Little is known about the migratory behavior of juvenile Green Sturgeon in the Sacramento River basin. It is likely that juvenile Green Sturgeon (larger than the 75 mm) will not enter the Delta prior to their first winter and thus would not be exposed to the open DCC gates. It is likely that these fish will enter the

Delta sometime in the winter or spring following their hatching upriver and encounter both types of gate configurations as they enter the Delta. More information is required to accurately assess the migratory movements of juvenile Green Sturgeon in the river system, as well as their movements within the Delta during their rearing phase in estuarine/Delta waters. Greater operational flexibility and increased gate reliability resulting from improvements would reduce the risk of gate failure that could result in higher rates of entrainment.

Potential changes to aquatic resources due to changes to Tracy and Skinner Fish Facility improvements

Upgrades to the TFCF will aim to minimize the effects of the salvage process on listed fishes, in particular juvenile salmonids and Green Sturgeon. Salvage improvements will improve survival of salvaged fish and potentially allow reduction of the expansion factors used to extrapolate take estimates from observed salvage.

As previously described, juvenile Green Sturgeon can occur in the Delta year-round (Reclamation 2019) and, therefore, have the potential to be exposed to the effects of construction of the CO_2 injection device proposed for the Tracy Fish Facility Improvements. If construction affects the efficiency of Green Sturgeon salvage (which is an element of entrainment risk; Figure 5.12-3), there could be a minor effect to a small number of individuals, although risk would be minimized through appropriate mitigation measures (Appendix E, *Mitigation Measures*).

Skinner Fish Facility improvements under Alternative 4, which involve predator control efforts, can reduce predation on listed fish species, following their entrainment into Clifton Court Forebay. This could also reduce pre-screen loss of juvenile southern DPS Green Sturgeon. It is unknown what proportion of juvenile Green Sturgeon are entrained into CCF but individuals are salvaged infrequently. Thus, Alternative 4 is not likely to negatively impact juvenile Green Sturgeon.

Potential changes to aquatic resources due to changes to the small screen program

Southern DPS Green Sturgeon are expected to be present in the Delta during the main irrigation period for small diversions (late spring-fall). Diversion screening under Alternative 4 could reduce entrainment of individual Green Sturgeon. However, there is currently no information on the proportion of juvenile Green Sturgeon that are entrained into small unscreened diversions. North American Green Sturgeon in the juvenile to subadult/adult life stage may be exposed to the effects of construction of screens since they are present in the Sacramento River year-round (Reclamation 2019). Effects are the same as described above for juveniles. Mitigation measures would minimize risk (Appendix E, Mitigation Measures).

Potential changes to aquatic resources from the Delta fish species conservation hatchery

None of the Green Sturgeon life stages would benefit from the Delta Fish Species Conservation Hatchery under Alternative 4. As with the other proposed construction activities in the Delta, the year-round occurrence of juvenile Green Sturgeon in the Delta (Reclamation 2019) means that this life stage, as well as the timing of the adult Green Sturgeon occurring in the Delta during May to October, could be exposed to Delta Fish Species Conservation Hatchery construction under Alternative 4. The in-water work constructing the hatchery intake and outfall could result in a small number of individuals experiencing effects such as temporary loss of habitat leading to predation, degraded water quality, noise-related delay in migration, and direct effects from contact with construction equipment or isolation/stranding within enclosed areas. The risks from these potential changes would be minimized with through the application of mitigation measures (Appendix E, *Mitigation Measures*).

O.3.10.3 *Nearshore Pacific Ocean on the California Coast*

O.3.10.3.1 Southern Resident Killer Whale

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

Consistent with Alternative 2, which has the same limited suite of programmatic activities as Alternative 4 (i.e., completion of 8,000 acres of tidal habitat restoration required by the USFWS 2008 BO), Alternative 4's programmatic activities would not be expected to have population-level effects to Southern Resident Killer Whale Chinook Salmon prey. This suggests limited effects of Alternative 4 programmatic activities on Southern Resident Killer Whale.

O.3.11 Mitigation Measures

Mitigation measures are included in this document to avoid, minimize, or compensate for adverse environmental effects of alternatives as compared to the No Action Alternative. A summary of how each of the measures will mitigate effects for each alternative is provided below.

O.3.11.1 *Species-Specific Mitigation Measures*

Reclamation will implement the following mitigation measures to avoid or minimize effects on aquatic resources. Mitigation Measures measures described below have been developed to avoid and minimize effects that could result from the proposed action on aquatic resources addressed in this appendix. Table O.3-75 below briefly summarizes the species-specific measures.

Table O.3-75. Mitigation Measures for Aquatic Resources in the Study Area

Number	Title	Summary
MM AQUA-1	Worker Awareness Training	Includes procedures and training requirements to educate construction personnel on the applicable environmental rules and regulations, the types of sensitive resources in the project area, and the measures required to avoid and minimize effects on these resources.
MM AQUA-2	Construction Best Management Practices and Monitoring	Standard practices and measures that will be implemented prior to, during, and after construction to avoid or minimize effects of construction activities on sensitive resources (e.g., species, habitat), and monitoring protocols for verifying the protection provided by the implemented measures.
MM AQUA-3	Develop and Implement Program to Expand Adult Holding, Spawning, Egg Incubation, and Fry/Juvenile Rearing Habitat.	Develop and implement a program to expand suitable adult holding, spawning, egg incubation, and fry/juvenile rearing habitat for Central Valley Spring-Run Chinook Salmon, Fall-/Late Fall-Run Chinook Salmon, and Central Valley Steelhead elsewhere in the Northwestern California Diversity Group.
MM AQUA-4	Erosion and Sediment Control Plan	Includes measures that will be implemented for ground-disturbing activities to control short-term and long-term erosion and sedimentation effects and to restore soils and vegetation in areas affected by construction activities, and that will be incorporated into plans developed and implemented as part of the National Pollutant Discharge Elimination System permitting process for covered activities.

Number	Title	Summary
MM AQUA-5	Spill Prevention, Containment, and Countermeasure Plan	Includes measures to prevent and respond to spills of hazardous material that could affect navigable waters, as well as emergency notification procedures.
MM AQUA-6	Disposal and Reuse of Spoils and Dredged Material	Includes measures for handling, storage, and disposal of excavation or dredge spoils, including procedures for the chemical characterization of this material or the decant water to comply with permit requirements, and reducing potential effects on aquatic habitat, as well as specific measures to avoid and minimize effects on species in the areas where materials would be used or disposed.
MM AQUA-7	Fish Rescue and Salvage Plan	Includes measures that detail procedures for fish rescue and salvage to avoid and minimize the number of Chinook salmon, steelhead, green sturgeon, and other listed species of fish stranded during construction activities, especially during the placement and removal of enclosures (e.g., cofferdams or exclusion netting) at construction sites.
MM AQUA-8	Underwater Sound Control and Abatement Plan	Includes measures to minimize the effects of underwater construction noise on fish, particularly from any required impact pile driving activities. Potential effects of pile driving will be minimized by restricting work to the least sensitive period of the year and by controlling or abating underwater noise generated during pile driving.
MM AQUA-9	Methylmercury Management	Design and construction of tidal wetland restoration and mitigation sites to minimize ecological risks of methylmercury production.
MM AQUA-10	Noise Abatement	Develop and implement a plan to avoid or reduce the potential in-air noise impacts related to construction, maintenance, and operations.
MM AQUA-11	Hazardous Material Management	Develop and implement site-specific plans that will provide detailed information on the types of hazardous materials used or stored at all sites associated with facilities and required emergency-response procedures in case of a spill. Before construction activities begin, establish a specific protocol for the proper handling and disposal of hazardous materials.
MM AQUA-12	Construction Site Security	Provide all security personnel with environmental training similar to that of onsite construction workers, so that they understand the environmental conditions and issues associated with the various areas for which they are responsible at a given time.
MM AQUA-13	Notification of Activities in Waterways	Before in-water construction or maintenance activities begin, notify appropriate agency representatives when these activities could affect water quality or aquatic species.
MM-AQUA-14	Fugitive Dust Control	Implement basic and enhanced control measures at all construction and staging areas to reduce construction-related fugitive dust and ensure the project commitments are appropriately implemented before and during construction, and that proper documentation procedures are followed.

MM AQUA-1: Worker Awareness Training

Reclamation or its designees will provide training to field management and construction personnel on the importance of protecting sensitive natural resources (i.e., listed species and designated critical and/or suitable habitat for listed species). Training will be conducted during preconstruction meetings so that construction personnel are aware of their responsibilities and the importance of compliance. All trainees will be required to sign a sheet indicating their attendance and completion of environmental training. The training sheets will be provided to the fish and wildlife agencies if requested. These requirements also pertain to operations and maintenance personnel working in and adjacent to suitable habitat for listed species.

Construction personnel will be educated on the types of sensitive resources located in the project area and the measures required to avoid and minimize effects on these resources. Materials covered in the training program will include environmental rules and regulations for the specific project, requirements for limiting activities to approved work areas, timing restrictions, and avoidance of sensitive resource areas. In general, trainings will include the following components.

- Important timing windows for listed species (i.e., timing of fish migration, spawning, and rearing; and wildlife mating, nesting, and fledging).
- Specific training related to the relevant mitigation measures that will be implemented during construction for the protection of listed species and their habitat.
- The legal requirements for resource avoidance and protection.
- Identification of listed species potentially affected at the worksite, which will depend upon the work to be performed and the location of the work.
- Protocol for identifying the proper mitigation measures to implement for the protection of listed species based upon the nature, timing, and location of construction activities to be performed.
- Brief discussions of listed species of concern.
- Boundaries of the work area.
- Avoidance and minimization commitments.
- Exclusion and construction fencing methods.
- Roles and responsibilities.
- What to do when listed species are encountered (dead, injured, stressed, or entrapped) in work areas.
- Penalties for noncompliance.

A fact sheet or other supporting materials containing this information will be prepared and will be distributed along with a list of contacts (names, numbers, and affiliations) prior to initiating construction activities. A representative will be appointed by the project proponent to be the primary point of contact for any employee or contractor who might inadvertently take a listed species, or a representative will be identified during the employee education program and the representative's name and telephone number provided to the fish and wildlife agencies.

If new construction personnel are added to the project, the contractor will ensure that the personnel receive the mandatory training and sign a sheet indicating their attendance and completion of the environmental training before starting work. The training sheets for new construction personnel will be provided to the fish and wildlife agencies, if requested.

MM AQUA-2 Construction Best Management Practices and Monitoring

All construction and operation and maintenance activities in and adjacent to suitable habitat for listed species will implement BMPs and have construction monitored by a qualified technical specialist(s). Depending on the resource of concern and construction timing, construction activities and areas will be monitored for compliance with water quality regulations (SWPPP monitoring) and with Mitigation Measures developed for sensitive biological resources (biological monitoring).

Before initiating construction, Reclamation or its designee will prepare a construction monitoring plan for the protection of listed species. The plan will include, but not be limited to, the following elements.

- Reference to or inclusion of the SWPPP prepared under the Construction General Permit (CGP), where one is needed.
- Summaries or copies of planning and preconstruction surveys (if applicable) for listed species.
- Description of Mitigation Measures to be implemented.
- Descriptions of monitoring parameters (e.g., turbidity), including the specific activities to be monitored (e.g., dredging, grading activities) and monitoring frequency and duration (e.g., once per hour during all in-water construction activities), as well as parameters and reporting criteria.
- Description of the onsite authority of the monitors to modify construction activity and protocols for notifying CDFW, NMFS, and USFWS, if needed.
- A daily monitoring log prepared by the construction monitor, which documents the day's construction activities, notes any problems identified and solutions implemented to rectify those problems, and notifies the construction superintendent and/or the fish and wildlife agencies of any exceedances of specific parameters (e.g., turbidity) or observations of listed species. The monitoring log will also document construction start/end times, weather and general site conditions, and any other relevant information.

The following measures will be implemented prior to and during performance of the proposed action, for the protection of listed species and their habitat.

- All in-water construction activities within jurisdictional waters will be conducted during the following in-water work windows:
  - Within the legal Delta and Suisun Bay/Suisun Marsh: August 1 to October 31;
  - Sacramento River upstream of the Delta:
    - Keswick Dam (RM 302) to approximately 1.5 miles downstream (Zone 1): year-round (any time flows are less than 15,000 cfs);
    - Approximately 1.5 miles downstream of Keswick Dam (RM 300.5) to Cow Creek (RM 280) (Zone 2): October 1 to May 15 (any time flows are less than 10,000 cfs; pre-construction salmonid redd surveys conducted);
    - Cow Creek (RM 280) to Red Bluff Diversion Dam (RM 243): October 1 to March 1 (any time flows are less than 10,000 cfs; pre-construction salmonid redd surveys conducted);
    - Downstream of Red Bluff Diversion Dam (RM 243) to the boundary with the legal Delta: June 1 to October 1.

- American River:
  - July 1 to September 30.
- Feather River:
  - August 1 to October 31.
- Stanislaus River:
  - July 15 to October 15.
- Other locations proposed through programmatic actions (e.g., San Joaquin River, Battle Creek):
  - To be developed through coordination with NMFS, USFWS, and DFW.
- Note: Work windows will be refined as necessary through coordination with NMFS, USFWS, and DFW. Work windows for some activities such as pile driving may be lengthened subject to agency approval based on demonstrated success of mitigation (e.g., bubble curtains) and real-time monitoring for fish presence. In-water activities associated with mobilization and demobilization are not subject to the work windows. Apart from impact pile driving, any other work may occur within a dewatered cofferdam regardless of the timing of in-water work windows. In-water impact pile installation may occur outside of the work windows if performed within a dewatered cofferdam and with in-channel acoustic monitoring to verify that generated sound thresholds do not exceed the 150-dB behavioral criterion. Any extension/reduction of work windows would focus on half-month increments.

- To the extent possible, in-water work will only occur for up to 12 hours per day, or from at least one hour after sunrise to at least one before sunset, in order to provide a crepuscular/nocturnal time window for fish migration without disturbance. Timing of this daily in-water work window will be refined as necessary through coordination with NMFS, USFWS, and DFW.
- Qualified biologists will monitor construction activities in areas identified as having listed species or their designated critical habitat. The intent of the biological monitoring is to ensure that specific Mitigation Measures that have been integrated into the project design and permit requirements are being implemented correctly during construction and are working appropriately and as intended for the protection of listed species.
- Biological monitors will be professional biologists selected for their knowledge of the listed species that may be affected by construction activities. The qualifications of the biologist(s) will be presented to the fish and wildlife agencies for review and written approval prior to initiating construction. The biological monitors will have the authority to temporarily stop work in any area where a listed species has been observed until that individual has passively or physically been moved outside of the work area, or when any Mitigation Measures are not functioning appropriately for the protection of listed species.
- Exclusionary fencing may be placed at the edge of active construction activities and staging areas (after having been cleared by biological surveys) to restrict wildlife access from the adjacent habitats. The need for exclusionary fencing will be determined during the preconstruction surveys and the construction planning phase and may vary depending on the species and habitats present. Exclusionary fencing will consist of taut silt fabric (non-monofilament), 24 inches high (36 inches high for California red-legged frog and giant garter snake), staked at 10-foot intervals, with the bottom buried 6 inches below grade. Fence stakes will face toward the work area (on the

opposite side of adjacent habitat) to prevent wildlife from using stakes to climb over the exclusionary fencing. Exclusionary fencing will be maintained such that it is intact during rain events. Fencing will be checked by the biological monitor or construction foreman periodically throughout each work day. If fencing becomes damaged, it will be immediately repaired upon detection and the monitoring biologist will stop work in the vicinity of the fencing as needed to ensure that no sensitive wildlife species have entered. Active construction and staging areas will be delineated with high-visibility temporary fencing at least 4 feet in height, flagging, or other barrier to prevent encroachment of construction personnel and equipment outside the defined project footprint. Such fencing will be inspected and maintained daily by the construction foreman until completion of the project. Fencing will be removed from work areas only after all construction activities are completed and equipment is removed. No project-related construction activities will occur outside the delineated project construction areas.

- Project-related vehicles will observe a speed limit of 20 miles per hour in construction areas where it is safe and feasible to do so, except on county roads and state and federal highways. A vehicle speed limit of 20 miles per hour will be posted and enforced on all nonpublic access roads, particularly on rainy nights when California tiger salamanders and California red-legged frogs are most likely to be moving between breeding and upland habitats. Extra caution will be used on cool days when giant garter snakes may be basking on roads.
- All ingress/egress at the project site will be restricted to those routes identified in the project plans and description.
- All vehicle parking will be restricted to established areas, existing roads, or other suitable areas.
- To avoid attracting predators, all food-related trash items such as wrappers, cans, bottles, and food scraps will be disposed of in enclosed containers and trash will be removed and disposed of at an appropriate facility at least once a week from the construction or project site.
- To avoid injury or death to wildlife, no firearms will be allowed on the project site except for those carried by authorized security personnel or local, state, or federal law enforcement officials.
- To prevent harassment, injury, or mortality of sensitive wildlife by dogs or cats, no canine or feline pets will be permitted in the construction area.
- To prevent inadvertent entrapment of wildlife during construction, all excavated, steep-walled holes or trenches more than 1 foot deep will be covered at the close of each working day with plywood or similar material, and/or provided with one or more escape ramps constructed of earth fill or wooden planks. Before such holes or trenches are filled, they will be thoroughly inspected for trapped animals. If a listed species is encountered during construction work, to the extent feasible, construction activities should be diverted away from the animal until it can be moved by a USFWS- or CDFW-approved biologist.
- Capture and relocation of trapped or injured wildlife will only be performed by personnel with appropriate USFWS and CDFW handling permits. Any sightings and any incidental take will be reported to CDFW and USFWS via email within 1 working day of the discovery. A follow-up report will be sent to these agencies, including dates, locations, habitat description, and any corrective measures taken to protect listed species encountered. For each listed species encountered, the biologist will submit a completed CNDDB field survey form (or equivalent) to CDFW no more than 90 days after completing the last field visit to the project site.

- Plastic monofilament netting or similar material will not be used for erosion control, because smaller wildlife may become entangled or trapped in it. This includes products that use photodegradable or biodegradable synthetic netting, which can take several months to decompose. Acceptable materials include natural fibers such as jute, coconut, twine, or other similar fibers or tackified hydroseeding compounds. This limitation will be communicated to the contractor through specifications or special provisions included in the construction bid solicitation package.
- Listed species of wildlife can be attracted to den-like structures such as pipes and may enter stored pipes and become trapped or injured. All construction pipes, culverts, or similar structures, construction equipment, or construction debris left overnight in areas that may be occupied by wildlife will be inspected by the biological monitor or the contractor prior to being used for construction. Such inspections will occur at the beginning of each day’s activities, for those materials to be used or moved that day. If necessary, and under the direct supervision of the biologist, the structure may be moved up to one time to isolate it from construction activities, until the listed species has moved from the structure of their own volition, been captured and relocated, or otherwise been removed from the structure.
- Rodenticides and herbicides will be used in accordance with the manufacturer-recommended uses and applications and in such a manner as to prevent primary or secondary poisoning of listed species and depletion of prey populations upon which they depend. All uses of such compounds will observe label and other restrictions mandated by the U.S. Environmental Protection Agency (EPA), the California Department of Pesticide Regulation, and other appropriate state and federal regulations, as well as additional project-related restrictions imposed by USFWS, NMFS and/or CDFW. If rodent control must be conducted in San Joaquin kit fox habitat, zinc phosphide should be used because of its proven lower risk to kit fox. In addition, the method of rodent control will comply with provisions of the 4(d) rule published in the final listing rule for California tiger salamander (69 *Federal Register* [FR] 47211–47248).
- Nets or bare hands may be used to capture and handle individuals of listed species. A professional biologist will be responsible for and direct any efforts to capture and handle listed species. Any person who captures and handles listed species will not use soaps, oils, creams, lotions, insect repellents, solvents, or other potentially harmful chemicals of any sort on their hands within 2 hours before handling listed species. Latex gloves will not be used either. To avoid transferring diseases or pathogens between aquatic habitats during the course of surveys or the capture and handling of listed species, all species captured and handled will be released in a safe, aquatic environment as close to the point of capture as possible, and not transported and released to a different water body. When capturing and handling listed species of amphibians, the biologists will follow the Declining Amphibian Task Force’s *Code of Practice* (U.S. Fish and Wildlife Service no date). While in captivity, individual amphibians will be kept in a cool, moist, aerated environment such as a dark (i.e., green or brown) bucket containing a damp sponge. Containers used for holding or transporting these species will be sanitized and will not contain any standing water.
- CDFW, NMFS and/or USFWS will be notified within 1 working day of the discovery of, injury to, or mortality of a listed species that results from project-related construction activities or is observed at the project site. Notification will include the date, time, and location of the incident or of the discovery of an individual listed species that is dead or injured. For a listed species that is

injured, general information on the type or extent of injury will be included. The location of the incident will be clearly indicated on a U.S. Geological Survey 7.5-minute quadrangle and/or similar map at a scale that will allow others to find the location in the field, or as requested by CDFW, NMFS and/or USFWS. The biologist is encouraged to include any other pertinent information in the notification.

- Permanent and temporary construction disturbances and other types of ongoing project-related disturbance activities in suitable habitat for listed species will be minimized by adhering to the following activities.
  - Project designs will limit or cluster permanent project features to the smallest area possible while still permitting achievement of project goals.
  - To minimize temporary disturbances, all project-related vehicle traffic and material storage will be restricted to established and/or designated ingress/egress points, construction areas, and other designated staging/storage areas. These areas will be included in preconstruction surveys and, to the extent possible, will be established in locations disturbed by previous activities to prevent further effects.
  - To the extent possible, minimize effects to sensitive habitats outside of construction footprints. For example, in upstream areas, conduct aerial or boat pre-construction redd surveys downstream of construction areas and implement avoidance and minimization measures to limit potential effects, e.g., modification of work area, turbidity management (such as a sediment curtain), or placement of a gravel berm to redirect flow away from sensitive areas.
  - Upon completion of the project, all areas subject to temporary ground disturbance will be recontoured to preproject elevations, as appropriate and necessary, and revegetated with native vegetation to promote restoration of the area to preproject conditions. An area subject to “temporary” disturbance is any area that is disturbed to allow for construction of the project, but is not required for operation or maintenance of any project-related infrastructure, will not be subject to further disturbance after project completion, and has the potential to be revegetated. Appropriate methods and native plant species used to revegetate such areas will be determined on a site-specific basis in consultation with USFWS, NMFS, and/or CDFW, and biologists.
- Equipment will be inspected prior to arrival at the construction area, including the physical removal of plant seed and parts from equipment, and freezing equipment and saturation of equipment in chemical solution(s) to avoid the spread of invasive species such as zebra and quagga mussels, New Zealand mudsnails and Chytrid Fungus.

Mitigation Measure AQUA-3 Develop and Implement Program to Expand Adult Holding, Spawning, Egg Incubation, and Fry/Juvenile Rearing Habitat.

Reclamation will develop and implement a program to expand suitable adult holding, spawning, egg incubation, and fry/juvenile rearing habitat for Central Valley Spring-Run Chinook Salmon, Fall-/Late Fall-Run Chinook Salmon, and Central Valley Steelhead elsewhere in the Northwestern California Diversity Group. The program will be designed to prevent hybridization and improve genetic integrity of Spring-Run Chinook Salmon, and to improve spawning success, fry/juvenile survival, and production of all three species, thereby contributing to their recovery. Increases in Salmon and Steelhead production potential created by the program will equal or exceed the reduced production potential in Clear Creek that would result from cessation of the Clear Creek Restoration

Program and reduced flows below Whiskeytown Dam. The program will be developed in coordination with and subject to approval by NMFS and CDFW.

Mitigation Measure AQUA-4 Erosion and Sediment Control Plan

An erosion and sediment control plan is typically required for ground-disturbing projects as part of the NPDES permitting process (U.S. Environmental Protection Agency 2007), depending on the size of the disturbed area. The proposed Phase II EPA rules would cover projects with greater than 1 acre of ground disturbance. Reclamation commits to implementing measures as described below as part of the construction activities and in advance of any necessary permit. In accordance with these environmental commitments, Reclamation will ensure the preparation and implementation of erosion and sediment control plans to control short-term and long-term erosion and sedimentation effects and to restore soils and vegetation in areas affected by construction activities. It is anticipated that multiple erosion and sediment control plans will be prepared for the construction activities included in the proposed action, each taking into account site-specific conditions such as proximity to surface water, erosion potential, drainage, etc. The plans will include all the necessary state requirements regarding erosion control and will implement BMPs for erosion and sediment control that will be in place for the duration of construction activities. These BMPs will be incorporated into the SWPPP (Section 3.F.1.1.1, *Conduct Planning-Level Surveys*).

The following erosion control measures will be included in the SWPPP.

- Install physical erosion control stabilization BMPs (hydroseeding with native seed mix, mulch, silt fencing, fiber rolls, sand bags, and erosion control blankets) to capture sediment and control both wind and water erosion. Erosion control may not utilize plastic monofilament netting or similar materials.
- Maintain emergency erosion control supplies onsite at all times during construction and direct contractor(s) to use these emergency stockpiles as needed. Ensure that supplies used from the emergency stockpiles are replaced within 48 hours. Remove materials used in construction of erosion control measures from the work site when no longer needed (property of the contractor).
- Design grading to be compatible with adjacent areas and result in minimal disturbance of the terrain and natural land features and minimize erosion in disturbed areas to the extent practicable.
- Divert runoff away from steep, denuded slopes, or other critical areas with barriers, berms, ditches, or other facilities.
- Retain native trees and vegetation to the extent feasible to stabilize hillsides, retain moisture, and reduce erosion.
- Limit construction, clearing of native vegetation, and disturbance of soils to areas of proven stability.
- Implement construction management and scheduling measures to avoid exposure to rainfall events, runoff, or flooding at construction sites to the extent feasible.
- Conduct frequent site inspections (before and after significant storm events) to ensure that control measures are intact and working properly and to correct problems as needed.
- Install drainage control features (e.g., berms and swales, slope drains) as necessary to avoid and minimize erosion.
- Install wind erosion control features (e.g., application of hydraulic mulch or bonded fiber matrix).

The following sediment control measures will be included in the SWPPP.

- Use sediment ponds, silt traps, wattles, straw bale barriers, or similar measures to retain sediment transported by onsite runoff.
- Collect and direct surface runoff at non-erosive velocities to the common drainage courses.
- When ground-disturbing activities are required adjacent to surface water, wetlands, or aquatic habitat, use of sediment and turbidity barriers, and implement measures for soil stabilization and revegetation of disturbed surfaces.
- Prevent mud from being tracked onto public roadways by installing gravel on primary construction ingress/egress points, and/or truck tire washing.
- Deposit or store excavated materials away from drainage courses and cover if left in place for more than 5 days or if storm events are forecast within 48 hours.

After construction is complete, site-specific restoration efforts will include grading, erosion control, and revegetation. Self-sustaining, local native plants that require little or no maintenance and do not create an extreme fire hazard will be used. All disturbed areas will be recontoured to preproject contours as feasible, and seeded with a native seed mix. Consideration will also be given to additional replacement of or upgrades to drainage facilities to avoid and minimize erosion. Paved areas damaged from use over and above ordinary wear-and-tear from lawful use by construction activities will be repaved to avoid erosion due to pavement damage.

Mitigation Measure AQUA-5 Spill Prevention, Containment, and Countermeasure Plan

As required by local, state, or federal regulations, Reclamation will require that construction contractors develop an SPCC plan for implementation at each site where ground-disturbing activities occur. Each SPCC plan will comply with the regulatory requirements of the Spill Prevention, Control, and Countermeasure Rule (40 Code of Federal Regulations [CFR] 112) under the Oil Pollution Act of 1990. This rule regulates non-transportation-related onshore and offshore facilities that could reasonably be expected to discharge oil into navigable waters of the United States or adjoining shorelines. The rule requires the preparation and implementation of site-specific SPCC plans to prevent and respond to oil discharges that could affect navigable waters. Each SPCC plan will address actions used to prevent spills in addition to specifying actions that will be taken should any spills occur, including emergency notification procedures. The SPCC plans will include the following measures and practices.

- Discharge prevention measures will include procedures for routine handling of products (e.g., loading, unloading, and facility transfers) (*40 CFR 112.7(a)(3)(i)*).
- Discharge or drainage controls will be implemented such as secondary containment around containers and other structures and equipment, and procedures for the control of a discharge (*40 CFR 112.7(a)(3)(ii)*).
- Countermeasures will be implemented for discharge discovery, response, and cleanup (both the facility's capability and those that might be required of a contractor) (*40 CFR 112.7(a)(3)(iii)*).
- Methods of disposal of recovered materials will comply with applicable legal requirements (*40 CFR 112.7(a)(3)(iv)*).
- Personnel will be trained in emergency response and spill containment techniques, and will also be made aware of the pollution control laws, rules, and regulations applicable to their work.

- Petroleum products will be stored in nonleaking containers at impervious storage sites from which an accidental spill cannot escape.
- Absorbent pads, pillows, socks, booms, and other spill containment materials will be stored and maintained at the hazardous materials storage sites for use in the event of an accidental spill.
- Watertight forms and other containment structures will be used to prevent spills or discharge of raw concrete, wash water, and other contaminants from entering surface waters and other sensitive habitats during overwater activities (e.g., casting of barge decks).
- Contaminated absorbent pads, pillows, socks, booms, and other spill containment materials will be placed in nonleaking sealed containers until transported to an appropriate disposal facility.
- When transferring oil or other hazardous materials from trucks to storage containers, absorbent pads, pillows, socks, booms, or other spill containment material will be placed under the transfer area.
- Refueling of construction equipment will occur only in designated areas that will be a minimum of 150 feet from surface waters and other sensitive habitats, such as wetlands.
- Equipment used in direct contact with water will be inspected daily for oil, grease, and other petroleum products. All equipment will be cleaned of external petroleum products prior to beginning work where contact with water may occur in order to prevent the release of such products to surface waters.
- Oil-absorbent booms will be used when equipment is used in or immediately adjacent to waters.
- All reserve fuel supplies will be stored only within the confines of a designated staging area, to be located a minimum of 150 feet from surface waters and other sensitive habitats, such as wetlands.
- Fuel transfers will take place a minimum of 150 feet from surface waters and other sensitive habitats, such as wetlands, and absorbent pads will be placed under the fuel transfer operation.
- Staging areas will be designed to contain contaminants such as oil, grease, fuel, and other petroleum products so that should an accidental spill occur they do not drain toward receiving waters or storm drain inlets.
- All stationary equipment will be staged in appropriate staging areas and positioned over drip pans.
- In the event of an accidental spill, personnel will identify and secure the source of the discharge and contain the discharge with sorbents, sandbags, or other material from spill kits and will contact appropriate regulatory authorities (e.g., National Response Center will be contacted if the spill threatens navigable waters of the United States or adjoining shorelines, as well as other appropriate response personnel).

Methods of cleanup may include the following.

- Physical methods for the cleanup of dry chemicals include the use of brooms, shovels, sweepers, or plows.
- Mechanical methods could include the use of vacuum cleaning systems and pumps.
- Chemical methods include the use of appropriate chemical agents such as sorbents, gels, and foams.

Mitigation Measure AQUA-6 Disposal of Spoils and Dredged Material

In the course of constructing or operating project facilities, substantial quantities of material are likely to be removed from their existing locations based upon their properties or the need for excavation of particular features. Spoils refer to excavated native soils and are associated with construction of proposed new facilities. Dredged material refers to sediment removed from the bottom of a body of water for the purposes of in-water construction. The quantities of these materials generated by construction or operation of proposed facilities will vary based on various factors, such as location, topography, and structure being constructed. These materials will require handling, storage, and disposal, as well as chemical characterization. Storage areas are designated for these materials. Many of these materials will be suitable for reuse (e.g., as engineered fill or for purposes of habitat restoration), but such use is not part of the PA and projects using this material have not been identified.

Storage Area Determination

Spoils and dredged material will be stored in designated storage areas, with these locations to be provided by Reclamation during consultation with NMFS and USFWS.

The designated storage areas are sized to accommodate all material expected to be generated by the proposed action, i.e., it is assumed that none of that material will be reused, sold, or otherwise relocated under the proposed action. In practice, the area that will be needed for material storage will depend on several factors.

- The speed with which material is brought to the surface, stored, dried, tested, and moved to storage locations will be important in determining the final size of storage areas. If alternative end uses for the material can be identified and if those uses can be permitted within the timeframe of the proposed action (such permitting is not included in the proposed action, so separate authorizations would have to be obtained), then a smaller area may be needed for material storage.
- The depth to which the material is stacked. Material that is stored in deeper piles will require less area but may dry more slowly. Calculation of needed materials storage areas has assumed that materials would be placed in piles with a depth of six feet.

Storage Site Preparation

A portion of the storage sites selected for storage of spoils and dredged material will be set aside for topsoil storage. The topsoil will be saved for reapplication to disturbed areas postconstruction. Vegetative material from work site clearing will be chipped, stockpiled, and spread over the topsoil after earthwork is completed, when practicable and appropriate to do so and where such material does not contain seeds of undesirable nonnative species (i.e., nonnative species that are highly invasive and threaten the ecological function of the vegetation community to be restored in that location). Cleared areas will be grubbed as necessary to prepare them for grading or other construction activities. Rocks and other inorganic grubbed materials will be used to backfill borrow areas. The contractor will remove from the work site all debris, rubbish, and other materials not directed to be salvaged, and will dispose of them in an approved disposal site after obtaining all permits required.

Draining, Chemical Characterization, and Treatment

In instances of spoils and dredged material being deemed unsuitable for reuse, the material will be disposed of at a site for which disposal of such material is approved.

Hazardous materials excavated during construction will be segregated from other construction spoils and properly handled in accordance with applicable federal, state, and local regulations. Riverine or in-Delta sediment dredging and dredged material disposal activities may involve potential contaminant discharges not addressed through typical NPDES or SWRCB CGP processes. Construction of dredge material disposal sites will likely be subject to the SWRCB General Permit (Order No. 2009-0009-DWQ).

To better define potential effects to listed species or aquatic habitat, and to streamline the collection and incorporation of newer information (i.e., monitoring data or site-specific baseline information), the following protocol will be followed. Reclamation will work with State and Federal resource agencies with authorization and jurisdiction to identify the timeline for information gathering in relation to initiation of the specific action, but it is anticipated to be at least several months prior to the initiation of the action. At that time, Reclamation will follow the protocol below.

- Reclamation will ensure the preparation and implementation of a pre-dredge sampling and analysis plan (SAP). The SAP will be developed and submitted by the contractor(s) as part of the water plan required per standard DWR contract specifications (Section 01570). Prior to initiating any dredging activity, the SAP will evaluate the presence of contaminants that may affect water quality from the following discharge routes.
    - Instream discharges during dredging.
    - Direct exposure to contaminants in the material through ingestion, inhalation, or dermal exposure.
    - Effluent (return flow) discharge from an upland disposal site.
    - Leachate from upland dredge material disposal that may affect groundwater or surface water.
- Concentrations of the identified chemical constituents in the core samples will be screened through appropriate contaminant screening tables to ensure compliance with applicable agency guidelines.
- Results of the sediment analyses and the quality guidelines screening will determine the risk associated with the disturbance of the sediment horizons by identifying specific pathways of exposure to adverse effects.
- Results of the testing will be provided to all relevant State and Federal agencies for their use in monitoring or regulating the activities under consideration.
- If the results of the chemical analyses of the sediment samples indicate that one or more chemical constituents are present at concentrations exceeding screening criteria, then additional alternative protocols to further minimize or eliminate the release of sediments into the surrounding water column must be implemented.
- The applicant must provide to CDFW, NMFS and USFWS a plan to reduce or eliminate the release of contaminated sediment prior to the start of any actions that will disturb the sediments in the proposed construction area. Plans using a shrouded hydraulic cutterhead, or an environmentally sealed clamshell bucket may be acceptable provided that adequate supporting information is provided with the proposed plan. Plans should also include descriptions of the methods employed to treat, transport, and dispose of the contaminated sediment, as well as any resulting decant waters.

The following list of BMPs will be implemented during handling and disposal of any potentially hazardous dredged material.

- Conduct dredging within the allowable in-water work windows specified in Mitigation Measure AQUA-2 *Construction Best Management Practices*.
- Conduct dredging activities in a manner that will not cause turbidity in the receiving water, as measured in surface waters 300 feet down-current from the construction site, to exceed the Basin Plan objectives beyond an approved averaging period by the Central Valley Regional Water Quality Control Board and CDFW. Existing threshold limits in the Basin Plan for turbidity generation are as follows.
    - Where natural turbidity is between 0 and 5 NTUs, increases will not exceed 1 NTU.
    - Where natural turbidity is between 5 and 50 NTUs, increases will not exceed 20%.
    - Where natural turbidity is between 50 and 100 NTUs, increases will not exceed 10 NTUs.
    - Where natural turbidity is greater than 100 NTUs, increases will not exceed 10%.
- If turbidity generated during dredging exceeds implementation requirements for compliance with the Basin Plan objectives, silt curtains will be used to control turbidity. Exceptions to turbidity limits set forth in the Basin Plan may be allowed for dredging operations; in this case, an allowable zone of dilution within which turbidity exceeds the limits will be defined and prescribed in a discharge permit.
- The dredged material disposal sites will be designed to contain all of the dredged material. All systems and equipment associated with necessary return flows from the dredged material disposal site to the receiving water will be operated to maximize treatment of return water and optimize the quality of the discharge.
- The dredged material disposal sites will be designed by a registered professional engineer.
- The dredged material disposal sites will be designed, constructed, operated, and maintained to prevent inundation or washout due to floods with a 100-year return frequency.
- Two feet of freeboard above the 100-year flood event elevation will be maintained in all dredged material disposal site settling ponds at all times when they may be subject to washout from a 100-year flood event.
- Dredging equipment will be kept out of riparian areas and dredged material will be disposed of outside of riparian corridors.

Temporary storage sites will be constructed using appropriate BMPs such as erosion and sediment control measures (Mitigation Measure AQUA-*4 Erosion and Sediment Control Plan*) to prevent discharges of contaminated stormwater to surface waters or groundwater.

Once the excavated spoils or dredged material have been suitably dewatered, and as the constituents of the material will allow, it will be placed in either a lined or unlined storage area suitable for long-term storage. These long-term storage areas may be the same areas in which the material was previously dewatered or it may be a new area adjacent to the dewatering site. The storage areas will be created by excavating and stockpiling the native topsoil for future reuse. Once the area has been suitably excavated, and if a lined storage area is required, an impervious liner will be placed on the invert of the material storage area and along the interior slopes of the berms surrounding the pond. Due to the expected high groundwater tables at some storage areas, it is anticipated that there will be minimal excavation for construction of the long-term material storage areas. Additional features of the long-term material storage areas will include berms and erosion protection measures to contain storm runoff as necessary and provisions to allow for truck traffic during construction.

Mitigation Measure AQUA-7 Fish Rescue and Salvage Plan

Fish rescue operations will occur at any in-water construction site where dewatering and resulting isolation of fish may occur, or where fish exclusion netting is placed to exclude fish. Fish rescue and salvage plans will be developed by Reclamation or its contractors and will include detailed procedures for fish rescue and salvage to minimize the number of individuals of listed fish species subject to stranding during placement and removal of cofferdams or enclosure by exclusion netting. The plans will identify the appropriate procedures for removing fish from construction zones and preventing fish from reentering construction zones prior to dewatering and other construction activities. A draft plan will be submitted to the fish and wildlife agencies for review and approval. An authorization letter from NMFS, USFWS, and CDFW will be required before in-water construction activities with the potential for stranding fish can proceed.

Some construction activities may involve placement of cofferdams to isolate construction areas and minimize adverse effects to aquatic species and habitat during construction activities. However, these species can become trapped within the cofferdam and will need to be rescued or salvaged prior to dewatering. Although the following discussion focuses primarily on the application of this plan to cofferdam construction, the plan will also need to describe potential fish protection methods that may be implemented during other in-water activities with the potential to trap fish. For example, potential measures to exclude fish from active dredging areas may include deployment of silt curtains in a manner that directs fish away from the silt curtains and prevents fish from re-entering these areas during dredging operations. To the extent possible, fish will be gently encouraged (e.g., swept with seine nets; see below) to leave any areas that are scheduled to be dewatered or otherwise disturbed.

All fish rescue and salvage operations will be conducted under the guidance of a qualified fish biologist and in accordance with required permits. Each fish rescue plan will identify the appropriate procedures for excluding fish from the construction zones, and procedures for removing fish, should they become trapped. The primary procedure will be to block off the construction area and use seines (nets) and/or dip nets to collect and remove fish, although electrofishing techniques may also be authorized under certain conditions. It is critical that fish rescue and salvage operations begin as soon as possible and be completed within 48 hours after isolation of a construction area to minimize potential predation and adverse water quality impacts (high water temperature, low dissolved oxygen) associated with confinement. In the case of cofferdam construction, the cofferdam will be installed to block off the construction area before fish removal activities occur. For other in-water construction activities, block nets or other temporary exclusion methods (e.g., silt curtains) could be used to exclude fish or isolate the construction area prior to the fish removal process. The appropriate fish exclusion or collection method will be determined by a qualified fish biologist, in consultation with a designated fish and wildlife agency biologist, based on site-specific conditions and construction methods. Capture, release, and relocation measures will be consistent with the general guidelines and procedures set forth in Part IX of the most recent edition of the California Salmonid Stream Habitat Restoration Manual (currently, California Department of Fish and Game 2010) to minimize impacts on listed species of fish and their habitat.

All fish rescue and salvage operations will be conducted under the guidance of a fish biologist meeting the qualification requirements of Section 3.F.2.8.1 Qualifications of Fish Rescue Personnel. The following description includes detailed fish collection, holding, handling, and release procedures of the plan. Unless otherwise required by project permits, the construction contractor will provide the following:

- A minimum 7-day notice to the appropriate fish and wildlife agencies, prior to an anticipated activity that could result in isolating fish, such as installation of a cofferdam.
- A minimum 48-hour notice to the appropriate fish and wildlife agencies of dewatering activities that are expected to require fish rescue.
- Unrestricted access for the appropriate fish and wildlife agency personnel to the construction site for the duration of implementation of the fish rescue plan.
- Temporary cessation of dewatering if fish rescue workers determine that water levels may drop too quickly to allow successful rescue of fish.
- A work site that is accessible and safe for fish rescue workers.

Qualifications of Fish Rescue Personnel

Personnel active in fish rescue efforts will include at least one person with a 4-year college degree in fisheries or biology, or a related degree. This person also must have at least 2 years of professional experience in fisheries field surveys and fish capture and handling procedures. The person will have completed an electrofishing training course such as Principles and Techniques of Electrofishing (USFWS, National Conservation Training Center), or similar course, if electrofishing is used. In order to avoid and minimize the risk of injury to fish, attempts to seine and/or net fish will always precede the use of electrofishing equipment.

Seining and Dipnetting

Fish rescue and salvage operations will begin prior to or immediately after completing the cofferdam. For example, it may be necessary to herd fish from the construction area before installing the last sections of the cofferdam. Where larger areas are being enclosed by cofferdams, fish exclusion and/or rescue activities may need to be conducted incrementally in coordination with cofferdam placement to minimize the number of fish subjected to prolonged confinement and stressful conditions associated with crowding, capture, and handling. If the enclosed area is wadable (less than 3 feet deep), fish can be herded out of the cofferdam enclosure by dragging a seine (net) through the enclosure, starting from the enclosed end and continuing to the cofferdam opening. Depending on conditions, this process may need to be conducted several times. After completing this fish herding process, the net or an exclusion screen will be positioned at the cofferdam opening to prevent fish from reentering the enclosure while the final section of the cofferdam is installed. The net or screen mesh will be no greater than 0.125 inch, with the bottom edge of the net (lead line) securely weighted down to prevent fish from entering the area by moving under the net. Screens will be checked periodically and cleaned of debris to permit free flow of water.

After installing the last sections of the cofferdam, remaining fish in the enclosed area will be removed using seines, dip nets, electrofishing techniques, or a combination of these depending on site conditions. If the water depth within the cofferdam is too deep to effectively remove fish using these methods, dewatering activities may be used to reduce the water level to an appropriate and safe depth (Section 3.F.2.8.5, *Contingency Plans*). Dewatering activities will also conform to the guidelines specified below (Section 3.F.2.8.4, *Dewatering*).

Following each sweep of a seine through the enclosure, the fish rescue team will do the following.

- Carefully bring the ends of the net together and pull in the wings, ensuring the lead line is kept as close to the substrate as possible.
- Slowly turn the seine bag inside out to reveal captured fish, ensuring fish remain in the water as long as possible before transfer to an aerated container.

- Follow the procedures outlined in Section 3.F.2.8.3, *Electrofishing*, and relocate fish to a predetermined release site.

Dipnetting is best suited for very small, shallow pools in which fish are concentrated and easily collected. Dip nets will be made of soft (nonabrasive) nylon material and small mesh size (0.125 inch) to collect small fish.

Electrofishing

After conducting the herding and netting operations described above, electrofishing may be necessary to remove as many fish as possible from the enclosure. Electrofishing will be conducted in accordance with NMFS electrofishing guidelines (NMFS 2000) and other appropriate fish and wildlife agency guidelines. Electrofishing will be conducted by one or two 3- to 4-person teams, with each team having an electrofishing unit operator and two or three netters. At least three passes will be made through the enclosed cofferdam areas to remove as many fish as possible. Fish initially will be placed in 5-gallon buckets filled with river water. Following completion of each pass, the electrofishing team will do the following.

- Transfer fish into 5-gallon buckets filled with clean river water at ambient temperature.
- Hold fish in 5-gallon buckets equipped with a lid and an aerator, and add fresh river water or small amounts of ice to the fish buckets if the water temperature in the buckets becomes more than 2°F warmer than ambient river waters.
- Maintain a healthy environment for captured fish, including low densities in holding containers to avoid effects of overcrowding.
- Use water-to-water transfers whenever possible.
- Release fish at predetermined locations.
- Segregate larger fish from smaller fish to minimize the risk of predation and physical damage to smaller fish from larger fish.
- Limit holding time to about 10 minutes, if possible.
- Avoid handling fish during processing unless absolutely necessary. Use wet hands or dip nets if handling is needed.
- Handle fish with hands that are free of potentially harmful products, including but not limited to sunscreen, lotion, and insect repellent.
- Avoid anesthetizing or measuring fish.
- Note the date, time, and location of collection; species; number of fish; approximate age (e.g., young-of-the-year, yearling, adult); fish condition (dead, visibly injured, healthy); and water temperature.
- If positive identification of fish cannot be made without handling the fish, note this and release fish without handling.
- In notes, indicate the level of accuracy of visual estimates to allow appropriate reporting to the appropriate fish and wildlife agencies (e.g., “Approx. 10–20 young-of-the-year steelhead”).
- Release fish in appropriate habitat either upstream or downstream of the enclosure, noting release date, time, and location.

- Stop efforts and immediately contact the appropriate fish and wildlife agencies if mortality during relocation or the limits on take (harm or harassment) of federally listed species exceeds 5%.
- Place dead fish of listed species in sealed plastic bags with labels indicating species, location, date, and time of collection, and store them on ice.
- Freeze collected dead fish of listed species as soon as possible and provide the frozen specimens to the appropriate fish and wildlife agencies, as specified in the permits.
- Sites selected for release of rescued fish either upstream or downstream of the construction area will be similar in temperature to the area from which fish were rescued, contain ample habitat, and have a low likelihood of fish reentering the construction area or being impinged on exclusion nets/screens.

Dewatering

Dewatering will be performed in coordination with fish rescue operations as described above. A dewatering plan will be submitted as part of the SWPPP/Water Pollution Control Program detailing the location of dewatering activities, equipment, and discharge point. Dewatering pump intakes will be screened to prevent entrainment of fish in accordance with NMFS screening criteria for salmonid fry (National Marine Fisheries Service 1997), including the following.

- Perforated plate: screen openings shall not exceed 3/32 inch (2.38 mm), measured in diameter.
- Profile bar: screen openings shall not exceed 0.0689 inch (1.75 mm) in width.
- Woven wire: screen openings shall not exceed 3/32 inch (2.38 mm), measured diagonally (e.g., 6–14 mesh).
- Screen material shall provide a minimum of 27% open area.

During the dewatering process, a qualified biologist or fish rescue team will remain onsite to observe the process and remove additional fish using the rescue procedures described above.

Contingency Plans

Where fish rescue and salvage operations cannot be conducted effectively or safely by fish rescue workers, it may be necessary to begin the dewatering process prior to fish rescue. During the dewatering process, a qualified biologist or fish rescue team will be onsite with the aim of minimizing the number of fish that become trapped in isolated areas or impinged on pump screen(s) or isolation nets, based on the professional judgment of the onsite fish biologist and the terms and conditions of the incidental take permit. In the event that the proposed methods are found to be insufficient to avoid undue losses of fish, the qualified biologist will modify these methods or implement alternative methods to minimize subsequent losses.

Final Inspections and Reporting

Upon dewatering to water depths at which neither electrofishing nor seining can effectively occur (e.g., less than 3 inches [0.1 meter]), the fish rescue team will inspect the dewatered areas to locate any remaining fish. Collection by dip net, data recording, and relocation will be performed as necessary according to the procedures outlined in Section 3.F.2.8.3, *Electrofishing*. The fish rescue team will notify the contractor when the fish rescue has been completed and construction can recommence. The results of the fish rescue and salvage operations (including date, time, location, comments, method of capture, fish species, number of fish, approximate age, condition, release location, and release time) will be reported to the appropriate fish and wildlife agencies, as specified in the pertinent permits.

Mitigation Measure AQUA-8 Underwater Sound Control and Abatement Plan

Reclamation will develop and implement an underwater sound control and abatement plan outlining specific measures that will be implemented to avoid and minimize the effects of underwater construction noise on listed species of fish, particularly the underwater noise effects associated with impact pile driving activities. Potential underwater noise effects on listed species from impact pile driving will be avoided and minimized by regulating the period during which impact pile driving is permitted and by controlling and/or abating underwater noise generated during impact pile driving.

The underwater sound control and abatement plan will be provided to the appropriate fish and wildlife agencies for their review and approval prior to implementation of any in-water impact pile driving activities. The plan will evaluate the potential effects of underwater noise on listed species of fish in the context of applicable and interim underwater noise thresholds established for disturbance and injury of fish (California Department of Transportation 2009). The thresholds include the following.

- Injury threshold for fish of all sizes includes a peak sound pressure level of 206 decibels (dB) relative to 1 micropascal.
- Injury threshold for fish less than 2 grams is 183 dB relative to 1 micropascal cumulative sound exposure level, and 187 dB relative to 1 micropascal cumulative sound exposure level for fish greater than or equal to 2 grams.
- Disturbance threshold for fish of all sizes is 150 dB root mean square relative to 1 micropascal.

The specific number of pilings that will be driven per day with an impact pile driver, and thus the number of pile strikes per day, will be defined as part of the design of project elements that require pilings.

The sound control and abatement plan will restrict in-water work to the in-water work windows specified in specified in Mitigation Measure AQUA-2 *Construction Best Management Practices*.

The underwater noise generated by impact pile driving will be abated using the best available and practicable technologies. Examples of such technologies include, but are not limited to, the use of cast-in-drilled-hole rather than driven piles; use of vibratory rather than impact pile driving equipment; using an impact pile driver to proof piles initially placed with a vibratory pile driver; noise attenuation using pile caps (e.g., wood or micarta), bubble curtains, air-filled fabric barriers, or isolation piles; or installation of piling-specific cofferdams. Specific techniques to be used will be selected based on site-specific conditions.

In addition to primarily using vibratory pile driving methods and establishing protocols for attenuating underwater noise levels produced during in-water construction activities, Reclamation will develop and implement operational protocols for when impact pile driving is necessary. These operational protocols will be used to minimize the effects of impact pile driving on listed species of fish. These protocols may include, but not be limited to, the following: monitoring the in-water work area for fish that may be showing signs of distress or injury as a result of pile driving activities and stopping work when distressed or injured fish are observed; initiating impact pile driving with a "soft-start," such that pile strikes are initiated at reduced impact and increase to full impact over several strikes to provide fish an opportunity to move out of the area; restricting impact pile driving activities to specific times of the day and for a specific duration to be determined through coordination with the fish and wildlife agencies; and, when more than one pile driving rig is employed, ensure pile driving activities are initiated in a way that provides an escape route and avoids "trapping" fish between pile drivers in waters exposed to underwater noise levels that could potentially cause injury. These protocols are expected to avoid and minimize the overall extent, intensity, and duration of potential underwater noise effects associated with impact pile driving activities.

Mitigation Measure AQUA-9 Methylmercury Management

Tidal and other habitat restoration under the proposed action has the potential to result in increased availability of mercury, and specifically the bioavailable form methylmercury, to the foodweb in the Delta and river systems where restoration would occur. Due to the complex and very site-specific factors that will determine if mercury becomes mobilized into the foodweb, Mitigation Measure AQUA-9 *Methylmercury Management* is included to provide for site-specific evaluation for each restoration project. Mitigation Measure AQUA-9 will be implemented in coordination with other similar efforts to address mercury in the Delta and other waterways, and specifically with the DWR Mercury Monitoring and Analysis Section, as further described below.

This Mitigation Measure will promote the following actions.

- Assessment of pre-restoration conditions to determine the risk that the project could result in increased mercury methylation and bioavailability
- Definition of design elements that minimize conditions conducive to generation of methylmercury in restored areas
- Definition of strategies that can be implemented to monitor and minimize actual postrestoration creation and mobilization of methylmercury into environmental media and biota

The restoration design will always focus on the ecosystem restoration objectives and design elements to mitigate mercury methylation that will not interfere with restoration objectives. Design elements that help to mitigate mercury methylation will be integrated into site-specific restoration designs based on site conditions, community type (tidal marsh, nontidal marsh, floodplain, riverine habitats), and potential concentrations of mercury in pre-restoration sediments. Strategies to minimize postrestoration creation and mobilization of methylmercury can be applied where site conditions indicate a high probability of methylmercury generation and effects on listed species.

Implementation

Mitigation Measure AQUA-9 will be developed and implemented in coordination with the Sacramento-San Joaquin Delta Methylmercury Total Maximum Daily Load (Methylmercury TMDL) (Central Valley Regional Water Quality Control Board 2011a) and Amendments to the Water Quality Control Plan for the Sacramento River and San Joaquin River Basins for the Control of Methylmercury and Total Mercury in the Sacramento-San Joaquin Delta Estuary (Mercury Basin Plan Amendments)(Central Valley Regional Water Quality Control Board 2010 and 2011). Mitigation Measure AQUA-9 will also be implemented to meet requirements of the U.S. Environmental Protection Agency (EPA) or the California Department of Toxic Substances Control actions.

The DWR Mercury Monitoring and Evaluation Section is currently working on DWR’s compliance with the Methylmercury TMDL and Mercury Basin Plan Amendments. The Methylmercury TMDL programs are responsible for developing measures to control methylmercury generation and loading into the Delta in accordance with Methylmercury TMDL goals. Phase I emphasizes studies and pilot projects to develop and evaluate management practices to control methylmercury. Phase I (effective October 2011) will be underway for the next 7 years, with an additional 2 years to evaluate Phase I results and plan for Phase II. Phase II involves implementation of mercury control measures.

The DWR Mercury Monitoring and Evaluation Section is required as part of Phase I to submit final reports that present the results and descriptions of methylmercury control options, their preferred methylmercury controls, and proposed methylmercury management plan(s) (including implementation schedules) for achieving methylmercury allocations. Results will be integrated into Project-Specific Mercury Management Plans, which will be developed for each tidal wetland restoration project. The Plans will include the components listed below.

- A brief review of available information on levels of mercury expected in site sediments/soils based on proximity to sources and existing analytical data.
- A determination if sampling for characterization of mercury concentrations
- A plan for conducting the sampling, if characterization sampling is recommended.
- A determination of the potential for the restoration action to result in increased mercury methylation
- If a potential for increased mercury methylation under the restoration action is identified, the following will also be included:
    - Identification of any restoration design elements, mitigation measures, adaptive management measures that could be used to mitigate mercury methylation, and the probability of success of those measures, including uncertainties
    - Conclusion on the resultant risk of increased mercury methylation, and if appropriate, consideration of alternative restoration areas

Because methylmercury is an area of active research in the Delta and elsewhere in the Central Valley, each new project-specific methylmercury management plan will be updated based on the latest information about the role of mercury in Delta and other ecosystems or methods for its characterization or management. Results from monitoring of methylmercury in previous restoration projects will also be incorporated into subsequent project-specific methylmercury management plans.

In each of the project-specific methylmercury management plans developed under Mitigation Measure AQUA-9, relevant findings and mercury control measures identified as part of TMDL Phase I control studies will be considered and integrated into restoration design and management plans.

Mitigation Measure AQUA-10 Noise Abatement

In addition to the underwater sound control and abatement plan (Mitigation Measure AQUA-8), Reclamation and contractors hired to construct any components of proposed facilities will implement a noise abatement plan to avoid or reduce potential in-air noise impacts related to construction, maintenance, and operations. As applicable, the following components will be included in the plan.

Construction and Maintenance Noise

- To the extent feasible, the contractor will employ best practices to reduce construction noise during daytime and evening hours (7:00 a.m. to 10:00 p.m.) such that construction noise levels do not exceed 60 dBA (A-weighted decibel) L_{eq} (1 hour) at the nearest residential land uses.
- Limit construction during nighttime hours (10:00 p.m. to 7:00 a.m.) such that construction noise levels do not exceed 50 dBA L_{max} (L_{max} is the maximum sound level measured for a given interval of time) at the nearest residential land uses. Limit pile driving to daytime hours (7 a.m. to 7 p.m.).
- In the event of complaints by nearby residents due to construction noise generated during nighttime hours, the contractor will monitor noise levels intermittently between 10:00 p.m. to 7:00 a.m. at the property line of the nearest residential use. In the event that construction noise during nighttime hours exceeds 50 dBA L_{max}, the construction contractor will cease nighttime

construction activity in the area until sound-attenuating mitigation measures, such as temporary sound walls, are implemented, and nighttime construction noise at the nearest residential use is reduced to a level of 50 dBA L_{max} or lower.

- Locate, store, and maintain portable and stationary equipment as far as possible from nearby residents.
- Employ preventive maintenance including practicable methods and devices to control, prevent, and minimize noise.
- Route truck traffic in order to reduce construction noise impacts and traffic noise levels at noise-sensitive land uses (i.e., places where people reside, schools, libraries, and places of worship).
- To the extent feasible, schedule construction activities so that the loudest noise events, such as blasting, occur during peak traffic commute hours.
- Limit offsite trucking activities (e.g., deliveries, export of materials) to the hours of 7:00 a.m. to 10:00 p.m. to minimize impacts on nearby residences.

Operation Noise

Facilities will be designed and constructed such that facility operation noise levels at nearby residential land uses do not exceed 50 dBA L_{eq} during daytime hours (7:00 a.m. to 10:00 p.m.) and 45 dBA L_{eq} during nighttime hours (10 p.m. to 7 a.m.). Acoustical measures such as terrain shielding, enclosures, and acoustical building treatments will be incorporated into the facility design to meet this performance standard.

Mitigation Measure AQUA-11 Hazardous Materials Management

Reclamation will ensure that each contractor responsible for site work under the proposed action will develop and implement a hazardous materials management plan (HMMP) before beginning construction. It is anticipated that multiple HMMPs will be prepared for the various construction sites, each taking into account site-specific conditions such as hazardous materials present onsite and known historical site contamination. A database on historical instances of contamination and results of any field inspections regarding the presence of hazardous chemicals will be maintained. The HMMPs will provide detailed information on the types of hazardous materials used or stored at all sites associated with the water conveyance facilities (e.g., intake pumping plants, maintenance facilities); phone numbers of applicable city, county, state, and federal emergency response agencies; primary, secondary, and final cleanup procedures; emergency-response procedures in case of a spill; and other applicable information. The HMMPs will include appropriate practices to reduce the likelihood of a spill of toxic chemicals and other hazardous materials during construction and facilities operation and maintenance. A specific protocol for the proper handling and disposal of hazardous materials will be established before construction activities begin and will be enforced by Reclamation.

The HMMPs will include, but not be limited to, the following measures or practices.

- Fuel, oil, and other petroleum products will be stored only at designated sites.
- Hazardous materials containment containers will be clearly labeled with the identity of the hazardous materials contained therein, handling and safety instructions, and emergency contact.
- Storage, use, or transfer of hazardous materials in or near wet or dry streams will be consistent with California Fish and Game Code (Section 5650) and/or with the permission of CDFW.

- Material Safety Data Sheets will be made readily available to the contractor's employees and other personnel at the work site.
- The accumulation and temporary storage of hazardous wastes will not exceed 90 days.
- Soils contaminated by spills or cleaning wastes will be contained and removed to an approved disposal site.
- Hazardous waste generated at work sites, such as contaminated soil, will be segregated from other construction spoils and properly handled, hauled, and disposed of at an approved disposal facility by a licensed hazardous waste hauler in accordance with state and local regulations. The contractor will obtain permits required for such disposal.
- Emergency spill containment and cleanup kits will be located at the facility site. The contents of the kits will be appropriate to the type and quantities of chemical or goods stored at the facility.

Mitigation Measure AQUA-12 Construction Site Security

To ensure adequate construction site security, Reclamation or their contractors will arrange to provide for 24-hour onsite security personnel. Security personnel will monitor and patrol construction sites, including staging and equipment storage areas. Security personnel will serve as the first line of defense against criminal activities and nuisances at construction sites. Private patrol security operators hired to provide site security will have the appropriate licenses from the California Bureau of Security and Investigative Services. Individual security personnel will have a minimum security guard registration license that meets the California Bureau of Security and Investigative Services requirements for training and continuation training as required for that license. All security personnel will also receive environmental training similar to that of onsite construction workers so that they understand the environmental conditions and issues associated with the various areas for which they are responsible at a given time.

Security operations and field personnel will be given the emergency contact phone numbers of environmental response personnel for rapid response to environmental issues resulting from vandalism or incidents that occur when construction personnel are not onsite. Security operations will also maintain a contact list of backup support from city police, county sheriffs, California Highway Patrol, water patrols (such as the Contra Costa County Marine Patrol), helicopter response, and emergency response (including fire departments, ambulances/emergency medical technicians). The appropriate local and regional contact list will be made available to security personnel by Reclamation or their contractors, as will the means to make that contact via landline phones, mobile phones, or radios. When on patrol, security personnel will always have the ability to contact backup using mobile phones or two way radios. Security personnel who are on patrol will have the appropriate geographic contact list for their location and the ability to summon appropriate backup or response via the security patrol local dispatch site or outside authorities.

Mitigation Measure AQUA-13 Notification of Activities in Waterways

Similar to the requirements specified in the fish rescue and salvage plan (Mitigation Measure AQUA-7), and underwater sound control and abatement plan (Mitigation Measure AQUA-8), before in-water construction or maintenance activities begin, Reclamation will ensure notification of appropriate fish and wildlife agency representatives when these activities could affect water quality or aquatic species. The notification procedures will follow stipulations included in applicable permit documents for the construction operations. However, in general, the notification information will include site location(s), schedules, and work activities. Information on detours will include site-specific details regarding any temporary partial channel closures, including contacting the U.S. Coast Guard, boating organizations, marina operators, city or county parks departments, and the California Department of Pesticide Regulation, where applicable.

Mitigation Measure AQUA-14 Fugitive Dust Control

Reclamation or their contractors will implement basic and enhanced control measures at all construction and staging areas to reduce construction-related fugitive dust. Although the following measures are outlined in the Sacramento Metropolitan Air Quality Management District's (SMAQMD) CEQA guidelines, they are required for the entirety of the construction area, including areas within the Bay Area Air Quality Management District (BAAQMD), San Joaquin Valley Air Pollution Control District (SJVAPCD), and Yolo-Solano Air Quality Management District (YSAQMD), and are sufficient to address BAAQMD, SJVAPCD, and YSAQMD fugitive dust control requirements. Reclamation or their contractors will ensure the project commitments are appropriately implemented before and during construction, and that proper documentation procedure is followed.

Basic Fugitive Dust Control Measures

Reclamation or their contractors will take steps to ensure that the following measures will be implemented to the extent feasible to control dust during general construction activities.

- Water will be applied to all exposed surfaces as reasonably necessary to prevent visible dust from leaving work areas. Frequency will be increased during especially dry or windy periods or in areas with a lot of construction activity. Exposed surfaces include (but are not limited to) soil piles, graded areas, unpaved parking areas, staging areas, and access roads.
- Cover or maintain at least 2 feet of freeboard space on haul trucks transporting soil, sand, or other loose material on the site. Any haul trucks that will be traveling along freeways or major roadways should be covered.
- Use wet power vacuum street sweepers to remove any visible trackout mud or dirt onto adjacent public roads at least once a day. Use of dry power sweeping is prohibited.
- Limit vehicle speeds on unpaved roads to 15 miles per hour.
- All roadway, driveway, sidewalk, and parking lot paving should be completed as soon as possible. In addition, building pads should be laid as soon as possible after grading unless seeding or soil binders, or other reasonable mitigation measures are used.

Enhanced Fugitive Dust Control Measures for Land Disturbance

Reclamation or their contractors will take steps to ensure that the following measures will be implemented to the extent feasible to control dust during soil disturbance activities.

- Water exposed soil with adequate frequency for continued moist soil. However, do not overwater to the extent that sediment flows off the site.
- Suspend excavation, grading, and/or demolition activity when wind speeds exceed 20 miles per hour.
- Install wind breaks (e.g., plant trees, solid fencing) on windward side(s) of construction areas.
- Plant vegetative ground cover (fast-germinating native grass seed) in disturbed areas as soon as possible after construction is completed. Water appropriately until vegetation is established.

Measures for Entrained Road Dust

Reclamation or their contractors will take steps to ensure that the following measures will be implemented to the extent feasible to control entrained road dust from unpaved roads.

- Install wheel washers for all exiting trucks, or wash off all trucks and equipment leaving the site.
- Treat site accesses to a distance of 100 feet from the paved road with a 6- to 12-inch layer of wood chips, mulch, or gravel to reduce generation of road dust and road dust carryout onto public roads.
- Post a publicly visible sign with the telephone number and person to contact at the lead agency regarding dust complaints. This person will respond and take corrective action within 48 hours. The phone number of the air quality management district will also be visible to ensure compliance.

Measures for Concrete Batching

Reclamation or their contractors will take steps to ensure that the following measures will be implemented to the extent feasible to control dust during concrete batching activities.

- Implementation of fugitive dust control measures to achieve a 70% reduction in dust from concrete batching.
- Implementation of fugitive dust control measures to achieve an 80% reduction in dust from aggregate and sand pile erosion at the concrete batch plants.
- Use of a hood system vented to a fabric filter/baghouse during cement delivery and hopper and central mix loading.

O.3.12 Summary of Impacts

Table O.3-76 includes a summary of impacts, the magnitude and direction of those impacts, and potential mitigation measures for consideration.

Table O.3-76. Summary of Aquatic Resources Impacts

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
Trinity River			
Seasonal Operations			
Potential changes to aquatic resources from changes in reservoir storage	No Action	No effect on focal fish species	
	Alternative 1	No effect on focal fish species	
	Alternative 2	No effect on focal fish species	
	Alternative 3	No effect on focal fish species	
	Alternative 4	No effect on focal fish species	
Potential changes to aquatic resources from variation in flow	No Action	Likely to continue to improve habitat conditions	
	Alternative 1	Possible minimal, negative effect due to increased likelihood of egg mortality due to red scour	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 2	Possible minimal, negative effect due to increased likelihood of egg mortality due to red scour	
	Alternative 3	Possible minimal, negative effect due to increased likelihood of egg mortality due to red scour	
	Alternative 4	Possible minimal, negative effect due to increased likelihood of egg mortality due to red scour	
Potential changes to aquatic resources due to variation in temperature	No Action	Likely to continue to improve habitat conditions	
	Alternative 1	Possible minimal, negative and positive effects of water temperature; negligible overall effect	
	Alternative 2	Possible minimal, negative and positive effects of water temperature; negligible overall effect	
	Alternative 3	Some possible negative effects of water temperature; effects vary with species	
	Alternative 4	Potential beneficial effects associated with reduced water temperature	
Trinity River Downstream of Lewiston Dam			
Potential changes in fishery resources due to contributing factors not included in seasonal operations	No Action		
	Alternative 1		
	Alternative 2		
	Alternative 3		
	Alternative 4		
Trinity River Record of Decision			
Potential changes to aquatic resources due to implementing variable annual flow regime under the Trinity ROD	No Action	Likely to continue to improve habitat conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to implementing restoration actions under the Trinity ROD	No Action	Likely beneficial effect on habitat conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
Potential changes to aquatic resources due to implementing monitoring and adaptive management under the Trinity ROD	No Action	Likely beneficial effects	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to fishery resources due to other contributing factors not included in the Trinity ROD	No Action	Multiple minor changes in effects possible but uncertain or unlikely	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to Trinity River flow during late summer	No Action	Range of potential effects from negligible to considerable and positive	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to Trinity River water temperatures	No Action	Range of potential effects from negligible to considerable and positive	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Grass Valley Creek Flows from Buckhorn Dam			
Potential changes to aquatic resources due to climate change in Grass Valley Creek	No Action	Possible minor, negative effects	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to past and ongoing restoration in Grass Valley Creek	No Action	Potential positive effects	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources from the decreasing storage capacity of Buckhorn Reservoir on Grass Valley Creek	No Action	Possible minor, negative temperature effects	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to changes in pulse flows in Grass Valley Creek	No Action	Likely continuation of current trends	
	Alternative 1	Net beneficial effect of channel maintenance and attraction flows	
	Alternative 2	Similar to No Action	
	Alternative 3	Net beneficial effect of channel maintenance and attraction flows	
	Alternative 4	Net beneficial effect of increased attraction flows	
Sacramento River			
Potential changes to aquatic resources from adult rescue activities (Program Level)	No Action	Limited negative effects possible with the potential for increased flooding and stranding frequency	
	Alternative 1	Minor, net positive effect	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources from trap and haul activities (Program Level)	No Action	Limited negative effects possible with the potential for increased exposure to lower flows and elevated water temperatures	
	Alternative 1	Potential beneficial effect	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources in the Sacramento River from seasonal operations (Project Level)	No Action	Not included in this alternative	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 1	Potential increases in survival of winter-run and spring-run eggs and alevins from improved water temperature management and TCD; potential reductions in juvenile winter-run and spring-run rearing habitat and smolt survival and quality of green sturgeon holding habitat from reduced September and November flow in Wet and Above Normal years	
	Alternative 2	Potential reductions in survival of winter-run and spring-run eggs and alevins from higher water temperatures in September of Wet and Above Normal years; potential reductions in winter-run and spring-run juvenile rearing habitat and smolt survival and quality of green sturgeon holding habitat from reduced September and November flow in Wet and Above Normal years	
	Alternative 3	Potential reductions in survival of winter-run and spring-run eggs and alevins from higher water temperatures in September of Wet and Above Normal years; potential reductions in winter-run and spring-run juvenile rearing habitat and smolt survival and quality of green sturgeon holding habitat from reduced September and November flow in Wet and Above Normal years	
	Alternative 4	Potential increases in survival of winter-run and spring-run eggs and alevins from improved water temperature management; potential reductions in juvenile winter-run and spring-run rearing habitat and smolt survival and quality of green sturgeon holding habitat from reduced September and November flow in Wet and Above Normal years	
Potential changes to aquatic resources in the Sacramento River from Shasta cold water pool management (Project level)	No Action	Not included in this alternative (however, NMFS RPA Action I.2.4 cold water pool management actions are included)	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 1	Potential increases in survival of winter-run and spring-run eggs and alevins from reduced late summer and fall water temperatures	
	Alternative 2	Potential reductions in survival of winter-run and spring-run eggs and alevins from increased water temperatures in September of Wet and Above Normal years	
	Alternative 3	Potential reductions in survival of winter-run and spring-run eggs and alevins from increased water temperatures in September of Wet and Above Normal years	
	Alternative 4	Potential increases in survival of winter-run and spring-run eggs and alevins from reduced late summer and fall water temperatures	
Potential changes to aquatic resources in the Sacramento River from spring pulse flows (Project level)	No Action	Not included in this alternative	
	Alternative 1	Potential improvement in conditions for immigration of adult winter-run, spring-run, and green sturgeon, and potential increase in survival of emigrating spring-run, fall-run, late fall-run and steelhead juveniles; potential reduction in survival of winter-run and spring-run eggs and alevins from increased risk of depleting cold water pool in late summer/early fall	
	Alternative 2	Not included in this alternative	
	Alternative 3	Not included in this alternative	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources in the Sacramento River from fall and winter refill and redd maintenance (Project level)	No Action	Not included in this alternative (however, NMFS RPA Action I.2.2 is included)	
	Alternative 1	Potential increase in survival of spring-run eggs and alevins and winter-run alevins from reduced redd dewatering in fall (winter-run eggs already hatched by fall)	
	Alternative 2	Not included in this alternative	
	Alternative 3	Not included in this alternative	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources in the Sacramento River from rice decomposition smoothing (Project level)	No Action	Not included in this alternative	
	Alternative 1	Potential increase in survival of winter-run and spring-run eggs and alevins from reduced risk of depleting cold water pool in late summer/early fall; potential increase in survival of fall-run eggs and alevins from reduced redd dewatering; potential reduction in survival of spring-run eggs and alevins from increased redd dewatering	
	Alternative 2	Not included in this alternative	
	Alternative 3	Not included in this alternative	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources in the Sacramento River from spring management of spawning locations (Project level)	No Action	Not included in this alternative	
	Alternative 1	Potential increase in survival of winter-run and spring-run eggs and alevins, depending on results of experiments	
	Alternative 2	Not included in this alternative	
	Alternative 3	Not included in this alternative	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from Battle Creek restoration (Program level)	No Action	Battle Creek restoration would continue under No Action, but restoration would not be accelerated as it would be under Alternative 1	
	Alternative 1	Accelerating implementation of restoration projects results in earlier realization of potential benefits, including: increase in population abundance, reduction in extinction risk, and increase in temperature compliance flexibility	
	Alternative 2	Same Battle Creek restoration as No Action	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 3	Accelerating implementation of restoration projects results in earlier realization of potential benefits, including: increase in population abundance, reduction in extinction risk, and increase in temperature compliance flexibility	
	Alternative 4	Same Battle Creek restoration as No Action	
Potential changes to aquatic resources from lower intakes near Wilkins Slough (Program level)	No Action	Not included in this alternative	
	Alternative 1	Potential increase in survival of winter-run and spring-run eggs and alevins from reduced risk of depleting cold water pool in late summer/early fall; potential increase in survival of juveniles of all fish species from reduced entrainment in diversions; potential reduction in condition or survival of all fish species from construction effects.	
	Alternative 2	Not included in this alternative	
	Alternative 3	Potential increase in survival of winter-run and spring-run eggs and alevins from reduced risk of depleting cold water pool in late summer/early fall; potential increase in survival of juveniles of all fish species from reduced entrainment in diversions; potential reduction in condition or survival of all fish species from construction effects.	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources due to Shasta TCD Improvements (Program level)	No Action	Not included in this alternative	
	Alternative 1	Potential increase in survival of winter-run and spring-run eggs and alevins from reduced risk of depleting cold water pool in late summer/early fall	
	Alternative 2	Not included in this alternative	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 3	Potential increase in survival of winter-run and spring-run eggs and alevins from reduced risk of depleting cold water pool in late summer/early fall	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from operation of the Livingston-Stone National Fish Hatchery (Winter-run Chinook Salmon) (Program level)	No Action	Not included in this alternative	
	Alternative 1	Potential increase in survival of winter-run early life stages during drought years; potential reduction in winter-run genetic fitness from genetic introgression with hatchery stock	
	Alternative 2	Not included in this alternative	
	Alternative 3	Potential increase in survival of winter-run early life stages during drought years; potential reduction in winter-run genetic fitness from genetic introgression with hatchery stock	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from small screen program installation (Program level)	No Action	Reclamation and DWR would continue existing small screen program	
	Alternative 1	Reclamation would accelerate existing small screen program resulting in potential increase in survival of rearing and emigrating juveniles of all focal species from reduced entrainment.	
	Alternative 2	Same small screen program as No Action	
	Alternative 3	Reclamation would accelerate existing small screen program resulting in potential increase in survival of rearing and emigrating juveniles of all focal species from reduced entrainment.	
	Alternative 4	Same small screen program as No Action	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
Potential changes to aquatic resources from spawning habitat restoration (Program level)	No Action	Not included in this alternative (existing smaller restoration program would continue)	
	Alternative 1	Potential increase spawning and survival of eggs and alevins of anadromous salmonids and sturgeon from greater quantity and quality of spawning habitat	
	Alternative 2	Same spawning habitat restoration as No Action	
	Alternative 3	Potential increase spawning and survival of eggs and alevins from greater quantity and quality of spawning habitat	
	Alternative 4	Same spawning habitat restoration as No Action	
Potential changes to aquatic resources from rearing habitat restoration (Program level)	No Action	Not included in this alternative	
	Alternative 1	Potential increase in growth and survival of juveniles of anadromous salmonids and most other focal species from increased quantity and quality of rearing habitat	
	Alternative 2	Not included in this alternative	
	Alternative 3	Potential increase in growth and survival of juveniles of anadromous salmonids and most other focal species from increased quantity and quality of rearing habitat	
	Alternative 4	Not included in this alternative	
Clear Creek			
Whiskeytown Reservoir Operations			
Potential changes to aquatic resources in Whiskeytown Reservoir due to operations	No Action		
	Alternative 1		
	Alternative 2		
	Alternative 3		
	Alternative 4		
Potential changes to aquatic resources in Clear Creek from seasonal variation in water surface elevation	No Action	Likely continuation of current population trends	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 1	Potential beneficial effect of increased usable stream habitat	
	Alternative 2	Potential for minor beneficial and adverse effects	
	Alternative 3	Potential for minor beneficial and adverse effects	
	Alternative 4	Potential for minor beneficial and adverse effects	
Clear Creek Flows			
Potential changes to aquatic resources in Clear Creek from variation in flow	No Action	Possible negligible, adverse effects due to reduced flows accompanying environmental changes	
	Alternative 1	Potential beneficial effects	
	Alternative 2	Adverse effects associated with reduced flow and lack of channel maintenance and pulse flows	
	Alternative 3	Similar to Alternative 2	
	Alternative 4	Potential beneficial effects	
Potential changes to aquatic resources in Clear Creek from variation in water temperature	No Action	Possible minimal, adverse effects due to increased temperatures accompanying environmental changes	
	Alternative 1	Minimal or slightly beneficial effects	
	Alternative 2	Negligible with implementation of mitigation	MM-AQUA-3
	Alternative 3	Similar to Alternative 2	MM-AQUA-3
	Alternative 4	Potential minimal, beneficial effects	
Spring Creek Debris Dam			
Potential changes to aquatic resources due to Spring Creek Debris Dam operations	No Action	Likely continuation of current trends; negative effects possible but unlikely or uncertain	
	Alternative 1	Potential beneficial effects	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Clear Creek Restoration Program			
Potential changes in aquatic resources due to gravel augmentation and segregation weir operation	No Action	Likely beneficial effects on habitat conditions	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 1	Similar to No Action	
	Alternative 2	Negligible with implementation of mitigation	MM-AQUA-3
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Feather River			
FERC Project #2100-134			
Potential changes to aquatic resources in the Feather River due to seasonal variation in flow	No Action	Possible slightly adverse effects due to lower flows associated with climate change	
	Alternative 1	Potential beneficial effects	
	Alternative 2	Negligible or potentially beneficial effects	
	Alternative 3	Negligible or potentially beneficial effects	
	Alternative 4	Potential beneficial effects	
Potential changes to aquatic resources in the Feather River due to changes in water temperature from differences in flow	No Action	Possible slightly adverse effects due to increased temperatures associated with climate change	
	Alternative 1	Negligible temperature-related effects; both slightly beneficial and slightly adverse effects possible	
	Alternative 2	Both slightly beneficial and slightly adverse effects possible	
	Alternative 3	Both slightly beneficial and slightly adverse effects possible	
	Alternative 4	Negligible and slightly adverse effects possible	
American River			
Potential changes to aquatic resources in the American River from flood control	No Action	No change from current conditions	
	Alternative 1	Very similar to the no action alternative. Flood control storage would be slightly greater in dry years, and the same in wet years, compared to the NAA.	
	Alternative 2	No change from current conditions	
	Alternative 3	No change from current conditions	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 4	Under average conditions, there would be little difference in flood control storage under Alt 4 in comparison to the NAA for average, dry, and wet years.	
Potential changes to aquatic resources from Folsom Reservoir operations in the American River to meet Delta salinity requirements	No Action	No change from current conditions	
	Alternative 1	No change from current conditions	
	Alternative 2	No change from current conditions	
	Alternative 3	No change from current conditions	
	Alternative 4	No change from current conditions	
Potential changes to aquatic resources from flows in the American River	No Action	No change from current conditions	
	Alternative 1	Lower minimum flows in October through January, higher minimum flows in February and March, and higher flows in July through September compared to the NAA.	
	Alternative 2	No change from current conditions	
	Alternative 3	No change from current conditions	
	Alternative 4	Minor changes would occur and vary by water year type and month. Similar flows in average and wet years compared to NAA. Dry and critically dry years, flows would be higher in February through March, slightly lower in July, and higher in August and September. In low water years, lower minimum flows in October through January, higher minimum flows in February and March, and higher flows in July through September compared to the No Action Alternative.	
Potential changes to aquatic resources in the American River due to changes in water temperature	No Action	No change from current conditions	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 1	Similar to the no action alternative. May be slightly cooler in summer months compared to NAA.	
	Alternative 2	No temperature objective included, but temperature expected to be similar to current conditions.	
	Alternative 3	No temperature objective included, but temperature expected to be similar to current conditions.	
	Alternative 4	Overall minor differences in water temperature. Lower maximum water temperature in wet versus dry years. Change likely to result in incremental differences that are unlikely to lead to notable impact.	
Potential changes to aquatic resources in the American River from habitat restoration	No Action	No change from current conditions	
	Alternative 1	Increased total spawning habitat area, increased and improved side channel habitat, improved intragravel incubation conditions, increased and improved total rearing habitat area, improved overall habitat complexity, and cover and refugia when compared to the NAA. Minor shortterm impacts due to construction such as sediment or erosion addressed through mitigation measure.	
	Alternative 2	No change from current conditions	
	Alternative 3	Increased total spawning habitat area, increased and improved side channel habitat, improved intragravel incubation conditions, increased and improved total rearing habitat area, improved overall habitat complexity, and cover and refugia when compared to the NAA. Minor shortterm impacts due to construction such as sediment or erosion addressed through mitigation measure.	
	Alternative 4	No change from current conditions	
Stanislaus River			

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
Potential changes to aquatic resources in the Stanislaus River due to changes in flow	No Action	No change from current conditions	
	Alternative 1	Similar flows, but slightly less than the NAA. Very minor differences.	
	Alternative 2	Decreased flows would occur primarily between February through September. Potential limited negative effects. Increased flows during January and February would result in limited positive effects during spawning and emergence for salmonids.	
	Alternative 3	No change from current conditions.	
	Alternative 4	Conditions are the same as Alternative 1	
Potential changes to aquatic resources in the Stanislaus River due to changes in water temperature	No Action	No change from current conditions	
	Alternative 1	Compliance point moved to Orange Blossom Bridge. Increased storage under Alt 1 would result in larger coldwater pool and potentially offset warming or delay warming water due to greater reserves of stored coldwater.	
	Alternative 2	Reduced flows may result in warmer water conditions primarily from March through May. Potential limited negative effects.	
	Alternative 3	No specific temperature objective, but change not expected to current conditions due to same flow schedule as the NAA.	
	Alternative 4	Conditions are the same as Alternative 1	
Potential change to aquatic resources in the Stanislaus River due to changes to dissolved oxygen	No Action	No change from current conditions	
	Alternative 1	Maintain 7mg/l of DO. Overall, similar conditions to the NAA.	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 2	Reduced flows may lower the amount of available DO incrementally, most notably in March through May. Potential limited negative effects.	
	Alternative 3	No change from current conditions	
	Alternative 4	Conditions are the same as Alternative 1	
Potential changes to salmonid habitat in the Stanislaus River related to habitat restoration (Program Level)	No Action	No change from current conditions	
	Alternative 1	Proposed habitat restoration will offer improved and expanded spawning and rearing habitat, including riparian vegetation. Minor shortterm impacts due to construction such as sediment or erosion addressed through mitigation measure.	
	Alternative 2	No change from current conditions	
	Alternative 3	Proposed habitat restoration will offer improved and expanded spawning and rearing habitat, including riparian vegetation. Minor shortterm impacts due to construction such as sediment or erosion addressed through mitigation measure.	
	Alternative 4	No change from current conditions	
San Joaquin River			
Potential changes to aquatic resources in the San Joaquin River due to changes in flow	No Action	No change from current conditions	
	Alternative 1	No change from current conditions	
	Alternative 2	No change from current conditions	
	Alternative 3	No change from current conditions	
	Alternative 4	No change from current conditions	
Potential changes to aquatic resources in the San Joaquin River due to changes in water temperature	No Action	No change from current conditions	
	Alternative 1	No change from current conditions	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 2	No change from current conditions	
	Alternative 3	No change from current conditions	
	Alternative 4	No change from current conditions	
Potential changes to aquatic resources in the San Joaquin River due to restoration activities	No Action	No change from current conditions	
	Alternative 1	No change from current conditions	
	Alternative 2	No change from current conditions	
	Alternative 3	No change from current conditions	
	Alternative 4	No change from current conditions	
Bay-Delta			
Delta Smelt			
Potential changes to Delta Smelt due to seasonal operations (Project-Level)	No Action	No change from current conditions, except effects on food availability potentially offset through completion of 8,000 acres of tidal habitat restoration	
	Alternative 1	Potential reductions in food availability (Eurytemora affinis, Pseudodiaptomus forbesi) and habitat extent relative to No Action, offset by tidal habitat restoration, food subsidies, and Delta Smelt Summer-Fall Habitat operations	
	Alternative 2	Potential increase in south Delta entrainment; reductions in food availability (E. affinis, P. forbesi) and habitat extent relative to No Action, offset to some extent by tidal habitat restoration	
	Alternative 3	Potential increase in south Delta entrainment; reductions in food availability (E. affinis, P. forbesi) and habitat extent relative to No Action, offset by tidal habitat restoration, and food subsidies	
	Alternative 4	Potential reduction in south Delta entrainment; spring/summer increases in food availability (E. affinis, P. forbesi) and habitat extent relative to No Action; reduced fall habitat extent relative to No Action, offset to some extent by tidal habitat restoration	
	No Action	No change from current conditions	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
Potential changes to Delta Smelt due to changes in Delta Cross Channel operations (Project-Level)	Alternative 1	Potential limited negative effects	
	Alternative 2	Potential limited negative effects	
	Alternative 3	Potential limited negative effects	
	Alternative 4	Potential limited negative effects	
Potential changes in Delta Smelt survival related to the Temporary Barriers Project (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action, although less near-field and far-field effects from no HOR barrier	
	Alternative 2	Similar to No Action, although less near-field and far-field effects from no HOR barrier, but potentially greater near-field effects from greater presence in south Delta with lower OMR	
	Alternative 3	Similar to No Action, although less near-field and far-field effects from no HOR barrier, but potentially greater near-field effects from greater presence in south Delta with lower OMR	
	Alternative 4	Similar to No Action, although less near-field and far-field effects from no HOR barrier, but potentially less near-field effects from less presence in south Delta with greater OMR	
Potential changes to Delta Smelt from Contra Costa Water District operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to Delta Smelt from North Bay Aqueduct operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action, with potential additional limited negative effect from sediment and aquatic weed removal	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action, with potential additional limited negative effect from sediment and aquatic weed removal	
	Alternative 4	Similar to No Action	
	No Action	No change from current conditions	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
Potential changes to Delta Smelt from water transfers (Project-Level)	Alternative 1	Minor increase in entrainment risk from expanded transfer window, although subject to OMR management	
	Alternative 2	No change from current conditions	
	Alternative 3	No change from current conditions	
	Alternative 4	No change from current conditions	
Potential changes to Delta Smelt from Clifton Court aquatic weed and algal bloom management (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to Delta Smelt due to changes from Tracy and Skinner fish facilities improvements (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential minor increase in salvage efficiency from reduced predation at Tracy (carbon dioxide device)	
	Alternative 2	Potential increases in salvage losses as a result of greater proportion of population in south Delta (reduced OMR flows compared to No Action)	
	Alternative 3	Potential minor increase in salvage efficiency from reduced predation at Tracy (carbon dioxide device), but potential increase in salvage loss as described for Alternative 2	
	Alternative 4	Potential minor decrease in salvage losses as a result of smaller proportion of population in south Delta (greater OMR flows compared to No Action)	
Potential changes to Delta Smelt due to changes from Suisun Marsh facilities (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action (except SMSCG and RRDS related to Delta Smelt Habitat Operations and Food Subsidies)	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to Delta Smelt due to changes from tidal habitat restoration (Program-Level)	No Action	Potential increased food availability (to offset seasonal operations effects) and habitat extent relative to current conditions; negative effects from contaminants	MM-AQUA 9

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 1	Same restoration extent as No Action, but offsetting effect may be less because of less spring outflow than No Action	MM-AQUA 9
	Alternative 2	Same restoration extent as No Action, but offsetting effect may be less because of less spring outflow than No Action	MM-AQUA 9
	Alternative 3	Same restoration extent as No Action, but offsetting effect may be less because of less spring outflow than No Action	MM-AQUA 9
	Alternative 4	Same restoration extent as No Action, but may add to potential positive effect from greater spring outflow than No Action	
Potential changes to Delta Smelt due to OMR management (Project-Level)	No Action	Included under Seasonal Operations	
	Alternative 1	Potential slight increase in entrainment relative to No Action	
	Alternative 2	Included under Seasonal Operations	
	Alternative 3	Included under Seasonal Operations	
	Alternative 4	Included under Seasonal Operations	
Potential changes to Delta Smelt from actions for Delta Smelt summer-fall habitat (Project-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential to increase juvenile to subadult survival from increased habitat extent in summer; potentially less fall habitat and therefore negative effects; effects dependent on specific components of the action that are implemented	
	Alternative 2	Not included in this alternative	
	Alternative 3	Not included in this alternative	
	Alternative 4	Not included in this alternative	
Potential changes to Delta Smelt from the San Joaquin Basin Steelhead Telemetry Study (Project-Level)	No Action	Not included in this alternative	
	Alternative 1	No effect	
	Alternative 2	Not included in this alternative	
	Alternative 3	No effect	
	Alternative 4	Not included in this alternative	
Potential changes to Delta Smelt due to reintroduction by the Fish Conservation and Culture Laboratory (Project-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential positive effect from increase in population abundance, assuming successful risk management	
	Alternative 2	Not included in this alternative	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 3	Potential positive effect from increase in population abundance, assuming successful risk management	
	Alternative 4	Not included in this alternative	
Potential changes to Delta Smelt from food subsidies (Sacramento Deepwater Ship Channel Food Study; North Delta Food Subsidies/Colusa Basin Drain Study; Suisun Marsh Roaring River Distribution System Food Subsidies Study) (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential positive effect from greater food availability, offsetting negative effects of seasonal operations; potential negative effect from Ship Channel sediment contaminants	
	Alternative 2	Not included in this alternative	
	Alternative 3	Potential positive effect from greater food availability, offsetting negative effects of seasonal operations; potential negative effect from Ship Channel sediment contaminants	
	Alternative 4	Not included in this alternative	
Potential changes to Delta Smelt from the predator hot spot removal program (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor positive effects from reduced predation	
	Alternative 2	Not included in this alternative	
	Alternative 3	Minor positive effects from reduced predation	
	Alternative 4	Not included in this alternative	
Potential changes to Delta Smelt from Delta Cross Channel gate improvements (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential limited effects	
	Alternative 2	Not included in this alternative	
	Alternative 3	Potential limited effects	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources due to changes from Tracy and Skinner Fish Facility improvements (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor positive effect to salvage efficiency	
	Alternative 2	Not included in this alternative	
	Alternative 3	Minor positive effect to salvage efficiency	
	Alternative 4	Not included in this alternative	
Potential changes to Delta Smelt from the small screen program (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor positive effect from reduction in entrainment	
	Alternative 2	Not included in this alternative	
	Alternative 3	Minor positive effect from reduction in entrainment	
	Alternative 4	Not included in this alternative	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
Potential changes to Delta Smelt from the Delta Fish Species Conservation Hatchery (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential positive effect from increase in population abundance, assuming successful risk management	
	Alternative 2	Not included in this alternative	
	Alternative 3	Potential positive effect from increase in population abundance, assuming successful risk management	
	Alternative 4	Not included in this alternative	
Potential changes to Delta Smelt from additional habitat restoration (25,000 acres within the Delta) (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Not included in this alternative	
	Alternative 2	Not included in this alternative	
	Alternative 3	Potential positive effect from increased food availability and habitat extent; negative effects from contaminants and potential reduction of P.forbesi subsidy to low salinity zone	
	Alternative 4	Not included in this alternative	
Longfin Smelt			
Potential changes to Longfin Smelt due to seasonal operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential reduction in population abundance from reduction in winter-spring Delta outflow; potential increased south Delta entrainment loss, although low proportional loss expected	
	Alternative 2	Potential reduction in population abundance from reduction in winter-spring Delta outflow; potential increased south Delta entrainment loss, although low proportional loss expected	
	Alternative 3	Potential reduction in population abundance from reductions in winter-spring Delta outflow; potential increased south Delta entrainment loss, although low proportional loss expected	
	Alternative 4	Potential increase in population abundance from increase in winter-spring Delta outflow; potential decreased south Delta entrainment loss, although low proportional loss expected	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
Potential changes to Longfin Smelt due to changes in Delta Cross Channel operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential limited negative effects	
	Alternative 2	Potential limited negative effects	
	Alternative 3	Potential limited negative effects	
	Alternative 4	Potential limited negative effects	
Potential changes in Longfin Smelt survival related to the Temporary Barriers Project (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential for slightly greater negative effects than No Action (e.g., near-field predation), although limited by low presence in south Delta	
	Alternative 2	Potential for slightly greater negative effects than No Action (e.g., near-field predation), although limited by low presence in south Delta	
	Alternative 3	Potential for slightly greater negative effects than No Action (e.g., near-field predation), although limited by low presence in south Delta	
	Alternative 4	Potential for slightly less negative effects than No Action (e.g., near-field predation), although limited by low presence in south Delta	
Potential changes to Longfin Smelt from Contra Costa Water District operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to Longfin Smelt from North Bay Aqueduct operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action, with potential additional limited negative effect from sediment and aquatic weed removal.	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action, with potential additional limited negative effect from sediment and aquatic weed removal.	
	Alternative 4	Similar to No Action	
Potential changes to Longfin Smelt from water transfers (Project-Level)	No Action	No change from current conditions	
	Alternative 1	No change from current conditions	
	Alternative 2	No change from current conditions	
	Alternative 3	No change from current conditions	
	Alternative 4	No change from current conditions	
	No Action	No change from current conditions	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
Potential changes to Longfin Smelt from Clifton Court aquatic weed and algal bloom management (Project-Level)	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to Longfin Smelt due to changes from Tracy and Skinner fish facilities improvements (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential minor increase in salvage efficiency from reduced predation at Tracy (carbon dioxide device) , but potential increases in salvage losses as a result of greater proportion of population in south Delta (reduced OMR flows compared to No Action), although low proportional loss expected	
	Alternative 2	Potential increases in salvage losses as a result of greater proportion of population in south Delta (reduced OMR flows compared to No Action), but low proportional loss expected	
	Alternative 3	Potential minor increase in salvage efficiency from reduced predation at Tracy (carbon dioxide device), but potential increase in salvage loss as described for Alternative 2, although low proportional loss expected	
	Alternative 4	Potential decreases in salvage losses as a result of greater proportion of population in south Delta (reduced OMR flows compared to No Action), but low proportional loss expected	
Potential changes to Longfin Smelt due to changes from Suisun Marsh facilities (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to Longfin Smelt due to changes from tidal habitat restoration (Program-Level)	No Action	Potential increased food availability and habitat extent relative to current conditions; negative effects from contaminants; overall effects limited because of species occurrence further downstream	MM-AQUA 9
	Alternative 1	Same restoration extent as No Action, but offsetting effect may be less because of less winter/spring outflow than No Action	MM-AQUA 9

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 2	Same restoration extent as No Action, but offsetting effect may be less because of less winter/spring outflow than No Action	MM-AQUA 9
	Alternative 3	Same restoration extent as No Action, but offsetting effect may be less because of less winter/spring outflow than No Action	MM-AQUA 9
	Alternative 4	Same restoration extent as No Action, but may add to potential positive effect from greater winter/spring outflow than No Action	MM-AQUA 9
Potential changes to Longfin Smelt due to OMR management (Project-Level)	No Action	Included under Seasonal Operations	
	Alternative 1	Potential increase in entrainment relative to No Action, although low proportional loss expected	
	Alternative 2	Included under Seasonal Operations	
	Alternative 3	Included under Seasonal Operations	
	Alternative 4	Included under Seasonal Operations	
Potential changes Longfin Smelt from actions for Delta Smelt summer-fall habitat (Project-Level)	No Action	Not included in this alternative	
	Alternative 1	No effect expected given timing/location relative to Longfin Smelt occurrence	
	Alternative 2	Not included in this alternative	
	Alternative 3	No effect expected given timing/location relative to Longfin Smelt occurrence

Potential changes to Longfin Smelt due to changes from Tracy and Skinner fish facility improvements (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor positive effect to salvage efficiency, although low proportional occurrence expected	
	Alternative 2	Not included in this alternative	
	Alternative 3	Minor positive effect to salvage efficiency, although low proportional occurrence expected	
	Alternative 4	Not included in this alternative	
Potential to Longfin Smelt from the small screen program (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minimal positive effect from reduction in entrainment	
	Alternative 2	Not included in this alternative	
	Alternative 3	Minimal positive effect from reduction in entrainment	
	Alternative 4	Not included in this alternative	
Potential changes to Longfin Smelt from the Delta Fish Species Conservation Hatchery (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential limited negative effects from hybridization, reduced by risk management strategies	
	Alternative 2	Not included in this alternative	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 3	Potential limited negative effects from hybridization, reduced by risk management strategies	
	Alternative 4	Not included in this alternative	
Potential changes to Longfin Smelt from additional habitat restoration (25,000 acres within the Delta) (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Not included in this alternative	
	Alternative 2	Not included in this alternative	
	Alternative 3	Potential positive effect from increased food availability and habitat extent; negative effects from contaminants; effects limited by general occurrence downstream of restored areas	
	Alternative 4	Not included in this alternative	
Sacramento River Winter Run Chinook Salmon			
Potential changes to aquatic resources due to seasonal operations (Project-Level)	No Action	No change from current conditions, except effects on food availability and rearing habitat potentially offset through completion of 8,000 acres of tidal habitat restoration	
	Alternative 1	Potential increase in south Delta entrainment however proportional entrainment is expected to remain low. These increases may be offset by higher flows in the Sacramento River that could increase survival and reduce routing into the interior Delta. Tidal habitat restoration could also increase survival of rearing winter run.	
	Alternative 2	Potential increase in south Delta entrainment however proportional entrainment is expected to remain low. These increases may be offset by higher flows in the Sacramento River that could increase survival and reduce routing into the interior Delta.	
	Alternative 3	Potential increase in south Delta entrainment however proportional entrainment is expected to remain low. These increases may be offset by higher flows in the Sacramento River that could increase survival and reduce routing into the interior Delta.	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 4	Potential increase in survival and reduced routing into the interior Delta due to higher Sacramento River flows	
Potential changes to aquatic resources due to OMR management (Project-Level)	No Action	Included under Seasonal Operations	
	Alternative 1	Included under Seasonal Operations

Spring Run Chinook Salmon			
Potential changes to aquatic resources due to seasonal operations (Project-Level)	No Action	No change from current conditions, except effects on food availability and rearing habitat potentially offset through completion of 8,000 acres of tidal habitat restoration.	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 1	Potential increase in south Delta entrainment however proportional entrainment is expected to remain low for Sacramento River-origin fish. These increases may be offset by higher flows in the Sacramento River that could increase survival and reduce routing into the interior Delta. Tidal habitat restoration could also increase survival of rearing Spring run. Spring run Chinook salmon originating from the San Joaquin River may experience an increase in entrainment and reduced flow velocities in the Old River migration route.	
	Alternative 2	Potential increase in south Delta entrainment however proportional entrainment is expected to remain low for Sacramento River-origin fish. These increases may be offset by higher flows in the Sacramento River that could increase survival and reduce routing into the interior Delta. Spring run Chinook salmon originating from the San Joaquin River may experience an increase in south Delta entrainment and lower water velocities in the Old River route.	
	Alternative 3	Potential increase in south Delta entrainment however proportional entrainment is expected to remain low for Sacramento River-origin fish. These increases may be offset by higher flows in the Sacramento River that could increase survival and reduce routing into the interior Delta. Spring run Chinook salmon originating from the San Joaquin River may experience an increase in south Delta entrainment and lower water velocities in the Old River route.	
	Alternative 4	Potential increase in survival and reduced routing into the interior Delta for Sacramento River-origin fish during peak migration times. Survival and entrainment for San Joaquin River origin fish will be similar to the No Action Alternative.	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
Potential changes to aquatic resources due to OMR management (Project-Level)	No Action	Included under Seasonal Operations	
	Alternative 1	Included under Seasonal Operations	
	Alternative 2	Included under Seasonal Operations	
	Alternative 3	Included under Seasonal Operations	
	Alternative 4	Included under Seasonal Operations	
Potential changes to aquatic resources due to Delta Cross Channel operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential limited negative effects. No effect on San Joaquin-origin fish.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to the Temporary Barriers Project (Project-Level	No Action	No change from current conditions.	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to Contra Costa Water District operations)	No Action	No change from current conditions

	Alternative 3	Potential limited negative effects for Sacramento River-origin fish	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to water transfers (Project-Level)	No Action	No change from current conditions	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 1	Early or late migrant juvenile Spring-Run Chinook Salmon could be exposed to increased effects of entrainment, routing, and decreased Delta survival as a result of the expanded water transfer window, especially San Joaquin River-origin Spring-Run Chinook. Increased flows during conveyance in the Sacramento River could provide small survival benefits to migrating juveniles.

	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources from the North Delta food subsidies/Colusa Basin drain study (Program-Level)	No Action		
	Alternative 1	Limited effects	
	Alternative 2	Similar to Alternative 1	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources from the Suisun Marsh Roaring River Distribution System food study (Program-Level)	No Action		
	Alternative 1	Limited effects	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Limited effects	
Potential changes to aquatic resources due to tidal habitat restoration (Program-Level)	No Action	Potential increased food availability and rearing habitat availability (to offset seasonal operations effects) and habitat extent relative to current conditions; negative effects from contaminants. San Joaquin origin fish will not be affected as they occur below the North Delta.	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
	Alternative 1	Same restoration extent as No Action	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
	Alternative 2	Same restoration extent as No Action	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
	Alternative 3	Same restoration extent as No Action	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
	Alternative 4	Same restoration extent as No Action	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
Potential changes to aquatic resources from the predator hot spot removal program (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential for increased survival	
	Alternative 2	Same as Alternative 1	
	Alternative 3	Potential for increased survival	
	Alternative 4	Same as Alternative 1	
Potential changes to aquatic resources from Delta Cross Channel gate improvements (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential limited effects	
	Alternative 2	Potential limited effects	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 3	Potential limited effects	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor positive effect to salvage efficiency	MM AQUA-1, 2, 7, 8, 10, 12
	Alternative 2	Not included in this alternative	
	Alternative 3	Same as Alternative 1	MM AQUA-1, 2, 7, 8, 10, 12
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from the small screen program (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor positive effect from reduction in entrainment	
	Alternative 2	Not included in this alternative	
	Alternative 3	Same as Alternative 1	
	Alternative 4	Same as Alternative 1	
Potential changes to aquatic resources from the Delta Fish Species Conservation Hatchery (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	The risk of potential effect would be minimized by mitigation and indicate impacts are less than significant.	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14,
	Alternative 2	Not included in this alternative	
	Alternative 3	Same as Alternative 1	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14
	Alternative 4	Not included in this alternative	
Fall-Run Chinook Salmon			
Potential changes to aquatic resources due to seasonal operations (Project-Level)	No Action	No change from current conditions, except effects on food availability and rearing habitat potentially offset through completion of 8,000 acres of tidal habitat restoration.	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 1	Potential increase in south Delta entrainment however proportional entrainment is expected to remain low for Sacramento River-origin fish. These increases may be offset by higher flows in the Sacramento River that could increase survival and reduce routing into the interior Delta. Increase in entrainment for San Joaquin River-origin fish and exposure to lower velocities in the Old River route	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative	
	Alternative 4	Little to no change compared to No Action alternative. Potential increase in survival and reduced routing into the interior Delta for Sacramento River-origin fish due to higher Sacramento River flows	
Potential changes to aquatic resources due to OMR management (Project-Level)	No Action	Included under Seasonal Operations	
	Alternative 1	Included under Seasonal Operations	
	Alternative 2	Included under Seasonal Operations	
	Alternative 3	Included under Seasonal Operations	
	Alternative 4	Included under Seasonal Operations	
Potential changes to aquatic resources due to Delta Cross Channel operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential limited negative effects. No effect on San Joaquin-origin fish.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to the Temporary Barriers Project (Project-Level	No Action	No change from current conditions	
	Alternative 1	Potential negative effects depending on when they are installed and whether the flap gates are down or tied up but overall would be low to moderate.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to Contra Costa Water District operations)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to North Bay Aqueduct operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential limited effects	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to water transfers (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources from Clifton Court aquatic weed removal (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Minimal negative effects as Fall-Run Chinook are not expected to be present during the action.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential minor increase in salvage efficiency from reduced predation at Tracy (carbon dioxide device); larger proportions of Late-Fall Run lost so this action would have greater effect on this run.	
	Alternative 2	Similar to Alternative 1	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to changes from Suisun Marsh facilities (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Minor benefit to juvenile salmonids by improving water quality and increasing foraging opportunities.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources from actions for Delta Smelt summer-fall habitat (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Minor benefits due to few fish being exposed to this action	
	Alternative 2	Not included in this alternative	
	Alternative 3	Not included in this alternative	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from Clifton Court predator management efforts	No Action	No change from current conditions	
	Alternative 1	The overall effect of the action is low for Sacramento River-Origin fish and moderate for San Joaquin River and Mokelumne River-origin fish.	
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to the San Joaquin Basin steelhead telemetry study (Project-Level)	No Action	No change from current conditions	
	Alternative 1	No effect	
	Alternative 2	Not included in this alternative	
	Alternative 3	No effect	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources due to reintroduction changes from Fish Conservation and Culture Laboratory (Project-Level)	No Action

Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor positive effect to salvage efficiency and reduced pre-screen loss.	MM AQUA-1, 2, 7, 8, 10, 12

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	MM AQUA-1, 2, 7, 8, 10, 12
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from the small screen program (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor negative effects minimized by mitigation and offset by positive effects of reduced entrainment	MM AQUA-7
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	MM AQUA-7
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from the Delta Fish Species Conservation Hatchery (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	The risk of potential effect would be minimized by mitigation.	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14
	Alternative 4	Not included in this alternative	
North American Green Sturgeon Southern DPS			
Potential changes to aquatic resources due to seasonal operations (Project-Level)	No Action	No change from current conditions, except effects on food availability and rearing habitat potentially offset through completion of 8,000 acres of tidal habitat restoration.	
	Alternative 1	Increased risk of entrainment over No Action though entrainment expected to remain low. Risk of decreased survival due to lower velocities in the south Delta however, low probability of presence in the area where negative velocities occur.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to OMR management (Project-Level)	No Action	Included under Seasonal Operations	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 1	Included under Seasonal Operations	
	Alternative 2	Included under Seasonal Operations	
	Alternative 3	Included under Seasonal Operations	
	Alternative 4	Included under Seasonal Operations	
Potential changes to aquatic resources due to Delta Cross Channel operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Potential limited negative effects	
	Alternative 2	Potential limited negative effects	
	Alternative 3	Potential limited negative effects	
	Alternative 4	Potential limited negative effects	
Potential changes to aquatic resources due to the Temporary Barriers Project (Project-Level)	No Action	No change from current conditions.	
	Alternative 1	Potential negative effects depending on timing of installation and operation of the flap gates. Fish not expected to be common in the area	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to Contra Costa Water District operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to North Bay Aqueduct operations (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Increase in the risk of vulnerability to entrainment should decrease to no effect as green sturgeon are expected to be 100% screened. Potential for limited effects from sediment removal and weed control	
	Alternative 2	Similar to No Action	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 3	Increase in the risk of vulnerability to entrainment should decrease to no effect as green sturgeon are expected to be 100% screened. Potential for limited effects from sediment removal and weed control.	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources due to water transfers (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Similar to No Action	
	Alternative 2	Similar to No Action	
	Alternative 3	Similar to No Action	
	Alternative 4	Similar to No Action	
Potential changes to aquatic resources from Clifton Court aquatic weed removal (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Not likely to occur making negative exposure impacts limited.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Not likely to occur making exposure impacts very low and balanced with slight increases in survival due to reduced pre-screen loss.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	
Potential changes to aquatic resources due to changes from Suisun Marsh facilities (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Juvenile green sturgeon in Suisun Marsh may experience improved water quality and increased foraging opportunities.	
	Alternative 2	Similar to Alternative 1	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Similar to Alternative 1	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
Potential changes to aquatic resources from Clifton Court predator management efforts	No Action

	Alternative 4		
Potential changes to aquatic resources due to tidal habitat restoration (Program-Level)	No Action	Potential increased food availability and rearing habitat availability (to offset seasonal operations effects) and habitat extent relative to current conditions; negative effects from contaminants.	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
	Alternative 1	Same restoration extent as No Action	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
	Alternative 2	Same restoration extent as No Action	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
	Alternative 3	Same restoration extent as No Action	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14
	Alternative 4	Same restoration extent as No Action	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
Potential changes to aquatic resources from the predator hot spot removal program (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential negative effects from capture during predator removal offset by potential to increase survival by removing predators if juveniles are present.	
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from Delta Cross Channel gate improvements (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Potential limited effects	
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources due to changes from Tracy and Skinner fish facility improvements (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor positive effect to salvage efficiency and reduced pre-screen loss.	MM AQUA-1, 2, 7, 8, 10, 12
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	MM AQUA-1, 2, 7, 8, 10, 12
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from the small screen program (Program-Level)	No Action	Not included in this alternative	
	Alternative 1	Minor negative effects minimized by mitigation and reduced entrainment.	MM AQUA-7
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	MM AQUA-7
	Alternative 4	Not included in this alternative	
Potential changes to aquatic resources from the Delta Fish Species Conservation Hatchery (Program-Level)	No Action	Not included in this alternative	

Impact	**Alternative**	**Magnitude and Direction of Impacts**	**Potential Mitigation Measures**
	Alternative 1	The risk of potential effect would be minimized by mitigation.	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14
	Alternative 2	Not included in this alternative	
	Alternative 3	Similar to Alternative 1	MM AQUA-1, 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14
	Alternative 4	Not included in this alternative	
Southern Resident Killer Whale			
Potential changes to Southern Killer Whale from Chinook Salmon prey abundance (Project-Level)	No Action	No change from current conditions	
	Alternative 1	Limited potential for effect because of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	
	Alternative 2	Potential negative effects, with some uncertainty as a result of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	
	Alternative 3	Potential negative effects, with some uncertainty as a result of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	
	Alternative 4	Potential for mixture of positive/negative effects, with some uncertainty as a result of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	
Potential changes to Southern Killer Whale from Chinook Salmon prey abundance (Program-Level)	No Action	Limited potential for effect because of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	
	Alternative 1	Limited potential for effect because of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	
	Alternative 2	Limited potential for effect because of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	Alternative 3	Possibly greater potential for positive effect than other alternatives because of greater extent of tidal habitat restoration, but uncertainty because of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	
	Alternative 4	Limited potential for effect because of medium priority of Central Valley Chinook Salmon stocks as prey and hatchery influence	

O.3.13 Cumulative Effects

This cumulative effects analysis evaluates the potential for project alternatives, including the No Action Alternative, to have an effect that would combine with an existing or potential adverse cumulative effect to make a considerable, incremental contribution to the existing or potential cumulative effect. The characterization of existing or probable future non-project effects is based on a qualitative assessment of the past, present, and probable future actions or projects that have affected or could affect aquatic biological resources in the analysis areas. These actions and projects are summarized in Appendix Y, *Cumulative Methodology*. No modeling or quantitative analysis was conducted to quantify the existing or potential future cumulative effects that may have resulted or could result from non-project activities. Further, this analysis does not distinguish between project-level and program-level actions. Therefore, the cumulative effects analysis is the same for both

O.3.13.1 *Trinity River*

Past and present human activities have substantially changed aquatic habitats in the Trinity River compared to historical conditions, resulting in cumulative adverse impacts on the distribution, abundance, population structure, and genetic integrity of native salmonids, and similar effects on other native fishes. Major factors contributing to the cumulative impacts (cumulative effects) on aquatic biological resources in the Trinity River in the project area have included hydropower development and operations, hatchery management, water diversions, recreational use, sport fisheries, introduction of nonnative fish species, and other management actions, water uses, and land uses. These actions have resulted in altered flows on the Trinity River, reducing sediment input to downstream locations, hindered important fluvial processes which support riparian habitat and river channel dynamics, increasing riparian vegetation encroachment through the reduction of vegetation scouring high flow events, reduced channel movement and the creation of natural levees isolating the channel from the floodplain, and other adverse effects on aquatic habitat. These alterations have led to a reduction in channel complexity and aquatic habitat for several fish species in the mainstem Trinity River downstream of Lewiston Dam.

Several management components have been established to mitigate for the adverse effects of dam construction on the Trinity River and are included in the Trinity River Restoration Program (TRRP) and the Trinity River ROD. The TRRP includes instream flow management, mechanical channel rehabilitation, fine and coarse sediment management, watershed restoration, infrastructure improvement, and adaptive environmental assessment and monitoring, and is focused on the 40-mile section of the

Trinity River from Lewiston Dam to the confluence with the North Fork Trinity River (TRRP 2014). Since 2008, over 75 projects have been completed under the TRRP. The ROD documents actions intended to restore and maintain anadromous fishery resources in the Trinity River based on the best available scientific information, while continuing to provide water supplies for beneficial uses and power generation. The ROD sets variable annual instream flows for the Trinity River, physical channel rehabilitation, sediment management, watershed restoration efforts, and infrastructure improvements and modifications (USDOI 2000).

While some projects and actions have had beneficial effects, the net short-term effect of many new and ongoing programs, projects, and restoration efforts remains uncertain. In the long term, however, the net effects are expected to include substantial improvements in river habitat conditions and conservation or recovery of special-status fish populations. Despite ongoing and potential future projects that could benefit native Trinity River fishes and their habitat, it is apparent that the effects of past and present actions have resulted in a cumulative adverse effect on Coho Salmon, Chinook Salmon, Steelhead, Green Sturgeon, White Sturgeon, Pacific Lamprey, and American Shad and designated critical habitat in the Trinity River.

O.3.13.1.1 Seasonal Operations

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

Alternatives 1-4

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the action alternatives.

O.3.13.1.2 Trinity River Record of Decision

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

Alternatives 1-4

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the action alternatives.

O.3.13.1.3 Long Term Plan to Protect Adult Salmon in the Lower Klamath River

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

Alternatives 1-4

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the action alternatives.

O.3.13.1.4 Grass Valley Creek Flows from Buckhorn Dam

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

Alternatives 1-4

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the action alternatives.

O.3.13.2 *Clear Creek*

Past and present human activities have substantially changed aquatic habitats in Clear Creek compared to historical conditions, resulting in cumulative adverse impacts on the distribution, abundance, population structure, and genetic integrity of native salmonids, and similar effects on other native fishes. Major factors contributing to the cumulative impacts (cumulative effects) on aquatic biological resources in Clear Creek have included hydropower development and operations, water withdrawals for irrigation and other uses, agriculture, timber harvest, roadbuilding, mining activities, channelization and levee construction, recreational use and development, sport and commercial fisheries, introduction of nonnative fish species, and other management actions, water uses, and land uses (Appendix Y, *Cumulative Methodology*). These actions have resulted in highly altered flow regimes, loss and disconnection of floodplains from the river channel, altered sediment transport, reduced aquatic habitat complexity, loss of riparian and off-channel aquatic habitat, elevated water temperature, degraded water quality, habitat fragmentation by physical barriers, and other adverse effects on aquatic biological resources. Several ecosystem improvement projects and actions, including the Central Valley Project Improvement Act (CVPIA), the CALFED Bay-Delta Program, the Clear Creek Restoration Program, the CDFW Ecosystem Restoration Program, removal of Saeltzer Dam in 2000, and various other conservation, management, and restoration programs (Appendix Y, *Cumulative Methodology*), have been initiated to offset the adverse effects of previous and ongoing activities.

In addition to the ongoing activities, several probable future projects and programs may affect listed fishes and other aquatic biological resources in Clear Creek. New projects and programs recently implemented or likely to be implemented in the near future are listed in Appendix Y, *Cumulative Methodology*. Some of these projects and programs may adversely affect special-status fishes and critical habitat in Clear Creek, but others are likely to be beneficial. While some projects and actions have had beneficial effects, the net short-term effect of many new and ongoing programs, projects, and restoration efforts remains uncertain. In the long term, however, the net effects are expected to include substantial improvements in river habitat conditions and conservation or recovery of special-status fish populations. Despite ongoing and potential future projects that could benefit native fishes and their habitat in Clear Creek, it is apparent that the effects of past and present actions have resulted in a cumulative adverse effect on Central Valley Spring-Run Chinook Salmon, Central Valley Steelhead and their designated critical habitat in Clear Creek.

O.3.13.2.1 Whiskeytown Reservoir Operations

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

Alternatives 1-4

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the action alternatives.

O.3.13.2.2 Clear Creek Flows

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

Alternatives 1-4

Under Alternative 1, flows in Clear Creek downstream of Whiskeytown Dam would not differ substantially from the No Action Alternative and there would be no adverse effects on aquatic biological resources. Under Alternative 2 and Alternative 3, average monthly flow in Clear Creek downstream of Whiskeytown Dam would decrease between 41 and 75% throughout the year in all water year types compared to the No Action Alternative. The decreases in flow would result in the following adverse effects:

- Reduced amount and suitability of habitat for all life stages of focal fish species in Clear Creek downstream of Whiskeytown Dam
- Increased likelihood of water temperature-related stress for Spring-Run Chinook Salmon eggs and emerging fry during September and October
- Increased likelihood of water temperature-related stress for Fall- and Late Fall-Run Chinook Salmon eggs and emerging fry and migrating Steelhead adults

With implementation of Mitigation Measure BIO-1, these adverse effects would be avoided or minimized and would not make a considerable contribution to existing adverse cumulative effects on Central Valley Spring-Run Chinook Salmon, Fall- /Late Fall-Run Chinook Salmon, and Central Valley Steelhead in Clear Creek. With mitigation, there would be no cumulative effects on aquatic biological resources under the action alternatives.

O.3.13.2.3 Spring Creek Debris Dam

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

O.3.13.2.4 Clear Creek Restoration Program

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

Alternatives 1-4

The Clear Creek Restoration Program would continue under Alternatives 1, 3 and 4 and there would be no cumulative effects on aquatic biological resources under these alternatives. Under Alternative 2, the Clear Creek Restoration Program would be discontinued, resulting in the following adverse effects:

- Reduced salmonid spawning success and egg survival due to decreased spawning habitat availability and increased likelihood of redd superimposition resulting from cessation of gravel injections.
- Reduced genetic integrity of Spring-Run Chinook Salmon due to increased hybridization resulting from discontinued operation of the segregation weir.

With implementation of Mitigation Measure BIO-XX, these adverse effects would be avoided or minimized and would not make a considerable contribution to existing adverse cumulative effects on Central Valley Spring-Run Chinook Salmon, Fall- /Late Fall-Run Chinook Salmon, and Central Valley Steelhead in Clear Creek. With mitigation, there would be no cumulative effects on aquatic biological resources under the action alternatives.

O.3.13.3 *Sacramento River*

Past and present human activities have substantially changed aquatic habitats in the Sacramento River compared to historical conditions, resulting in cumulative adverse impacts on the distribution, abundance, population structure, and genetic integrity of native salmonids, and similar effects on other native fishes. Major factors contributing to the cumulative impacts (cumulative effects) on aquatic biological resources in the Sacramento River in the project area have included major instream water storage dams, hydropower development and operations, hatchery management, water withdrawals for irrigation and other uses, agricultural and urban development, channelization and levee construction, mining activities, recreational use and development, sport and commercial fisheries, introduction of nonnative fish species, and other management actions, water uses, and land uses (Appendix Y, *Cumulative Methodology*). These actions have resulted in highly altered flow regimes, loss and disconnection of floodplains from the river channel, altered sediment transport, reduced aquatic habitat complexity, loss of riparian and off-channel aquatic habitat, loss of upstream habitat, elevated water temperature, degraded water quality, habitat fragmentation by physical barriers, and other adverse effects on aquatic biological resources. Several ecosystem improvement projects and actions, including the Central Valley Project Improvement Act (CVPIA), the CALFED Bay-Delta Program, California EcoRestore, California WaterFix, the CDFW Ecosystem Restoration Program, and various other conservation, management, and restoration programs (Appendix Y, *Cumulative Methodology*), have been initiated to offset the adverse effects of previous and ongoing activities.

In addition to the ongoing activities, several probable future projects and programs may affect listed fishes and other aquatic biological resources in the Sacramento River. New projects and programs recently implemented or likely to be implemented in the near future are listed in Appendix Y, *Cumulative Methodology*. Some of these projects and programs may adversely affect special-status fishes and critical habitat in the Sacramento River, but others are likely to be beneficial. While some projects and actions have had beneficial effects, the net short-term effect of many new and ongoing programs, projects, and restoration efforts remains uncertain. In the long term, however, the net effects are expected to include substantial improvements in river habitat conditions and conservation or recovery of special-status fish populations. Despite ongoing and potential future projects that could benefit native Sacramento River fishes and their habitat, it is apparent that the effects of past and present actions have resulted in a cumulative adverse effect on Sacramento River Winter-Run Chinook Salmon, Central Valley Spring-Run Chinook Salmon, Central Valley Steelhead, Southern DPS Green Sturgeon, and designated critical habitat in the Sacramento River for each of these species.

Anadromous Salmonids

This section addresses cumulative effects on the Sacramento River populations of the following anadromous salmonids: Winter-Run Chinook Salmon, Spring-Run Chinook Salmon, Central Valley Steelhead, Fall-Run Chinoook Salmon and Late fall-run Chinook Salmon. Winter-Run, Spring-Run and steelhead are federally listed, while fall-run and late fall-run are not listed.

The following are the proposed actions that were identified in the evaluation of the alternatives to have potential effects (adverse or beneficial) on one or more of the anadromous salmonid species or runs:

Project-Level Actions

- Seasonal operations
- Shasta coldwater pool management
- Spring pulse flows
- Fall and winter refill and redd maintenance
- Rice decomposition smoothing
- Spring management of spawning locations

Program-Level Actions

- Battle Creek restoration
- Lower intakes near Wilkins Slough
- Shasta TCD improvements
- Conservation hatchery (increased Winter-Run Chinook Salmon production)
- Small screen program
- Spawning habitat restoration
- Rearing habitat restoration
- Adult rescue
- Trap and haul

The No Action Alternative would include none of the proposed actions of the alternatives nor any effects on anadromous salmonids resulting from them and, therefore, by definition, there would be no cumulative effects on anadromous salomonids under the No Action Alternative. Most of the project-level proposed actions are included in Alternative 1 only, while all of the program-level actions are included in

Alternatives 1 and 3, but not in Alternatives 2 and 4. Therefore, with respect to the project-level proposed actions, Alternatives 2 through 4, but not Alternative 1, are largely the same as the No Action Alternative, and with respect to the program-level proposed actions, Alternatives 2 and 4, but not Alternatives 1 and 3, are the same as the No Action Alternative. The one exception is the project-level proposed action, seasonal operations, which for all the action alternatives is different than the No Action Alternative.

All of the program-level proposed actions are expected to benefit the anadromous salmonid species or runs, and only one of these actions, the conservation hatchery increased Winter-Run production, would potentially have an adverse effect as well. On the other hand, all of the project-level proposed actions are expected to have both benefits and adverse effects on some of the anadromous salmonids. The expected benefits and impacts typically involve a tradeoff between the benefit of releasing water from storage in one year and with the impact of conserving insufficient storage for the next year. For instance, seasonal operations (the first proposed action listed above) must balance the benefits to incubating Winter-Run and Spring-Run eggs and alevins of releasing cold water in one year with the impact of providing insufficient storage for conservation of coldwater pool in the following year. This applies to seasonal operations of all the alternatives. For some of the other actions, the tradeoff is between flow releases to benefit migration or to prevent redd dewatering in one year versus sufficient coldwater pool in the following year. In addition to seasonal operations, such trade-offs are a central feature of Shasta coldwater pool management, fall and winter refill and redd maintenance, spring pulse flow, rice decomposition smoothing, and spring management of spawning locations. The costs and benefits of using water in one year versus using it in the following year are difficult to guage and likely vary from year to year, so the net effect on the salmonid populations is uncertain.

The competing benefits of storage releases in successive years described abovc principally affect Winter-Run and Spring-Run because the timing of their life cycles result in frequent exposure of eggs and alevins to injuriously warm water temperatures during summer and fall, falling water levels that lead to redd dewatering during the fall, or inadequate pulse flows for rearing and emigrating juveniles in the spring. Steelhead, fall-run and late fall-run are less affected by the management tradeoffs because they spawn when river water temperatures are cooler.

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology*, may have effects on anadromous salmonids of the Sacramento River that are related to the effects of the proposed actions of Alternative 1 described above, including postivie and negative effects. The cumulative projects include actions that affect the timing and magnitidue of flow releases and seasonal water temperatures and actions that improve habitat of rearing and migrating salmonids in the Sacramento River. Flow and temperature effects of completed projects are generally accounted for in the operational modeling of the No Action Alternative. Of the water supply and water quality projects that have not been completed, those most likely to have cumulative effects related to the flow and water temperature effects of Alternative 1 are the Shasta Lake Water Resources Investigation (Shasta Dam Raise Project), the SWRCB Bay-Delta Water Quality Control Plan Update, and the Sites Reservoir Project.

Potential cumulative benefical effects from the Shasta Dam Raise Project would be to increase the volume of the Shasta Reservoir coldwater pool, enhancing the supply of cold water available for release to the river and thereby benefiting early life stages of Winter-Run and Spring-Run salmon. A greater supply of cold water would also alleviate the constraints of balancing requirements for cold water against benefits of other water release benefits for fish, including redd maintenance, emigration pulse flows, immigration attraction flows, and overbank flows to improve rearing habitat.

Potential cumulative beneficial effects of the Sites Reservoir Project would result from supplying some Shasta water demand with Sites water and thereby conserving some Shasta storage for fish benefits, including benefits to anadromous salmonid spawsning and rearing habitat. However, the Sites Project may also have a cumulative adverse effect on salmonids because it would reduce Sacramento River flow as far upstream as the TCCA intake near Red Bluff when diverting water to the Sites Reservoir, which would add to the potential adverse flow effects for rearing and emigrating Winter-Run and Spring-Run smolts under Alternative 1 (See Section 3/12 *Impacts Summary*). However, the Sites diversions would occur primarily in the winter and early spring, when water temperatures remain cool.

The Bay-Delta Water Quality Control Plan has the potential to modify Sacramento River flow, but what the modifications would be and what their effects on Sacramento River salmonids would be are uncertain.

Given the mixture of potential negative and positive effects from the actions in Alternative 1 and related actions in Shasta Dam Raise and Sites, there is some uncertainty in how Alternative 1 would ultimately affect Winter-Run and Spring-Run salmon. However, in consideration of the likely positive effects of Shasta Dam Raise and Sites on Winter-Run and Spring-Run spawning habitat in the upper Sacramento River, as well as the benefits of the non-operations-related programmatic actions included in Alternative 1, Alternative 1's contribution to adverse cumulative effects would not be substantial.

There are many projects listed in Appendix Y designed to improve habitat for Sacramento River salmonids, but most of these target habitat improvements in the Delta or the Yolo and Sutter Bypasses, so the cumulative effects of these projects are addressed in the cumulative effects sections for those areas.

Relative to the No Action Alternative, Alternative 2 and 3 would have no effect on Sacramento River anadromous salmonids except for reduced flows in September and November of wet and above normal years, which would have adverse temperature effects and migration and rearing habitat flow effects on Winter-Run and Spring-Run salmon. Alternatives 4, like Alternative 1, would also have adverse effects from the reduced September and November flow releases on migration and rearing habitat, but not on water temperatures. And Alternative 3, like Alternative 1 would have a number of beneficial programmatic actions. For Alternatives 3 and 4, the potentially adverse impacts are small relative to their potential benefits, and for Alternatives 2, 3 and 4, the potentially adverse impacts are small relative to the potential benefits of the Shasta Dam Raise and Sites projects. Therefore, the cumulative adverse effects of all three alternatives would not be substantial.

<u>Green and White Sturgeon</u>

This section addresses cumulative effects on the Sacramento River populations of Green Sturgeon and White Sturgeon. Southern DPS Green Sturgeon is federally listed; White Sturgeon is not listed.

The proposed actions that were identified in the evaluation of the alternatives as having potential effects (adverse or beneficial); the alternatives that included each of the actions; and a comparison of each of the action alternative to the No Action Alternative are presented above in the section for anadromous salmonids.

Most of the proposed actions primarily target anadromous salmonids, but many of them potentially affect sturgeon as well. Green Sturgeon is generally more likely to be affected than White Sturgeon because its spawning, holding and rearing habitats are further upstream than those of White Sturgeon and most of the proposed actions primarily target conditions in the upper Sacramento River. None of the proposed actions is expected to affect White Sturgeon. Therefore, there are no cumulative effects on White Sturgeon. Potential effects of the actions on Green Sturgeon include reduced quality of holding habitat from lower September and November flow in wet and above normal years relative to the No Action Alternative, and improved quality of spawning habitat from the proposed spawning habitat restoration action.

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology*, may have effects on Green Sturgon that are related to the effects of the proposed actions of Alternative 1 described above, including positive and negative effects. The cumulative projects include actions that affect the timing and magnitidue of flow releases and seasonal water temperatures, and actions that improve habitat of rearing and migrating Green Sturgeon in the Sacramento River. Flow and temperature effects of completed projects are generally accounted for in the operational modeling of the No Action Alternative. Of the water supply and water quality projects that have not been completed, those most likely to have cumulative effects related to the flow and water temperature effects of Alternative 1 are the Shasta Lake Water Resources Investigation (Shasta Dam Raise Project), the SWRCB Bay-Delta Water Quality Control Plan Update, and the Sites Reservoir Project.

Potential cumulative benefical effects from the Shasta Dam Raise Project would be to increase the volume of the Shasta Reservoir coldwater pool, enhancing the supply of cold water available for release to the river. A greater supply of cold water would alleviate the constraints of balancing cold water requirements for Winter-Run and Spring-Run salmon against of other water release benefits for species such as Green Sturgeon. Increased flow would potentially improve Green Sturgeon holding and rearing habitat and provide improved conditions for dispersal and emigration of Green Sturgeon larvae and juveniles.

Potential cumulative beneficial effects of the Sites Reservoir Project on Green Sturgeon would be similar to those of Shasta Dam Raise Project for the river upstream of the TCCA intake near Red Bluff. The Sites Project may also have a cumulative adverse effect because it would reduce Sacramento River flow as far upstream as the TCCA intake near Red Bluff when diverting water to the Sites Reservoir, and thereby potentially add to the potential adverse effect on Green Sturgeon holding habitat under Alternative 1 (See Section ?, *Impacts Summary*).

The Bay-Delta Water Quality Control Plan has the potential to modify Sacramento River flow, but what the modifications would be and what their effects on Green Sturgeon would be are uncertain.

Given the mixture of potential negative and positive effects from the actions in Alternative 1 and related actions in Shasta Dam Raise and Sites, there is some uncertainty in how Alternative 1 would ultimately affect Green Sturgeon. However, in consideration of the likely positive effects of Shasta Dam Raise on Green Sturgeon habitat in the upper and middle Sacramento River, as well as the benefits of the non-operations-related programmatic actions included in Alternative 1, Alternative 1's contribution to adverse cumulative effects would not be substantial.

There are many projects listed in Appendix Y designed to improve habitat for Sacramento River salmonids, and while some of these would likely benefit Green Sturgeon as well, most of them target habitat improvements in the Delta or the Yolo and Sutter Bypasses, so the cumulative effects of these projects are addressed in the cumulative effects sections for those areas.

Relative to the No Action Alternative, Alternatives 2, 3, and 4, like Alternative 1, would have no significant effect on Green Sturgeon, except for reduced holding habitat quality from lower flows in September and November of wet and above normal years. This potentially adverse impact is small relative to the potential benefits of spawning and rearing habitat restoration actions under Alternatives 3. Additionally, the impact of the reduced quality of holding habitat under Alternatives 2, 3 and 4 is small relative to the potential benefits of the Shasta Dam Raise Project, so the cumulative adverse effects of all three alternatives would not be substantial.

Other Focal Fish Species

This section addresses cumulative effects on the remaining Sacramento River populations of the focal fish species not included as anadromous salmonids or Green Sturgeon and White Sturgeon: Sacraemtno Spllittail, Pacific Lamprey, River Lamprey, Hardhead, Central California Roach, Striped Bass, American Shad, Largemouth Bass, Smallmouth Bass, and Spotted Bass. None of these is a federally listed species.

The proposed actions that were identified in the evaluation of the alternatives as having potential effects (adverse or beneficial); the alternatives that included each of the actions; and a comparison of each of the action alternative to the No Action Alternative are presented above in the section for anadromous salmonids.

Most of the proposed actions primarily target anadromous salmonids and none of them are expected to affect any of the focal species listed above. Therefore, there are no cumulative effects on these species.

O.3.13.4 *Feather River*

Past and present human activities have substantially changed aquatic habitats in the lower Feather River compared to historical conditions, resulting in cumulative adverse impacts on the distribution, abundance, population structure, and genetic integrity of native salmonids, and similar effects on other native fishes. Major factors contributing to the cumulative impacts (cumulative effects) on aquatic biological resources in the lower Feather River have included hydropower development and operations, hatchery management, water withdrawals for irrigation and other uses, agricultural and urban development, channelization and levee construction, mining activities, recreational use and development, sport and commercial fisheries, introduction of nonnative fish species, and other management actions, water uses, and land uses. These actions have resulted in highly altered flow regimes, loss and disconnection of floodplains from the river channel, altered sediment transport, reduced aquatic habitat complexity, loss of riparian and off-channel aquatic habitat, elevated water temperature, degraded water quality, habitat fragmentation by physical barriers, and other adverse effects on aquatic biological resources. Several ecosystem improvement projects and actions, including the Central Valley Project Improvement Act (CVPIA), the CALFED Bay-Delta Program, California EcoRestore, the CDFW Ecosystem Restoration Program, and various other conservation, management, and restoration programs (Appendix Y, *Cumulative Methodology*), have been initiated to offset the adverse effects of previous and ongoing activities.

In addition to the ongoing activities, several probable future projects and programs may affect listed fishes and other aquatic biological resources in the lower Feather River. New projects and programs recently implemented or likely to be implemented in the near future are listed in Appendix Y, *Cumulative Methodology*. Some of these projects and programs may adversely affect special-status fishes and critical habitat in the lower Feather River, but others are likely to be beneficial. While the net short-term effect of new and ongoing programs, projects, and restoration efforts is uncertain, the net long-term effects are expected to include substantial improvements in river habitat conditions and conservation or recovery of special-status fish populations. Despite ongoing and potential future projects that could benefit native Feather River fishes and their habitat, it is apparent that the effects of past and present actions have resulted in a cumulative adverse effect on Central Valley Spring-Run Chinook Salmon, Central Valley Steelhead, Southern DPS Green Sturgeon, and critical habitat for each of these species in the lower Feather River.

O.3.13.4.1 FERC Project #2100-134

No Action Alternative

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the No Action Alternative.

Alternatives 1-4

There were no adverse effects identified. Therefore, there would be no cumulative effects on aquatic biological resources under the action alternatives.

O.3.13.5 *American River*

The American River is a highly altered watershed. Historic actions and management led to the reduction of available habitat, degraded habitat conditions, and substantial reduction of fish populations in the river. While these impacts were acknowledged as a trade-off for other water management priorities in the past, measures have been taken to improve conditions in the lower American river. As such, there are numerous ongoing actions in and around the American River that may result in cumulative effects. Many of these actions are working to restore or improve conditions, so the resultant effect may not necessarily be a negative cumulative impact.

Several processes and measures are under way to that may lead to revision to flows in the Lower American River, with the objective of providing suitable instream flow and temperature conditions for fall-Chinook Salmon and Steelhead, and also benefiting other aquatic species in the river. The implementation of the Lower American River Flow Management Standard Implementation is intended to improve the condition of aquatic resources in the lower American River, particularly Fall-Run Chinook Salmon and Steelhead through management of water temperature and flow. The Lower American River Temperature Reduction Modeling Project would develop predictive tools that will reduce uncertainties in the performance of identified temperature control actions that could be implemented to improve the management of cold water resources in the Folsom/Natoma Reservoir system and the lower American River. Under the Sacramento River Water Reliability Project, Future Water Supply Projects, Reclamation and Placer County Water Agency are investigating the viability of a joint water supply diversion from the Sacramento River that includes the objective of maintaining a reliable water supply while reducing diversions of surface water from the American River in future dry years to preserve the river ecosystem. The proposed Folsom Reservoir Temperature Control Device on the bank of Folsom Reservoir would withdraw water from the warm upper reaches of the lake while preserving the coldwater pool at the bottom of the lake to protect downstream aquatic species. Implementation of these measures to would help to improve habitat conditions in the American River, particularly in dry years, by maintaining minimum instream flows and suitable water temperatures.

O.3.13.6 *Stanislaus River*

Natural hydrologic processes have been altered on the Stanislaus River, as they have been on most California rivers. More than 40 dams exist on the Stanislaus River (Merz, n.d.). The lower Stanislaus River has been extensively developed to provide water, flood control, hydroelectric power, gravel, and conversion of floodplain habitat for agricultural and residential uses (Merz, n.d.). The construction of new Melones Reservoir and its operation have resulted in a highly altered channel that has experienced gravel extraction, levee construction and removal of woody debris. These changes have affected fish and wildlife populations in the lower San Joaquin River. Processes and measures have occurred within the watershed to restore or improve conditions within the river, so the resultant effect may not necessarily be a negative cumulative effect.

A couple of processes and measures are underway in the Stanislaus River watershed. The SWRCB is updating the 2006 Bay-Delta Water Quality Control Plan (WQCP) in two phases (SWRCB 2018). The first Plan amendment (Phase 1) is focused on San Joaquin River flows and southern Delta salinity and would modify water quality objectives (i.e., establishes minimum flows) on the Stanislaus River to protect the beneficial use of fish and wildlife and modifies the water quality objectives in the southern Delta to protect the beneficial use of agriculture. The proposed final amendments to the Bay-Delta Plan and the Final Supplemental Environmental Document for Phase I was released in July 2018 and the SED was approved in December 2018.

Additionally, there are 22 hydroelectric generation Federal Energy Regulatory Commission permits that expire prior to 2030 (FERC 2015). Of the 22 hydroelectric permits, one is on the Stanislaus River. The FERC must complete analyses under NEPA and ESA to consider the effects of the hydropower operations on the environment, including flow regimes, water quality, fish passage, recreation, aquatic and riparian habitat, and special status species. The FERC relicensing activity in the Stanislaus River will eventually result in a new license that may increase flows into the river, and subsequently to the San Joaquin River.

O.3.13.7 *San Joaquin River*

The San Joaquin River is a highly altered watershed that is currently discontinuous. Historic actions and management led to the extirpation of native fishes, including Spring-Run Chinook Salmon that once persisted. While these impacts were acknowledged as a trade-off for other water management priorities in the past, current policy has worked to reverse the degraded river. As such, there are numerous ongoing actions in and around the San Joaquin River that may result in cumulative effects. Many of these actions are working to restore or improve conditions, so the resultant effect may not necessarily be a negative cumulative impact.

The San Joaquin River Restoration Program is a large and comprehensive effort to reverse some of the negative alterations to the upper San Joaquin River aquatic habitat while reintroducing spring-Run Chinook Salmon. The project manages for both Fall- and Spring-Run Chinook Salmon alike, but has reintroduced Spring-Run Chinook through an experimental population. The Salmon population will be supported by a conservation hatchery, which operates under more significant scrutiny considering genetic diversity and overall viability. The program seeks to connect flow from Friant Dam down to the mouth of the Merced River to provide habitat capable of supporting populations of Chinook Salmon in good condition. While water management and habitat restoration are significant components to the project, the overall impact to irrigators is required to be *de minimus*.

Several regulatory processes are currently underway that might lead to general revisions to flow in the San Joaquin River. The Bay-Delta Water Quality Control Plan Update is seeking for 40 to 60% unimpaired flow from the lower San Joaquin, Merced, Tuolumne, and Stanislaus Rivers. This level of unimpaired flow would significantly increase outflow through the lower San Joaquin River to the Delta. FERC relicensing activity in the Merced and Tuolumne Rivers will eventually result in a new license that may increase required base flows from these tributaries to the San Joaquin River.

Any increased flow releases in the upper San Joaquin River may result in lower storage. The upper San Joaquin River basin Storage Investigation is investigating the potential to add 1,260 TAF of storage along the upper San Joaquin River upstream of Millerton Lake in an area known as Temperance Flat.

Additional storage would help to offset additional water demands for agricultural needs, the environment and municipal usage.

Flood risk management in the lower San Joaquin River may modify the channel structure through repair of levee walls. The overall study area includes the mainstem of the San Joaquin River from the Mariposa Bypass downstream to the city of Stockton. The study area also includes Paradise Cut and Old River as far north as Tracy Boulevard and Middle River as far north as Victoria Canal. These areas have commonly flooded and resulted in damage and risk to surrounding homes and property. The project will balance levee repairs by also improving aquatic and riparian habitat.

O.3.13.8 *Bay-Delta*

O.3.13.8.1 <u>Delta Smelt</u>

The following are the main potential effects to Delta Smelt identified in the evaluation of alternatives (effects apply to all alternatives, except as otherwise indicated):

Potential changes to Delta Smelt due to seasonal operations (Project-Level)

Potential changes to Delta Smelt due to OMR management (Project-Level, Alternative 1 only)

Potential Effects from Delta Smelt Habitat Operations (Project-Level, Alternatives 1 and 3 only)

Potential changes to Delta Smelt due to reintroduction by the Fish Conservation and Culture Laboratory (Project-Level, Alternatives 1 and 3 only)

Potential changes to Delta Smelt from food subsidies (Sacramento Deepwater Ship Channel Food Study; North Delta Food Subsidies/Colusa Basin Drain Study; Suisun Marsh Roaring River Distribution System Food Subsidies Study)(Program-Level, Alternatives 1 and 3 only)

Potential changes to Longfin Smelt from tidal habitat restoration (Program-Level)

Potential changes to Delta Smelt from the Delta fFsh Species Conservation Hatchery (Program-Level, Alternatives 1 and 3 only)

Potential changes to Delta Smelt from additional habitat restoration (25,000 acres within the Delta) (Program-Level, Alternative 3 only)

The No Action Alternative would not result in any changes to water operations from current operations and therefore additional effects on Delta Smelt would be avoided by design. Thus, no cumulative effects on aquatic resources under the No Action alternative were identified.

Alternative 1 would contribute to cumulative effects on Delta Smelt from seasonal operations and Delta Smelt habitat operations (e.g., food availability and habitat extent) and OMR management (south Delta entrainment risk). However, Alternative 1 would be subject to the regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB. Also, there may be offsetting, potential positive effects to Delta Smelt from food subsidies (studies related to Sacramento Deepwater Ship Channel, North Delta/Colusa Basin Drain, and Suisun Marsh RRDS), reintroduction of Delta Smelt by the Fish Conservation and Culture Laboratory and the Delta Fish Species Conservation Hatchery, and completion of 8,000 acres of tidal habitat restoration.

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology*, may have effects on Delta Smelt related to the effects described above related to Alternative 1. The listed projects that have been completed have had their effects accounted for in the operational modeling of Alternative 1, e.g., effects on Delta outflow. Of the water supply and water quality projects not included in the modeling, those most likely to have cumulative effects of the nature described for Alternative 1 are the SWRCB Bay-Delta Water Quality Control Plan Update, the Sites Reservoir Project, and the Delta Wetlands project. The Bay-Delta Water Quality Control Plan has the potential to increase Delta inflow and Delta outflow, and reduce south Delta exports. The Sites Reservoir Project has the potential to reduce winter/early spring Delta inflow and outflow, as well as to increase south Delta exports during the summer water transfer window, but also has the potential to increase summer/fall flows into the north Delta from the Colusa Basin Drain/Yolo Bypass for Delta Smelt food web benefits. The Delta Wetlands project would have potential negative effects from entrainment of Delta Smelt too small to be screened, in addition to reductions in Delta outflow during winter/early spring diversion periods, but may provide positive effects from release of water to contribute to Delta outflow. Given the mixture of potential negative and positive effects from these actions, there is some uncertainty in how Alternative 1 would ultimately affect seasonal operations; for example, increases in Delta outflow requirement under the Bay-Delta Water Quality Control Plan would regulate Delta outflow under the proposed action and any other actions potentially affecting outflow. As previously noted for Alternative 1, other projects would be subject to regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB, in order to limit potential negative effects. In consideration of these requirements, as well as the non-operations-related measures included in Alternative 1 such as tidal habitat restoration and food subsidy actions and other projects' restoration activities such as California EcoRestore, Alternative 1's contribution to cumulative effects would not be substantial.

Relative to the No Action Alternative, Alternatives 2 through 4would have somewhat differing effects compared to Alternative 1's effects because of differences in seasonal operations and differing extent of habitat restoration, for example, but the overall conclusion regarding cumulative effects remains the same as Alternative 1 because of the common regulatory and permitting requirements that all Alternatives are subject to.

O.3.13.8.2 Longfin Smelt

The following are the main potential effects to Longfin Smelt identified in the evaluation of alternatives (effects apply to all alternatives, except as otherwise indicated):

Potential changes to Longfin Smelt due to seasonal operations (Project-Level)

Potential changes to Longfin Smelt due to OMR management (Project-Level, Alternative 1 only)

The No Action Alternative would not result in any changes to water operations from current operations and therefore additional effects on Delta Smelt would be avoided by design. Thus, no cumulative effects on aquatic resources under the No Action alternative were identified.

Key aspects of the above effects for Longfin Smelt under Alternative 1 and Alternatives 2 through 4 are potential changes that could occur to Delta outflow in particular, with reductions in winter/spring outflow having the potential to reduce abundance relative to the No Action Alternative. However, Alternative 1 would be subject to the regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB. As discussed in more detail for Delta Smelt, completed project effects are captured in the operations modeling for the project. As also discussed for Delta Smelt, other projects (Bay-Delta Water Quality Control updates, Sites Reservoir Project, and Delta Wetlands) could positively or negatively affect Delta outflow, but all projects would be subject to regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB. Therefore Alternative 1's contribution to cumulative effects would not be substantial. For the same reason, Alternatives 2 through 4also would not substantially contribute to cumulative effects.

O.3.13.8.3 Sacramento Winter-Run Chinook Salmon

The following are the main potential effects to Sacramento River Winter-Run identified in the evaluation of alternatives (effects apply to all alternatives, except as otherwise indicated):

Potential negative effects from seasonal operations (Project-Level)

Potential negative effects from OMR Management (Project-Level)

Potential negative effects from Delta Cross Channel Operations (Project Level)

Potential positive effects from Tracy and Skinner Fish Facilities (Project-Level)

Potential positive effects from Predator Hot Spot Removal (Program-Level, Alternatives 1 and 3 only)

Potential negative effects from Delta Cross Channel Gate Improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from Tracy and Skinner Fish Facility Improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from Small Screen Program (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from Tidal Habitat Restoration (Complete 8,000 Acres from 2008 BO) (Program-Level)

Potential positive effects from Additional Habitat Restoration (25,000 acres within the Delta) (Program-Level, Alternative 3 only)

The No Action Alternative would not result in any changes to water operations from current operations and therefore additional effects on Winter-Run Chinook Salmon would be avoided by design. Thus, no cumulative effects on aquatic resources under the No Action alternative were identified.

Alternative 1 would contribute to cumulative effects on Winter-Run Chinook Salmon from seasonal operations, OMR management (south Delta entrainment risk), and Delta Cross Channel Operations. However, Alternative 1 would be subject to the regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB. Also, there may be offsetting, potential positive effects to Winter Run Chinook salmon from improvements at the Tracy and Skinner Fish Facilities, predator hot-spot removal, the small screen program, and completion of 8,000 acres of tidal habitat restoration.

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology*, may have effects on Winter Run Chinook Salmon related to the effects described above related to Alternative 1. The listed projects that have been completed have had their effects accounted for in the operational modeling of Alternative 1, e.g., effects on Delta outflow. Of the water supply and water quality projects not included in the modeling, those most likely to have cumulative effects of the nature described for Alternative 1 are the SWRCB Bay-Delta Water Quality Control Plan Update, the Sites Reservoir Project, and the Delta Wetlands project. The Bay-Delta Water Quality Control Plan has the potential to increase Delta inflow and reduce south Delta exports. The Sites Reservoir Project has the potential to reduce winter/early spring Delta inflow and outflow, as well as to increase south Delta exports during the summer water transfer window. The Delta Wetlands project would have potential reductions in Delta outflow during winter/early spring diversion periods but may provide positive effects from release of water to contribute to Delta outflow. Given the mixture of potential negative and positive effects from these actions, there is some uncertainty in how Alternative 1 would ultimately affect seasonal operations; for example, increases in Delta outflow requirements under the Bay-Delta Water Quality Control Plan would regulate Delta outflow under the proposed action and any other actions potentially affecting flow in migratory channels and south delta exports. As previously noted for Alternative 1, other projects would be subject to regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB, in order to limit potential negative effects. In consideration of these requirements, as well as the non-operations-related measures included in Alternative 1 such as tidal habitat restoration and food subsidy actions and other projects' restoration activities such as California EcoRestore, Alternative 1's contribution to cumulative effects would not be substantial.

Relative to the No Action Alternative, Alternatives 2 through 4 would have somewhat differing effects compared to Alternative 1's effects because of differences in seasonal operations and differing extent of habitat restoration, for example, but the overall conclusion regarding cumulative effects remains the same as Alternative 1 because of the common regulatory and permitting requirements that all Alternatives are subject to.

O.3.13.8.4 Central Valley Spring Run Chinook Salmon

The following are the main potential effects to Central Valley Spring Run identified in the evaluation of alternatives (effects apply to all alternatives, except as otherwise indicated):

Potential negative effects from seasonal operations (Project-Level)

Potential negative effects from OMR Management (Project-Level)

Potential negative effects from Delta Cross Channel operations (Project Level)

Potential positive effects from Tracy and Skinner Fish Facilities (Project-Level)

Potential positive effects from predator hot Spot removal (Program-Level, Alternatives 1 and 3 only)

Potential negative effects from Delta Cross Channel Gate improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from Tracy and Skinner Fish Facility improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from small screen program (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from Tidal Habitat Restoration (Program-Level)

Potential positive effects from Additional Habitat Restoration (25,000 acres within the Delta) (Program-Level, Alternative 3 only)

The No Action Alternative would not result in any changes to water operations from current operations and therefore additional effects on Spring-Run Chinook Salmon would be avoided by design. Thus, no cumulative effects on aquatic resources under the No Action alternative were identified.

Alternative 1 would contribute to cumulative effects on Spring-Run Chinook Salmon from seasonal operations, OMR management (south Delta entrainment risk), and Delta Cross Channel Operations (Sacramento River populations). However, Alternative 1 would be subject to the regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB. Also, there may be offsetting, potential positive effects to Spring-Run Chinook salmon from improvements at the Tracy and Skinner Fish Facilities, predator hot-spot removal, the small screen program, and completion of 8,000 acres of tidal habitat restoration.

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology*, may have effects on Spring Run Chinook Salmon related to the effects described above related to Alternative 1. The listed projects that have been completed have had their effects accounted for in the operational modeling of Alternative 1, e.g., effects on Delta outflow. Of the water supply and water quality projects not included in the modeling, those most likely to have cumulative effects of the nature described for Alternative 1 are the SWRCB Bay-Delta Water Quality Control Plan Update, the Sites Reservoir Project, and the Delta Wetlands project. The Bay-Delta Water Quality Control Plan has the potential to increase Delta inflow and reduce south Delta exports. The Sites Reservoir Project has the potential to reduce winter/early spring Delta inflow and outflow, as well as to increase south Delta exports during the summer water transfer window. The Delta Wetlands project would have potential reductions in Delta outflow during winter/early spring diversion periods but may provide positive effects from release of water to contribute to Delta outflow. Given the mixture of potential negative and positive effects from these actions, there is some uncertainty in how Alternative 1 would ultimately affect seasonal operations; for example, increases in Delta outflow requirements under the Bay-Delta Water Quality Control Plan would regulate Delta outflow under the proposed action and any other actions potentially affecting flow in migratory channels and south delta exports. As previously noted for Alternative 1, other projects would be subject to regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB, in order to limit potential negative effects. In consideration of these requirements, as well as the non-operations-related measures included in Alternative 1 such as tidal habitat restoration and food subsidy actions and other projects' restoration activities such as California EcoRestore, Alternative 1's contribution to cumulative effects would not be substantial.

Relative to the No Action Alternative, Alternatives 2 through 4 would have somewhat differing effects compared to Alternative 1's effects because of differences in seasonal operations and differing extent of habitat restoration, for example, but the overall conclusion regarding cumulative effects remains the same as Alternative 1 because of the common regulatory and permitting requirements that all Alternatives are subject to.

O.3.13.8.5 Central Valley Fall Run Chinook Salmon

The following are the main potential effects to Central Valley Fall-Run identified in the evaluation of alternatives (effects apply to all alternatives, except as otherwise indicated):

Potential negative effects from seasonal operations (Project-Level)

Potential negative effects from OMR Management (Project-Level)

Potential negative effects from Delta Cross Channel operations (Project Level)

Potential positive effects from Tracy and Skinner Fish Facilities (Project-Level)

Potential positive effects from predator hot spot removal (Program-Level, Alternatives 1 and 3 only)

Potential negative effects from Delta Cross Channel Gate improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from Tracy and Skinner Fish Facility improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from small screen program (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from tidal habitat restoration

Potential positive effects from additional habitat restoration (25,000 acres within the Delta) (Program-Level, Alternative 3 only)

The No Action Alternative would not result in any changes to water operations from current operations and therefore additional effects on Fall-Run Chinook Salmon would be avoided by design. Thus, no cumulative effects on aquatic resources under the No Action alternative were identified.

Alternative 1 would contribute to cumulative effects on Fall-Run Chinook Salmon from seasonal operations, OMR management (south Delta entrainment risk), and Delta Cross Channel Operations (Sacramento River populations). However, Alternative 1 would be subject to the regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB. Also, there may be offsetting, potential positive effects to Fall Run Chinook salmon from improvements at the Tracy and Skinner Fish Facilities, predator hot-spot removal, the small screen program, and completion of 8,000 acres of tidal habitat restoration.

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology*, may have effects on Fall-Run Chinook Salmon related to the effects described above related to Alternative 1. The listed projects that have been completed have had their effects accounted for in the operational modeling of Alternative 1, e.g., effects on Delta outflow. Of the water supply and water quality projects not included in the modeling, those most likely to have cumulative effects of the nature described for Alternative 1 are the SWRCB Bay-Delta Water Quality Control Plan Update, the Sites Reservoir Project, and the Delta Wetlands project. The Bay-Delta Water Quality Control Plan has the potential to increase Delta inflow and reduce south Delta exports. The Sites Reservoir Project has the potential to reduce winter/early spring Delta inflow and outflow, as well as to increase south Delta exports during the summer water transfer window. The Delta Wetlands project would have potential reductions in Delta outflow during winter/early spring diversion periods but may provide positive effects from release of water to contribute to Delta outflow. Given the mixture of potential negative and positive effects from these actions, there is some uncertainty in how Alternative 1 would ultimately affect seasonal operations; for example, increases in Delta outflow requirements under the Bay-Delta Water Quality Control Plan would regulate Delta outflow under the proposed action and any other actions potentially affecting flow in migratory channels and south delta exports. As previously noted for Alternative 1, other projects would be subject to regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB, in order to limit potential negative effects. In consideration of these requirements, as well as the non-operations-related measures included in Alternative 1 such as tidal habitat restoration and food subsidy actions and other projects' restoration activities such as California EcoRestore, Alternative 1's contribution to cumulative effects would not be substantial.

Relative to the No Action Alternative, Alternatives 2 through 4 would have somewhat differing effects compared to Alternative 1's effects because of differences in seasonal operations and differing extent of habitat restoration, for example, but the overall conclusion regarding cumulative effects remains the same as Alternative 1 because of the common regulatory and permitting requirements that all Alternatives are subject to.

O.3.13.8.6 California Central Valley Steelhead

The following are the main potential effects to California Central Valley steelhead identified in the evaluation of alternatives (effects apply to all alternatives, except as otherwise indicated):

Potential negative effects from seasonal operations (Project-Level)

Potential negative effects from OMR Management (Project-Level)

Potential negative effects from Delta Cross Channel operations (Project Level)

Potential positive effects from Tracy and Skinner Fish Facilities (Project-Level)

Potential positive effects from predator hot spot removal (Program-Level, Alternatives 1 and 3 only)

Potential negative effects from Delta Cross Channel Gate improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from Tracy and Skinner Fish Facility improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from small screen program (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from tidal habitat restoration (Program-Level)

Potential positive effects from additional habitat restoration (25,000 acres within the Delta) (Program-Level, Alternative 3 only)

The No Action Alternative would not result in any changes to water operations from current operations and therefore additional effects on CCV steelhead would be avoided by design. Thus, no cumulative effects on aquatic resources under the No Action alternative were identified.

Alternative 1 would contribute to cumulative effects on CCV steelhead from seasonal operations, OMR management (south Delta entrainment risk), and Delta Cross Channel Operations (Sacramento River populations). However, Alternative 1 would be subject to the regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB. Also, there may be offsetting, potential positive effects to CCV steelhead from improvements at the Tracy and Skinner Fish Facilities, predator hot-spot removal, the small screen program, and completion of 8,000 acres of tidal habitat restoration.

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology*, may have effects on CCV steelhead related to the effects described above related to Alternative 1. The listed projects that have been completed have had their effects accounted for in the operational modeling of Alternative 1, e.g., effects on Delta outflow. Of the water supply and water quality projects not included in the modeling, those most likely to have cumulative effects of the nature described for

Alternative 1 are the SWRCB Bay-Delta Water Quality Control Plan Update, the Sites Reservoir Project, and the Delta Wetlands project. The Bay-Delta Water Quality Control Plan has the potential to increase Delta inflow and reduce south Delta exports. The Sites Reservoir Project has the potential to reduce winter/early spring Delta inflow and outflow, as well as to increase south Delta exports during the summer water transfer window. The Delta Wetlands project would have potential reductions in Delta outflow during winter/early spring diversion periods but may provide positive effects from release of water to contribute to Delta outflow. Given the mixture of potential negative and positive effects from these actions, there is some uncertainty in how Alternative 1 would ultimately affect seasonal operations; for example, increases in Delta outflow requirements under the Bay-Delta Water Quality Control Plan would regulate Delta outflow under the proposed action and any other actions potentially affecting flow in migratory channels and south delta exports. As previously noted for Alternative 1, other projects would be subject to regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB, in order to limit potential negative effects. In consideration of these requirements, as well as the non-operations-related measures included in Alternative 1 such as tidal habitat restoration and food subsidy actions and other projects' restoration activities such as California EcoRestore, Alternative 1's contribution to cumulative effects would not be substantial.

Relative to the No Action Alternative, Alternatives 2 through 4 would have somewhat differing effects compared to Alternative 1's effects because of differences in seasonal operations and differing extent of habitat restoration, for example, but the overall conclusion regarding cumulative effects remains the same as Alternative 1 because of the common regulatory and permitting requirements that all Alternatives are subject to.

O.3.13.8.7 North American Green Sturgeon southern DPS

The following are the main potential effects to North American Green Sturgeon identified in the evaluation of alternatives (effects apply to all alternatives, except as otherwise indicated):

Potential negative effects from seasonal operations (Project-Level)

Potential negative effects from OMR Management (Project-Level)

Potential positive effects from Tracy and Skinner Fish Facilities (Project-Level)

Potential positive effects from predator hot spot removal (Program-Level, Alternatives 1 and 3 only)

Potential negative effects from Delta Cross Channel Gate improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from Tracy and Skinner Fish Facility improvements (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from small screen program (Program-Level, Alternatives 1 and 3 only)

Potential positive effects from tidal habitat restoration (Program-Level)

Potential positive effects from additional habitat restoration (25,000 acres within the Delta) (Program-Level, Alternative 3 only)

The No Action Alternative would not result in any changes to water operations from current operations and therefore additional effects on North American Green Sturgeon would be avoided by design. Thus, no cumulative effects on aquatic resources under the No Action alternative were identified.

Alternative 1 would contribute to cumulative effects on North American Green Sturgeon from seasonal operations, OMR management (south Delta entrainment risk), and Delta Cross Channel Operations (Sacramento River populations). However, Alternative 1 would be subject to the regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB. Also, there may be offsetting, potential positive effects to North American Green Sturgeon from improvements at the Tracy and Skinner Fish Facilities, predator hot-spot removal, the small screen program, and completion of 8,000 acres of tidal habitat restoration.

Past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology*, may have effects on North American Green Sturgeon related to the effects described above related to Alternative 1. The listed projects that have been completed have had their effects accounted for in the operational modeling of Alternative 1, e.g., effects on Delta outflow. Of the water supply and water quality projects not included in the modeling, those most likely to have cumulative effects of the nature described for Alternative 1 are the SWRCB Bay-Delta Water Quality Control Plan Update, the Sites Reservoir Project, and the Delta Wetlands project. The Bay-Delta Water Quality Control Plan has the potential to increase Delta inflow and reduce south Delta exports. The Sites Reservoir Project has the potential to reduce winter/early spring Delta inflow and outflow, as well as to increase south Delta exports during the summer water transfer window. The Delta Wetlands project would have potential reductions in Delta outflow during winter/early spring diversion periods but may provide positive effects from release of water to contribute to Delta outflow. Given the mixture of potential negative and positive effects from these actions, there is some uncertainty in how Alternative 1 would ultimately affect seasonal operations; for example, increases in Delta outflow requirements under the Bay-Delta Water Quality Control Plan would regulate Delta outflow under the proposed action and any other actions potentially affecting flow in migratory channels and south delta exports. As previously noted for Alternative 1, other projects would be subject to regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB, in order to limit potential negative effects. In consideration of these requirements, as well as the non-operations-related measures included in Alternative 1 such as tidal habitat restoration and food subsidy actions and other projects' restoration activities such as California EcoRestore, Alternative 1's contribution to cumulative effects would not be substantial.

Relative to the No Action Alternative, Alternatives 2 through 4 would have somewhat differing effects compared to Alternative 1's effects because of differences in seasonal operations and differing extent of habitat restoration, for example, but the overall conclusion regarding cumulative effects remains the same as Alternative 1 because of the common regulatory and permitting requirements that all Alternatives are subject to.

O.3.13.9 *Nearshore Pacific Ocean of the California Coast*

O.3.13.9.1 <u>Southern Resident Killer Whale</u>

The following main potential effects on Southern Resident Killer Whale were identified in the evaluation of alternatives:

Potential changes to Southern Killer Whale from Chinook Salmon prey abundance

In general, the analysis of Alternatives 1–4 noted that potential effects on Chinook Salmon prey for Southern Resident Killer Whale may be limited as a result of the medium importance of Central Valley Chinook Salmon stocks in the Southern Resident Killer Whale diet and the relatively high representation in the stocks by hatchery-origin fish, many of which are released downstream of the Delta. As described previously for the smelts above, other projects that could contribute to cumulative effects to Chinook Salmon as Southern Resident Killer Whale prey would be subject to regulatory and permitting requirements of the USACE, USFWS, CDFW, NMFS, and SWRCB, which would tend to limit the potential for effects and would be expected to result in Alternatives 1–4 not substantially contributing to cumulative effects.

Appendix P Terrestrial Biological Resources Technical Appendix

This appendix documents the biological resources technical analysis to support the impact analysis in the environmental impact statement (EIS).

P.1 Background Information

P.1.1 Vegetation and Wildlife

P.1.1.1 *Trinity River*

The Trinity River region includes the area along the Trinity River from Trinity Lake to the confluence with the Klamath River; and along the lower Klamath River from the confluence with the Trinity River to the Pacific Ocean. The Trinity River region includes Trinity Lake, Lewiston Reservoir, the Trinity River between Lewiston Reservoir and the confluence with the Klamath River, and along the lower Klamath River. The study area only includes the aquatic areas and associated margins.

P.1.1.1.1 Trinity Lake and Lewiston Reservoir

Along the margins of Trinity Lake and Lewiston Reservoir, vegetation is consistent with species associated with a reservoir environment and standing water, including floating species, rooted aquatic species, and emergent wetland species. Emergent wetland and riparian vegetation is constrained by fluctuating water levels and steep banks (California North Coast Regional Water Quality Control Board [NCRWQCB] and Bureau of Reclamation [Reclamation] 2009; U.S. Fish and Wildlife Service [USFWS] et al. 1999).

The reservoirs attract resting and foraging waterfowl and other species that favor standing or slow-moving water. Impounded water in the reservoirs also provides foraging habitat for eagles and other raptors that prey on fish (e.g., ospreys) and waterfowl.

P.1.1.1.2 Trinity River from Lewiston Reservoir to Klamath River

Between the North Fork and the South Fork, the Trinity River channel is restricted by steep canyon walls that limit riparian vegetation to a narrow band (NCRWQCB and Reclamation 2009; USFWS et al. 1999). Between the South Fork and the confluence with the Klamath River, there are confined reaches with little riparian vegetation, alternating with vegetation similar to the pre-dam conditions in the upper reach below Lewiston dam.

Many wildlife species that inhabited river and riparian habitats prior to dam construction still occur along the Trinity River. Species that prefer early-successional stages or require greater riverine structural diversity are likely to be less abundant under current conditions (NCRWQCB and Reclamation 2009; USFWS et al. 1999). For example, western pond turtle declined since completion of the dams in response to diminishing instream habitat. In contrast, species such as northern goshawk and black salamander that favor mature, late-successional riparian habitats increased with more upland habitat along the riparian corridor.

Current vegetation along the Trinity River includes annual grassland, fresh emergent wetland, montane riparian, valley-foothill riparian, and riverine habitats (NCRWQCB and Reclamation 2009; NCRWQCB et al. 2013). The annual grassland species include grasses (e.g., wild oat, soft brome, ripgut brome, cheatgrass, and barley); forbs (e.g., broadleaf filaree, California poppy, true clover, and bur clover); and native perennial species (e.g., creeping wildrye).

The annual grassland habitat supports mourning dove, savannah sparrow, white-crowned sparrow, American kestrel, red-tailed hawk, coyote, California ground squirrel, Botta's pocket gopher, California kangaroo rat, deer mouse, gopher snake, western fence lizard, western skink, western rattlesnake, and yellow-bellied racer.

The fresh emergent wetland species occur along the backwater areas, depressions, and along the river edges, including American tule, narrow-leaved cattail, dense sedge, perennial ryegrass, Himalayan blackberry, and narrow-leaved willow. Wildlife species along the fresh emergent wetland include western toad, Pacific chorus frog, bullfrog, green heron, mallard, and red-winged blackbird.

The montane riparian habitat adjacent to the river include trees, including bigleaf maple, white alder, Oregon ash, black cottonwood, and Goodding's black willow; and understory species, including mugwort, virgin's bower, American dogwood, Oregon golden-aster, dalmatian toadflax, white sweet clover, musk monkeyflower, straggly gooseberry, California grape, and California blackberry. The valley-foothill riparian habitat occurs along alluvial fans, slightly dissected terraces, and floodplains and includes cottonwood, California sycamore, valley oak, white alder, boxelder, Oregon ash, wild grape, wild rose, California blackberry, blue elderberry, poison oak, buttonbush, willow, sedge, rushes, grasses, and miner's lettuce. Riparian woodlands along the montane riparian habitat support breeding, foraging, and roosting habitat for tree swallow, bushtit, white-breasted nuthatch, Nuttall's woodpecker, downy woodpecker, spotted towhee, and song sparrow; cover for amphibians, including western toad and Pacific chorus frog; and habitat for deer mouse, raccoon, and Virginia opossum. The riverine habitat supports amphibians and reptiles, including western toad, Pacific chorus frog, bullfrog, and western pond turtle; birds, including mallard, great blue heron, osprey, and belted kingfisher; and mammals, including river otter, beaver, big brown bat, and Yuma myotis (bat).

The lands upslope of the Trinity River are characterized by mixed chaparral, montane hardwood-conifer, blue oak-foothill pine, foothill pine, and Klamath mixed conifer (NCRWQCB and Reclamation 2009; NCRWQCB et al. 2013). The trees include Pacific madrone, bigleaf maple, canyon live oak, black oak, blue oak, ponderosa pine, Douglas fir, and incense cedar. Shrubs include greenleaf manzanita, buckbrush, cascara, snowberry, and poison oak. Underlying herbaceous vegetation includes ripgut brome, blue wild rye, silver bush lupine, purple sanicle, and false hedge-parsley. The habitats support numerous birds, including northern flicker, Steller's jay, hairy woodpecker, acorn woodpecker, wrentit, Bewick's wren, California quail, mountain quail, blue grouse, sharp-shinned hawk, red-tailed hawk, and great horned owl; mammals, including black-tailed deer, gray fox, coyote, black-tailed jackrabbit, raccoon, Virginia opossum, spotted skunk, gray squirrel, Allen's chipmunk, deer mouse, and pallid bat; and reptiles and amphibians, including California kingsnake, western rattlesnake, sharp-tailed snake, western fence lizard, southern alligator lizard, and ensatina.

Inundation of lands by Trinity Lake, Lewiston Reservoir, and Whiskeytown Lake removed approximately 20,500 acres of habitat for an estimated 8,500 black-tailed deer (USFWS 1975). The California

Department of Fish and Wildlife (CDFW) established a deer herd management plan for the Critical Winter Range for the Weaverville deer herd. A portion of the winter range is located along the Trinity River (NCRWQCB and Reclamation 2009).

P.1.1.1.3 Lower Klamath River Watershed from Trinity River to the Pacific Ocean

The Klamath River from the confluence with the Trinity River to the Pacific Ocean is characterized by a forested river canyon with riparian vegetation occurring along the channel. There is a greater diversity of riparian vegetation along the lower Klamath River below the mouth of the Trinity River, partly as a result of a more natural hydrograph on the Klamath River than exists on the Trinity River. Plant species composition changes as the Klamath River nears the Pacific Ocean; because the river slows, temperatures increase, and the tides affect salinity.

Grazing, timber harvest, and roads have degraded riparian conditions along the lower Klamath River (Yurok Tribe 2000). Riparian areas are dominated by deciduous trees including red alder. Red alder is a typical hardwood in riparian zones, tanoak is a typical hardwood on mid to upper slopes, and Pacific madrone occurs in small stands on drier sites (Green Diamond Resource Company 2006).

The broad lower Klamath River meanders within the floodplain and supports wetland habitats similar to those that existed pre-dam along the Trinity River. Wetland habitats along the lower Klamath River are dominated by cattails, tules, and a variety of rushes and sedges. As the river nears the ocean, salt-tolerant plants such as cord grass and pickleweed increase in abundance as the salinity increases (USFWS et al. 1999). Wildlife species in the lower Klamath River watershed are similar to those found in the Trinity River watershed.

P.1.1.2 *Sacramento River*

Much of the Sacramento River from Shasta Dam to Redding is deeply entrenched in bedrock, which precludes development of extensive areas of riparian vegetation (Reclamation 2013). The upper banks along these steep-sided, bedrock-constrained segments of the upper Sacramento River are characterized primarily by upland communities, including woodlands and chaparral. Outside the river corridor, other vegetation communities along the upper Sacramento River include riparian scrub, annual grassland, and agricultural lands.

The river corridor between Redding and Red Bluff once supported extensive areas of riparian vegetation (Reclamation 2013). Agricultural and residential development has permanently removed much of the native and natural habitat. Riparian vegetation now occupies only a small portion of floodplains. Willow and blackberry scrub and cottonwood- and willow-dominated riparian communities are still present along active channels and on the lower flood terraces, whereas valley oak-dominated communities occur on higher flood terraces. Although riparian woodlands along the upper Sacramento River typically occur in narrow or discontinuous patches, they provide value for wildlife and support both common and special-status species of birds, mammals, reptiles, amphibians, and invertebrates.

Portions of the adjacent land along the Sacramento River from Red Bluff to Hamilton City include substantial remnants of the pre-European Sacramento Valley historical riparian forest (Reclamation 2013). Along the Sacramento River below Red Bluff, riparian vegetation is characterized by narrow linear stands of trees and shrubs, in single- to multiple-story canopies. These patches of riparian vegetation may be on or at the toe of levees. Riparian communities in this region include woodlands and riparian scrub.

From Red Bluff to Colusa, the Sacramento River contains point bars, islands, high and low terraces, instream woody cover, and early-successional riparian plant growth, reflecting river meander and erosional processes (Reclamation 2013). Major physiographic features include floodplains, basins, terraces, active and remnant channels, and oxbow sloughs. These features sustain a diverse riparian community and support a wide range of wildlife species including raptors, waterfowl, and migratory and resident avian species, plus a variety of mammals, amphibians, and reptiles that inhabit both aquatic and upland habitats.

Downstream of Colusa, the Sacramento River channel changes from a dynamic and active meandering one to a confined, narrow channel (Reclamation 2013). Surrounding agricultural lands encroach directly adjacent to the levees, which have cut the river off from most of its riparian corridor, especially on the eastern side of the river. Most of the levees in this reach are lined with riprap, allowing the river no erodible substrate and limiting the extent of riparian vegetation and riparian wildlife habitat.

P.1.1.3 *Clear Creek*

Riparian communities within the Whiskeytown Unit of the Whiskeytown-Shasta-Trinity National Recreation Area, which includes Whiskeytown Reservoir, include the following species: grey pine, willow, white alder, dogwoods, Oregon ash, bigleaf maple, and Fremont and black cottonwood. Wild grape is also very common; other riparian shrubs include snowberry, California blackberry, toyon, buckeye, and button willow. Flowering herbaceous plants, cattails, sedges, rushes, and ferns make up the riparian understory. The riparian habitats are generally vigorous and well-vegetated, especially in the most favorable locations, such as canyons and stream bottoms (National Park Service [NPS] 1999).

Riparian vegetation is limited to a narrow band along the channel margins in the confined canyon reaches of Clear Creek between Whiskeytown Dam and Clear Creek Bridge, where the alluvial section of the creek begins. Downstream of Clear Creek Bridge, where the valley widens, the channel becomes predominately alluvial, and floodplains and terraces allow riparian vegetation to be more extensive (California Bay-Delta Authority 2004).

Fresh emergent wetlands occur throughout the entire reach of lower Clear Creek from Whiskeytown Dam to the Sacramento River. These wetlands are more prominent in the reach below Clear Creek Road Bridge where soils are deeper and the valley becomes wider and is subject to periodic flooding. Valley-foothill riparian is found primarily in the lower reaches of lower Clear Creek from Clear Creek Road Bridge to the Sacramento River. In addition, smaller linear patches occur scattered throughout the system up to Whiskeytown Dam (U.S. Bureau of Land Management [BLM] and NPS 2008).

Due to the diversity of habitats present within the watershed, the areas adjacent to Whiskeytown Lake and lower Clear Creek support a diverse assemblage of wildlife species. More than 200 vertebrate species are known to occur within the Whiskeytown Unit of the Whiskeytown-Shasta-Trinity National Recreation Area, including at least 35 mammal species, 150 bird species, and 25 reptile and amphibian species (NPS 2014).

P.1.1.4 *Feather River*

P.1.1.4.1 Upper Feather River Lakes

The Upper Feather River lakes, including Antelope Lake, Lake Davis, and Frenchman Lake, are State Water Project (SWP) facilities on the upper Feather River upstream of Lake Oroville. These lakes are part of the Plumas National Forest and provide habitat for raptor nesting and wintering areas, waterfowl nesting area, and deer movement area (California Department of Water Resources [DWR] 2013; Plumas County 2012). Deer movement and fawning areas also occur around Lake Davis.

P.1.1.4.2 Lake Oroville and Thermalito Complex

Lake Oroville is situated in the foothills on the western slope of the Sierra Nevada Mountains, about a mile downstream of the confluence of its major tributaries. Below the dam, a portion of the river flow is diverted at the Thermalito Diversion Dam and routed to the Thermalito Forebay, which is an offstream reservoir with a surface area up to 630 acres (DWR 2007a, 2007b). Downstream of the forebay, water is stored in Thermalito Afterbay (up to 4,300 surface acres), which among other purposes serves as a warming basin for agricultural water.

The majority of vegetation around Lake Oroville consists of a variety of native vegetation associations, including mixed oak woodlands, foothill pine/mixed oak woodlands, and oak/pine woodlands with a mosaic of chaparral (DWR 2004, 2007a). Open areas within the woodlands consist of annual grassland species. Native riparian habitats are restricted to narrow strips along tributaries, consisting mostly of alder, willow, and occasional cottonwood and sycamore. There is minimum wetland vegetation around Lake Oroville, and most is associated with seeps and springs that are a natural part of the landscape above the high-water line. Emergent wetlands are generally absent within the drawdown zone of Lake Oroville.

Lack of vegetative cover within the drawdown zone severely limits wildlife use of this area. Thirty-six wildlife species were detected using habitats within the drawdown zone on at least one occasion during field surveys (DWR 2004). Several of these species may use habitats within the drawdown zone for reproduction including belted kingfisher, Canada goose, canyon wren, American dipper, killdeer, mallard, common merganser, and northern rough-winged swallow.

Riparian vegetation occurs around the north shore of Thermalito Forebay as a thin strip of mixed riparian species (mostly willows), with an understory of emergent wetland vegetation. Cottonwoods and willows occur in scattered areas around the high water surface elevation of Thermalito Afterbay shoreline (Federal Energy Regulatory Commission 2007). Emergent wetlands ranging from thin strips to more extensive areas are found around Thermalito Forebay and Thermalito Afterbay. Waterfowl brood ponds constructed in inlets of Thermalito Afterbay support emergent vegetation along much of their shores.

Species observed within the wetland margin of Thermalito Afterbay include barn swallow, black phoebe, white-tailed kite, black-tailed jackrabbit, brown-headed cowbird, bullfrog, common garter snake, common yellowthroat, gopher snake, northern harrier, Pacific tree frog, raccoon, red-winged blackbird, ring-necked pheasant, short-eared owl, striped skunk, tree swallow, Virginia opossum, and violet-green swallow (DWR 2004).

In contrast to the drawdown area around the margin of Lake Oroville, the drawdown zone of Thermalito Afterbay supports a richer wildlife community and greater habitat diversity. Survey data collected as part of the relicensing process indicate that exposed mudflats seasonally provide habitat for a variety of migratory waterbirds including black-necked stilt, black tern, California gull, Caspian tern, Forster’s tern, greater yellowlegs, least sandpiper, long-billed dowitcher, ring-billed gull, semipalmated sandpiper, spotted sandpiper, and white-faced ibis. Wading birds and other waterfowl have been observed on the mudflats as well as shallow flooded areas (DWR 2004). Potentially suitable giant garter snake habitat is present along portions of the afterbay and forebay margins. The existing waterfowl brood ponds provide a refuge for giant garter snakes during periods of afterbay drawdown.

Several invasive plant species are found around Lake Oroville and downstream in and around the Thermalito Complex. Invasive species associated with riparian and wetland areas include purple loosestrife, giant reed, tree-of-heaven, and red sesbania. About 85 of the roughly 900 acres of wetlands and riparian areas along the margin of Thermalito Afterbay contain varying densities of purple loosestrife (DWR 2007a). Purple loosestrife adversely affects native vegetation.

P.1.1.4.3 <u>Feather River from Oroville Complex to the Sacramento River</u>

The Feather River from Oroville Dam to the confluence with the Sacramento River supports stands of riparian vegetation, which have been restricted over time by flood control levees and land clearing for agriculture and urbanization. As a consequence, the vegetation generally occurs in a narrow zone along much of the river in this reach. However, remnant riparian forest exists in areas where wide meander bends persist, such as at Abbott Lake and O'Connor Lake near the Lake of the Woods State Recreation Area. This area contains mixed riparian forests, including Fremont cottonwood, willow, boxelder, alder, and Oregon ash. The riparian strip along the river is bordered mostly by agricultural fields. Downstream of Yuba City near the confluence with the Sacramento River, valley oak and cottonwood riparian stands becomes more common. Riparian areas provide value for wildlife and support a wide range of species of birds, mammals, reptiles, amphibians, and invertebrates.

P.1.1.5 *American River*

Downstream of Lake Natoma, the lower American River flows to the confluence with the Sacramento River. In the upper reaches of the lower American River, the river channel is controlled by natural bluffs and terraces. Levees have been constructed along the northern and southern banks for approximately 13 miles upstream of the confluence with the Sacramento River (Reclamation et al. 2006).

Most of the lower American River is encompassed by the American River Parkway, which preserves what remains of the historic riparian zone (Reclamation et al. 2006). Vegetation communities along the lower American River downstream of Nimbus Dam include freshwater emergent wetland, riparian forest, and scrub. Oak woodland and annual grassland are present in the upper, drier areas farther away from the river. The current distribution and structure of riparian communities along the river reflects the human-induced changes caused by activities such as gravel extraction, dam construction and operations, and levee construction and maintenance, as well as by both historical and ongoing streamflow and sediment regimes, and channel dynamics.

In general, willow and alder tend to occupy areas within the active channel of the river that are repeatedly disturbed by river flows, with cottonwood-willow thickets occupying the narrow belts along the active river channel (Reclamation et al. 2006). Typical species in these thickets include Fremont cottonwood, willow, poison oak, wild grape, blackberry, northern California black walnut, and white alder.

Cottonwood forest is found on the steep, moist banks along much of the river corridor (Reclamation et al. 2006). Valley oak woodlands occur on upper terraces where fine sediment and adequate soil moisture provide a long growing season. Live oak woodland occurs on the more arid and gravelly terraces that are isolated from the fluvial dynamics and moisture of the river. Annual grassland occurs in areas that have been disturbed by human activity and can be found in many areas within the river corridor.

The cottonwood-dominated riparian forest and areas associated with backwater and off-river ponds are highest in wildlife diversity and species richness relative to other river corridor habitats (Reclamation et al. 2006). More than 220 species of birds have been recorded along the lower American River and more than 60 species are known to nest in the riparian habitats. Typical species that can be found along the river include great blue heron, mallard, red-tailed hawk, American kestrel, California quail, killdeer, belted kingfisher, western scrub jay, swallows, and American robin. Additionally, more than 30 species of mammals reside along the river, including skunk, rabbit, raccoon, squirrel, vole, muskrat, deer, fox, and coyote. Reptiles and amphibians that occupy riparian habitats along the river include western toad, Pacific tree frog, bullfrog, western pond turtle, western fence lizard, common garter snake, and gopher snake (Reclamation 2005a).

Backwater areas and off-river ponds are located throughout the length of the river, but occur predominantly at the Sacramento Bar, Arden Bar, Rossmoor Bar, and between Watt Avenue and Howe Avenue (Reclamation 2005a; Reclamation et al. 2006). Plant species that dominate these backwater areas include various species of willow, sedge, cattail, bulrush, and rush. Riparian vegetation around these ponded areas is composed of mixed-age willow, alder, and cottonwood. These backwater ponds may be connected to the river by surface water during high winter flood flows and by groundwater during other times of the year. Wildlife species typical of these areas include pied-billed grebe, American bittern, green heron, common merganser, white-tailed kite, wood duck, yellow warbler, warbling vireo, dusky-footed woodrat, western gray squirrel, Pacific tree frog, and western toad.

Several non-native weed populations are rapidly expanding in the riparian vegetation of the lower American River (County of Sacramento 2008). In particular, red sesbania is expanding along shorelines of streams and ponds, along with other invasive species such as Chinese tallowtree, giant reed, pampasgrass, Spanish broom, Himalayan blackberry, and tamarisk, which can rapidly colonize exposed bar surfaces and stream banks.

P.1.1.6 *Stanislaus River*

Near the Stanislaus River, vegetation is characterized by riparian woodland with cottonwood, willows, white alder, blue elderberry, and Himalayan berry. Some low-gradient areas along the shoreline of Goodwin Lake, especially in coves, support small patches of emergent aquatic vegetation such as bulrush and cattail (Goodwin Power 2013). Wildlife occurrences are similar to conditions near Tulloch Reservoir.

From Goodwin Dam to Knight’s Ferry, the Stanislaus River flows through a bedrock canyon with nearly vertical walls and rock outcrops (California Department of Fish and Game [CDFG] 1995). The riparian edge includes valley foothill riparian vegetation in a very narrow band for the entire length of this reach. This habitat is characterized by a canopy layer of cottonwood, California sycamore, and valley oak. Subcanopy cover trees are white alder, boxelder, and Oregon ash. Typical understory shrub layer plants include wild grape, wild rose, California blackberry, elderberry, button brush, and willow. The herbaceous layer consists of sedges, rushes, grasses, miner’s lettuce, poison-hemlock, and stinging nettle.

From Knight’s Ferry to the Orange Blossom Bridge, located to the east of the City of Oakdale, the valley foothill riparian habitat continues along the river (CDFG 1995). Further away from the river, vegetation is dominated by blue oak-digger pine woodland and shrub, including California redbud, California buckeye, ceanothus, manzanita, poison oak, and grasslands. Vernal pools and vernal pool complexes are found within adjacent grasslands.

Downstream of the Orange Blossom Bridge, the riparian corridor is virtually nonexistent in some areas with agricultural land uses extending into the riparian corridor (CDFG 1995). In a few areas the riparian corridor is wide, such as within Caswell Memorial State Park. The major habitats include valley foothill riparian along the Stanislaus River with annual grasslands and fresh emergent wetlands among the agricultural and urban developments.

P.1.1.7 *San Joaquin River*

A multilayered riparian forest dominated by cottonwoods occurs on the active low floodplain of the San Joaquin River along with older stands of cottonwood-dominated riparian forest in areas that were formerly active floodplains prior to the completion of Friant Dam and associated diversion channels, and the resulting reduction in river flow (DWR and Reclamation 2002; Reclamation and DWR 2011). Other areas on the low floodplain are dominated by willow, with occasional scattered cottonwood, ash, or white alder. California buttonbush is often present and may even dominate the river bank for stretches.

The intermediate terrace of the floodplain of the San Joaquin River is primarily a mixed-species riparian forest (DWR and Reclamation 2002; Reclamation and DWR 2011). Species dominance in this mixed riparian forest depends on site conditions, such as availability of groundwater and frequency of flooding. Typical dominant trees in the overstory and midstory include Fremont cottonwood, boxelder, Goodding’s black willow, Oregon ash, and California sycamore. Immediately along the water’s edge, white alder occurs in the upper reaches of the San Joaquin River. Typical shrubs include red willow, arroyo willow, and California buttonbush.

Tree-dominated habitats with an open-to-closed canopy are typically found on the higher portions of the floodplain (DWR and Reclamation 2002; Reclamation and DWR 2011). These areas are exposed to less flood-related disturbance than areas lower on the floodplain. Valley oak is the dominant tree species while California sycamore, Oregon ash, and Fremont cottonwood are present in small numbers. Typical understory species include creeping wild rye, California wild rose, Himalayan blackberry, California wild grape, and California blackberry.

Dense stands of willow shrubs frequently occur within the active floodplain of the river in areas subject to more frequent scouring flows and often occupy stable sand and gravel point bars immediately above the active channel (DWR and Reclamation 2002; Reclamation and DWR 2011). Dominant species include sandbar willow, arroyo willow, and red willow. Occasional emergent Fremont cottonwood may also be present.

Other areas have vegetation consisting of woody shrubs and herbaceous species dominated by different species depending on river reach. Some areas are dominated by mugwort, together with stinging nettle and various tall weedy herbs. Other areas are dominated either by blackberry (usually the introduced Himalayan blackberry) or wild rose in dense thickets, with or without scattered small emergent willows.

Areas with fine-textured, rich alluvium located outside the active channels but in areas that are subject to periodic flooding contain a shrub-dominated community characterized by widely spaced blue elderberry shrubs (DWR and Reclamation 2002; Reclamation and DWR 2011). The herbaceous understory is typically dominated by nonnative grasses and forbs that are characteristic of annual grassland communities, including ripgut brome, foxtail fescue, foxtail barley, red-stemmed filaree, and horseweed.

Emergent wetlands typically occur in the river bottom immediately adjacent to the low-flow channel (DWR and Reclamation 2002; Reclamation and DWR 2011). Backwaters and sloughs where water is present through much of the year support emergent marsh vegetation, such as tule and cattails. More ephemeral wetlands, especially along the margins of the river and in swales adjacent to the river, support native and nonnative herbaceous species.

Prevalent invasive species found in this portion of the San Joaquin River corridor include red sesbania, tamarisk, giant reed, Chinese tallow, tree-of-heaven, and perennial pepperweed (Reclamation and DWR 2011). Water hyacinth, water milfoil, parrot's feather, curly-leaf pondweed, and sponge plant occur within the streams, especially in areas with slow or ponded water.

The riparian forest trees and understory provide habitat for raptors, cavity-nesting birds, and songbirds, including red-tailed hawk, red-shouldered hawk, Swainson's hawk, white-tailed kite, downy woodpecker, wood duck, northern flicker, ash-throated flycatcher, Pacific-slope flycatcher, olive sided flycatcher, tree swallow, oak titmouse, white-breasted nuthatch, western wood-pewee, warbling vireo, orange-crowned warbler, yellow warbler, Bullock's oriole, and spotted towhee (DWR and Reclamation 2002; Reclamation and DWR 2011). Western wood-pewee, bushtit, Bewick's wren, lazuli bunting, blue grosbeak, and American goldfinch inhabit the riparian scrub vegetation. Song sparrow, common yellowthroat, marsh wren, and red-winged blackbird inhabit the emergent wetlands. Coyote, river otter, raccoon, desert cottontail, and striped skunk occur in the riparian forest and shrub communities. Killdeer, mallard duck, California vole, common muskrat, Norway rat, Pacific chorus frog, western pond turtle, and western terrestrial garter snake occur near the river.

The reach of the San Joaquin River immediately downstream of the Merced River is more incised than areas further downstream and has a less developed riparian area with less understory vegetation. Between the Merced River and the Delta, agricultural land use has encroached on the riparian areas, leaving only a narrow band of riparian habitat. Near the confluence with tributary rivers, in cutoff oxbows, and in the San Joaquin River National Wildlife Refuge (NWR), there are more extensive riparian habitat areas. Remnant cattail-dominated marshes and tules occur in these areas.

P.1.1.8 *Bay-Delta*

P.1.1.8.1 Delta and Suisun Marsh

The Delta overlies the western portions of the Sacramento River and San Joaquin River watersheds. The Delta is a network of islands, channels, and marshland at the confluence of the Sacramento and San Joaquin Rivers. Major rivers entering the Delta are the Sacramento River flowing from the north, the San Joaquin River flowing from the south, and eastside tributaries (Cosumnes, Mokelumne, and Calaveras Rivers). Suisun Marsh is a tidally influenced brackish marsh located about 35 miles northeast of San Francisco in southern Solano County. It is a critical part of the San Francisco Bay/Sacramento–San Joaquin Delta (Bay-Delta) estuary ecosystem. The Delta, together with Suisun Marsh and greater San Francisco Bay, make up the largest estuary on the west coast of North and South America (DWR 2009).

The Delta was once composed of extensive freshwater and brackish marshes, with tules and cattails, broad riparian thickets of scrub willows, buttonwillow, and native brambles. In addition, there were extensive riparian forests of Fremont cottonwood, valley oak, Oregon ash, boxelder, white alder, and Goodding's black willow. Upland, non-riparian stands of valley oak and coast live oak occurred in a mosaic with seasonally flooded herbaceous vegetation, including vernal pools and alkali wetlands (San Francisco Estuary Institute—Aquatic Science Center [SFEI] 2012).

Substantial areas of the Delta and Suisun Marsh have been modified by agricultural, urban and suburban, and recreational land uses (Reclamation et al. 2011; SFEI 2012). Over the past 150 years, levees were constructed in the Delta and Suisun Marsh to provide lands for agricultural, municipal, industrial, and recreational land uses. The remaining natural vegetation is fragmented, and largely restricted to the edges of waterways, flooded islands, and small protected areas such as parks, wildlife areas, and nature reserves

(Hickson and Keeler-Wolf 2007). A substantial portion of the emergent wetlands exists as thin strips along the margins of constructed levees (SFEI 2012). Current habitat along the Delta waterways includes seasonal wetlands, tidal wetlands, managed wetlands, riparian forests, and riparian scrub.

Seasonal wetlands historically had occurred along the riparian corridor at elevations that were inundated during high flow events. Many of the levees were constructed along the riparian corridor edges; therefore, historic seasonal wetlands were substantially modified (SFEI 2012). Adjacent areas of perennial wetlands on the water-side of the riparian corridor were modified as levees were constructed and channels enlarged. In many of these areas the perennial wetlands were replaced by seasonal wetlands. The vegetation of seasonal wetlands is typically composed of wetland generalist species that occur in frequently disturbed sites such as hyssop loosestrife, cocklebur, dallisgrass, Bermuda grass, barnyard grass, and Italian ryegrass.

Alkali-related habitats occur near salt-influenced seasonal and perennial wetlands. Alkali seasonal wetlands occur on fine-textured soils that contain relatively high concentrations of dissolved salts. These types of soils are typically found at the historical locations of seasonal ponds in the Yolo Basin in and around the CDFW Tule Ranch Preserve, and upland in seasonal drainages that receive salts in runoff from upslope salt-bearing bedrock such as areas near Suisun Marsh and the Clifton Court Forebay. Alkali wetlands include saltgrass, alkali weed, saltbush, alkali heath, and iodine bush. Small stands of alkali sink scrub (also known as valley sink scrub) are characterized by iodine bush.

Tidal wetlands consist of tidal brackish wetlands that occur either as relatively substantial tracts of complex tidal wetlands, or in narrow bands of fringing tidal wetlands (Siegel et al. 2010a). Fringing tidal marsh exists along the outboard side exterior levees and generally has formed since diking for managed wetlands began. Fringing tidal wetlands vary in size and vegetation composition, exhibit less geomorphic complexity, and have a low area-to-edge ratio. Fringing marshes lack connection with the upland transition, are often found in small, discontinuous segments, and can limit movement of terrestrial marsh species.

Plant zones in complex tidal wetlands are influenced by inundation regime and salinity. Tidal wetlands can be divided into three zones: low marsh, middle marsh, and high marsh (Reclamation et al. 2011). The low tidal wetland zone is tidally inundated once or twice per day. At the lowest elevations, vegetation is inhibited by frequent, prolonged, often deep inundation and by disturbance by waves or currents. The dominant plant species are bulrushes. Other species occurring in the low tidal wetland zone are pickleweed, lowclub rush, common reed, and cattails. The low tidal wetland zone provides foraging habitat for waterfowl and shorebirds, California Ridgway's rail, California black rail, and other wading birds.

The middle tidal wetland zone is tidally inundated at least once per day; there is relatively little cover and no refuge from higher tides, which completely flood the vegetation of the middle marsh. The dominant plant species are pickleweed, saltgrass, and bulrush. Other species occurring in the middle tidal marsh are fleshy jaumea, sea milkwort, rushes, salt marsh dodder, alkali heath, cattail, sneezeweed, and marsh gumplant (Siegel et al. 2010b). The middle tidal wetland zone provides foraging habitat for salt marsh harvest mouse and Suisun shrew, as well as common and special-status bird species, including waterfowl and shorebirds, California Ridgway's rail, California black rail, and other wading birds. This zone also provides nesting and foraging habitat for Suisun song sparrow and salt marsh common yellowthroat (Reclamation et al. 2011).

The high tidal wetland zone receives intermittent inundation during the monthly tidal cycle, with the higher elevations being inundated during only the highest tides. Historically, the high marsh was an expansive transitional zone between the tidal wetlands and adjacent uplands. The high marsh and associated upland transition zone have been affected by land use changes (e.g., managed wetlands, agriculture). The dominant plants are native species, such as saltgrass, pickleweed, and Baltic rush, and nonnative species, including perennial pepperweed, poison hemlock, and fennel. Other species occurring in the high tidal marsh are saltmarsh dodder, fleshy jaumea, seaside arrowgrass, alkali heath, brass button, and rabbitsfoot grass.

The high tidal marsh provides habitat for special-status plants, including Suisun marsh aster, soft bird's beak, and Suisun thistle (Siegel et al. 2010b). The high marsh zone provides foraging and nesting habitat for waterfowl, shorebirds, California Ridgway's rail, California black rail, and other birds. It also provides foraging and nesting habitat for special-status species such as salt marsh harvest mouse and Suisun shrew, and provides escape cover for salt marsh harvest mouse and Suisun shrew during periods when the middle and lower portions of the high tidal wetland zone are inundated (Reclamation et al. 2011).

Managed wetlands are primarily located within the Suisun Marsh, Cache Slough, and near the confluence of the Mokelumne and Sacramento Rivers within the historical limits of the high tidal marsh and adjacent uplands that were diked and leveled for agricultural purposes and later managed to enhance habitat values for specific wildlife species (CALFED Bay-Delta Program [CALFED] 2000). Diked managed wetlands and uplands are the most typical land cover type in the Suisun Marsh area. Managed wetlands are considered seasonal wetlands because they may be flooded and drained several times throughout the year. Watergrass and smartweed are typically the dominant species in managed wetlands that use fresher water. Bulrush, cattail, and tule are the dominant species in managed wetlands that employ late drawdown management. Pickleweed, fat hen, and brass buttons are typical in the higher elevations of the managed wetlands. In marshes with higher soil salinity, pickleweed, saltgrass, and other salt-tolerant species are dominant. Managed wetlands are managed specifically as habitat for wintering waterfowl species, including northern pintail, mallard, American wigeon, green-winged teal, northern shoveler, gadwall, cinnamon teal, ruddy duck, canvasback duck, white-fronted goose, and Canada goose. Some wetlands are also managed for breeding waterfowl, especially mallard.

Riparian forest areas are still present in some portions of the Delta along many of the major and minor waterways, oxbows, and levees (CALFED 2000). Riparian forest and woodland communities dominated by tree species are mostly limited to narrow bands along sloughs, channels, rivers, and other freshwater features throughout the Delta. Isolated patches of riparian vegetation are also found on the interior of reclaimed Delta islands, along drainage channels, along pond margins, and in abandoned, low-lying fields. Cottonwoods and willows, Oregon ash, boxelder, and California sycamore, are the most typical riparian trees in central California. Valley oak and black walnut are typical in riparian areas in the Delta. Riparian trees are used for nesting, foraging, and protective cover by many bird species and riparian canopies provide nesting and foraging habitat for a variety of mammals. Understory shrubs provide cover for ground-nesting birds that forage among the vegetation and leaf litter.

Riparian scrub in the Delta and Suisun Marsh consists of woody riparian shrubs in dense thickets (SFEI 2012). Riparian scrub thickets are usually associated with higher, sloping, better drained edges of marshes or topographic high areas, such as levee remnants and elevated flood deposits, and along shorelines of ponds or banks of channels in tidal or non-tidal freshwater habitats. Plant species may include willow, blackberry, buttonbush, mule fat, and other shrub species. Willow-dominated habitat types appear to be increasing in extent in recent years; willows line many miles of artificial levees where waterways historically had flowed into freshwater emergent wetland. Nonnative Himalayan blackberry thickets are a typical element of riparian scrub communities along levees and throughout pastures in the levees. Willow thickets provide habitat for a wide range of wildlife species, including the song sparrow, lazuli bunting, and valley elderberry longhorn beetle.

P.1.1.8.2 Yolo Bypass

The Yolo Bypass is a 59,280-acre floodway through the natural-overflow of the Yolo Basin on the west side of the Sacramento River (DWR 2012). The Yolo Bypass generally extends north to south from Fremont Weir along the Sacramento River (near Verona) to upstream of Rio Vista along the Sacramento River in the Delta. The bypass, part of the Sacramento River Flood Control Project, conveys floodwaters around the Sacramento River near the cities of Sacramento and West Sacramento. The bypass is utilized as a flood bypass approximately once every 3 years, generally during the period from November to April. Land use in the Yolo Bypass is generally restricted to specific agriculture, managed wetlands, and vegetation communities to ensure that floodway function is maintained (CALFED et al. 2001; USFWS 2002). Agricultural crops include corn, tomatoes, melons, safflower, and rice within the northern bypass; and corn, milo, safflower, beans, tomatoes, and Sudan grass in the southern bypass. Waterfowl hunting areas are generally located in the southern bypass, and include rice fields, permanent open water, or a mixture of water and upland habitat. The U.S. Army Corps of Engineers (USACE) has developed criteria for managing emergent vegetation (e.g., cattails and bulrushes) in the Yolo Bypass to maintain flood capacity, including no more than 5% of the vegetation in seasonal wetlands can be emergent wetlands; no more than 50% of the vegetation in permanent wetlands can be emergent wetlands; and riparian vegetation can only occur in specified areas to maintain flood capacity (CDFG and Yolo Basin Foundation 2008).

The Yolo Bypass supports several major terrestrial vegetation types, including riparian woodland, valley oak woodland, open water, and wetland. Historically, riparian woodland and freshwater wetland were the dominant habitat types in the Yolo Basin (CALFED et al. 2001; USFWS 2002). Currently, riparian woodland and associated riparian scrub habitats are primarily found adjacent to Green’s Lake, Putah Creek, and along the East Toe Drain within the Yolo Bypass Wildlife Area. Riparian woodland is a tree-dominated community found adjacent to riparian scrub on older river terraces which have lower flooding frequency and duration. Riparian woodlands include Fremont cottonwood, valley oak, sycamore, willow, eucalyptus, giant reed, and black oak. The understory is typically sparse in this community with limited areas of California grape, blackberry, poison oak, mugwort, grasses, and forbs. The woodland canopy provides habitat for hawks, owls, American crow, great egret, great blue heron, red-tailed kite, yellow-rumped warbler, black phoebe, various woodpecker species, wood duck, bat species, and raccoon. The Yolo Bypass also includes riparian scrub, a shrub-dominated community described above for the Delta/Suisun Marsh area.

Remnants of valley oak woodlands and savanna occur on floodplain terraces in fragmented areas, including downstream of Fremont Weir and along the southern portion of the Toe Drain (CALFED et al. 2001). The habitat also includes sycamore, black walnut, wild grape, poison oak, elderberry, blackberry, grass, and sedge.

Depending on the duration of inundation, local soil factors, site history, and other characteristics, seasonal wetlands typically are dominated by species characteristic of one of three natural wetland communities: freshwater marshes, alkali marshes, or freshwater seasonal (often disturbed) wetlands (CALFED et al. 2001). Freshwater marsh communities are typically found in areas subjected to prolonged flooding during the winter months, and frequently do not dry down until early summer. Permanent open water is found throughout the Yolo Bypass, including Gray's Bend near Fremont Weir, Green's Lake near Interstate 80, ponds in the Yolo Bypass Wildlife Area, along Cache and Prospect sloughs, and within canals and drainage ditches. The wetlands support duck breeding habitat and habitat for many lifestages of grebe, ibis, heron, egret, bittern, coot, rails, raptors, muskrat, raccoon, opossum, beaver, ring-necked pheasant, garter snake, Pacific tree frog, and bullfrog.

Managed wetlands in the Yolo Bypass occur near Fremont Weir, in the 16,770 acre Yolo Bypass Wildlife Area, and within and near Cache Slough. The managed wetlands are generally flooded in the fall, with standing water maintained continuously throughout the winter until drawdown occurs in the following spring (CALFED et al. 2001; CDFG and Yolo Basin Foundation 2008). A primary objective of seasonal wetland management is to provide an abundance and diversity of seeds, aquatic invertebrates, and other foods for wintering waterfowl and other wildlife. The wetlands also are managed to control the extent of tules and cattails, and more recently, water hyacinth. A portion of the managed wetlands occur within rice fields which are flooded in the winter to provide waterfowl feeding and resting habitats. A variety of annual plants germinate on the exposed mudflats of seasonal wetlands during the spring draw down, including swamp timothy, watergrass, smartweed, and cocklebur. These plants are then managed through the timing, duration, or absence of summer irrigation. The mudflats support sandpiper, plover, avocet, stilt, and other shorebirds.

Managed semi-permanent wetlands, commonly referred to as "brood ponds," are flooded during the spring and summer, but may experience a 2- to 6-month dry period each year. These semi-permanent wetlands provide breeding ducks, ducklings, and other wetland wildlife with protection from predators and abundant invertebrate food supplies (CDFG and Yolo Basin Foundation 2008). Permanent wetlands remain flooded throughout the year. Due to year-round flooding, permanent wetlands support a diverse, but usually not abundant, population of invertebrates. Permanent managed wetlands provide deep water habitat for diving ducks, such as ruddy duck, scaup, and goldeneye, and other water birds, including pied-billed grebe, coot, and moorhen. They often have dense emergent cover on their edges that is the preferred breeding habitat for marsh wren and red-winged blackbird, and roosting habitat for black-crowned night heron, white-faced ibis, and egret.

The managed wetlands are operated by private hunting clubs; private conservation entities, including conservation banks; and the federal and state governments (CALFED et al. 2001). Some of the hunting clubs have implemented wetland management agreements with CDFW under the state Presley Program or Wetland Easement Program to coordinate the timing and patterns of flooding, drawdowns, irrigation, soil disturbance, and maintenance of brood habitat. The patterns may be adjusted annually to respond to specific wildlife and hydrologic needs. A similar program focused on providing spring habitat for breeding is provided by the federal Waterbank Program.

Habitat in the Yolo Bypass is affected by periodic flooding (CALFED et al. 2001). Following a flood, roads, canals, and ditches may need to be excavated; debris needs to be removed from habitat; and water delivery facilities may need to be repaired. Flooding also disrupts nesting and resting activities of birds.

P.1.1.8.3 Central Valley Project Reservoirs

The Central Valley Project (CVP) reservoirs in the Bay-Delta include Contra Loma and San Justo reservoirs.

Contra Loma Reservoir

The Contra Loma Reservoir is a CVP facility in Contra Costa County that provides offstream storage along the Contra Costa Canal. The 80-acre reservoir is part of 661-acre Contra Loma Regional Park and Antioch Community Park (Reclamation 2014). The Contra Loma Reservoir area includes open space and recreation facilities. In the open space, vegetative communities include grasslands, blue oak woodland, valley foothill riparian, fresh emergent wetlands, riverine, and open water communities. The annual grasslands include smooth brome, slender wild oats, Italian ryegrass, yellow star thistle, white-stem filaree, and mouse-ear chickweed. Valley foothill riparian occurs along intermittent streams and includes valley oaks, cottonwoods, red willows, Himalayan blackberry, poison oak, and mule fat. The riverine and fresh emergent wetland communities include ryegrass, curly dock, hyssop, loosestrife, Baltic rush, flowering quillwort, cattails, rushes, dallis grass, nutsedge, and cocklebur. Watermilfoil occurs along portions of the shoreline. Recreation areas include urban trees with Oregon ash, black walnut, Fremont cottonwood, blue oak, valley oak, interior live oak, fig, and eucalyptus. East Bay Regional Parks District has initiated restoration actions to improve native grasslands and riparian and provide habitat for quail.

Wildlife in the grasslands areas includes burrowing owl, horned lark, western meadowlark, turkey vulture, northern harrier, American kestrel, white-tailed kite, red-tailed hawk, Brewer’s blackbird, mourning dove, western fence lizard, common garter snake, western rattlesnake, black-tailed jackrabbit, California ground squirrel, Botta’s pocket gopher, western harvest mouse, California vole, American badger, mule deer, and coyote (Reclamation 2014). The valley foothill riparian and blue oak woodland vegetation support a wide range of birds including northern flicker, yellow warbler, acorn woodpeckers, western scrub jay, white-tailed kite, Cooper’s hawk, red-shouldered hawk, American kestrel, great horned owl, song sparrow, black phoebe, European starling, western bluebird, and tree swallow. The valley foothill riparian and blue oak woodland vegetation also support Pacific tree frog, red-legged frog, sharp-tailed snake, California alligator lizard, common garter snake, mule deer, raccoon, coyote, striped skunk, deer mouse, harvest mouse, dusky-footed woodrat, and gray fox. Riverine, wetlands, and open water support Brewer’s blackbird, red-winged blackbird, brown-headed cowbird, great blue heron, great egret, duck species, American coot, common merganser, double-crested cormorant, American wigeon, Canada goose, western grebe, and gull species; Pacific tree frog, red-legged frog, bullfrog, California tiger salamander, western pond turtle, western toad, and garter snakes; deer mouse, California vole, long-tailed weasel, and other mammals that use the adjacent woodlands and grasslands.

San Justo Reservoir

The San Justo Reservoir is a CVP facility in San Benito County that provides offstream storage as part of the San Felipe Division. The reservoir is surrounded by steep hills with recreational facilities on the northeast side reservoir and intermittent streams, wetlands, and open water downslope of the reservoir (San Benito County Water District 2012). Adjacent land uses are dominated by irrigated row crops, orchards, and rangeland. Vegetation and wildlife resources of the reservoir area are consistent with grasslands vegetation on uplands.

P.1.1.8.4 <u>State Water Project Reservoirs</u>

Bethany Reservoir, Patterson Reservoir, and Lake Del Valle are SWP facilities associated with the South Bay Aqueduct in Alameda County.

Vegetative communities around Bethany Reservoir are characterized by nonnative grasses with several areas of woodland habitat (DWR 2014). The grassland habitat includes slender oat, ripgut brome, soft chess, wild barley, Italian ryegrass, black mustard, bull thistle, redstem filaree, dissected geranium, English plantain, tumble mustard, and forbs, including sweet fennel, Great Valley gumweed, Mediterranean linseed, and Ithuriel's spear. The woodland habitat includes white ironbark, casuarina, and Bishop pine. Coyote bush occurs along the water edge. The grasslands provide habitat for mourning dove, western scrub-jay, finch species, sparrow species, owl species, hawk species, California ground squirrel, black-tailed jackrabbit, Audubon's cottontail, Botta's pocket gopher, California vole, mice, and various species of frogs, toads, salamanders, snakes, lizards, and turtles. The woodlands support red-tailed hawk, osprey, owl species, black phoebe, Bullock's oriole, yellow warbler, coyote, and various species of amphibians and reptiles. Emergent vegetation does not occur along the shoreline at Bethany Reservoir (DWR 2005).

Patterson Reservoir is a small, 100-acre-foot, SWP reservoir located along the South Bay Aqueduct between Bethany Reservoir and Lake Del Valle. Vegetation around Patterson Reservoir is characterized by grasslands and upland habitat. Red-legged frog has been observed in the vicinity of Patterson Reservoir (DWR 2014).

Lake Del Valle is a 77,100 acre-foot SWP facility located along the South Bay Aqueduct (DWR 2016). Vegetation around Lake Del Valle includes grasslands, chaparral, shrub, oak woodland, and riparian and freshwater habitats (East Bay Regional Park District [EBRPD] 1996, 2001, 2012, 2013). The grasslands include nonnative grasses and native perennial bunchgrass. The nonnative grasslands include grasses, such as wild oats, bromes, ryegrass, wild barley, silver hairgrass, and dogtail grass; forbs, including filaree, clover, and plantain; and lupine, yarrow, and soap plant. Native grasses include annual and perennial fescues, needlegrass, wild ryes, junegrass, and California bromegrass. The coastal scrub and chaparral vegetation includes coyote brush-scrub, California sagebrush, manzanita, black sage, cream bush, California coffeeberry, yerba santa, blackberry, bush monkeyflower, and poison oak. The oak woodlands and riparian woodlands include coast live oak, black oak, valley oak, scrub oak, California bay, and California buckeye. Mixed deciduous riparian woodlands occur along perennial streams, including white alder, big-leaf maple, western sycamore, willow, and Fremont cottonwood. Along springs and seeps, the vegetation includes rabbitsfoot grass, saltgrass, bentgrasses, rushes, tules, sedges, horsetails, cattail, buttercup, brass-button, mint, duckweed, pondweed, and ferns.

Contra Costa Water District Los Vaqueros Reservoir

Los Vaqueros Reservoir is a Contra Costa Water District offstream storage facility in Contra Costa County. The area around the Los Vaqueros reservoir includes grasslands, upland scrub, valley and foothill woodlands, freshwater wetlands, and open water habitats (Reclamation et al. 2009). The grasslands include perennial and alkali habitats with wild oats, ripgut brome, yellow star thistle, fescue, filaree, mustard, fiddleneck, lupine, popcorn flower, and California poppy. The grasslands support northern harrier, burrowing owl, western meadowlark, California horned lark, turkey vulture, red-tailed hawk, American kestrel, white-tailed kite, western fence lizard, common garter snake, western rattlesnake, California tiger salamander, western harvest mouse, California ground squirrel, black-tailed jackrabbit, and black-tailed deer.

The upland scrub habitat is dominated by evergreen chaparral species and coastal scrub, including chamise, California sagebrush, black sage, poison oak, bush monkeyflower, and California buckwheat underlain by annual grasses and purple needlegrass (Reclamation et al. 2009). This habitat supports California quail, western scrub-jay, bushtit, California thrasher, spotted towhee, sage sparrow, western fence lizard, common garter snake, common king snake, western rattlesnake, deer mouse, and feral pig.

The valley and foothill woodlands and riparian woodlands includes willow, Fremont cottonwood, valley oak, sycamore, black walnut, California buckeye, Mexican elderberry, and Himalayan blackberry, which occurs along much of Kellogg Creek (Reclamation et al. 2009). This habitat supports many birds, reptiles, amphibians, and mammals, including red-legged frog. The freshwater emergent habitat includes meadows with wetland species and stream channels. The vegetation includes tules, bulrushes, and cattail. Wildlife that occurs in this area includes marsh wren, common yellowthroat, red-winged blackbird, red-legged frog, and western pond turtle. The open water habitat of the Los Vaqueros Reservoir provides forage, winter, and brood habitat for Canada goose, American wigeon, gadwall, mallard, northern shoveler, northern pintail, green-winged teal, canvasback, redhead, greater scaup, lesser scaup, bufflehead, common goldeneye, hooded merganser, common merganser, and ruddy ducks; and other habitat values for grebe, sandpiper, pelican, cormorant, egret, heron, and gull.

East Bay Municipal Utility District Reservoirs

The East Bay Municipal Utility District (EBMUD) reservoirs in Alameda and Contra Costa County used to store water within and near the East Bay Municipal Utility District service area include Briones Reservoir, San Pablo Reservoir, Lafayette Reservoir, Upper San Leandro Reservoir, and Lake Chabot. Water stored in these reservoirs includes water from local watersheds, the Mokelumne River watershed, and CVP water supplies.

The Briones Reservoir watershed is characterized by grasslands, chaparral, coastal scrub, oak and bay woodlands, riparian, and freshwater wetlands (EBMUD 1999; EBRPD 1996, 2001, 2013). The San Pablo Reservoir watershed is characterized by grasslands, hardwood forest, coastal scrub, Monterey pine planted along the reservoir shoreline, riparian woodland, and eucalyptus. The Lafayette Reservoir watershed is characterized by grasslands, oak and bay woodland, and coastal scrub. The Upper San Leandro Reservoir watershed includes grasslands, chamise-black sage chaparral, coastal scrub, oak and bay woodland, redwood forest, knobcone forest with a dense manzanita understory, and an 18-acre freshwater marsh. The Lake Chabot watershed includes grasslands, coastal scrub, oak and bay woodland, and riparian and freshwater vegetation.

The grasslands vegetative communities generally include nonnative grasses and native perennial bunchgrass (EBMUD 1999; EBRPD 1996, 2001). The nonnative grasslands include grasses such as wild oat, bromegrass, ryegrass, wild barley, bluegrass, silver hairgrass, and dogtail grass; forbs, including filaree, bur clover, clovers, owl's clover, cat's ear, and English plantain; and brodiaeas, lupine, mariposa lilies, mule's ear, yarrow, farewell to spring, and soap plant. Native grasses include annual and perennial fescues, needlegrass, wild rye, California oatgrass, junegrass, bluegrass, squirreltail, meadow barley, and California bromegrass. Grasslands are used by wildlife similar to those described for other San Francisco Bay Area reservoirs, including hawks, owls, shrikes, swallows, turkey vulture, reptiles, coyote, fox, bobcat, and mice.

The coastal scrub and chaparral vegetation includes coyote brush-scrub, California sagebrush, bitter cherry scrub, manzanita, chamise-black sage, cream bush, California coffeeberry, wild lilac, yerba santa, blackberry, bush monkeyflower, and poison oak (EBMUD 1999; EBRPD 1996, 2001). The woodlands include native and nonnative plants. The native redwood and knobcone pine forests are located at Upper San Leandro Reservoir and provide unique habitat. Nonnative eucalyptus and Monterey pine forests occur at San Pablo Reservoir and Lake Chabot. The eucalyptus trees provide specific habitat for hummingbird, bald eagle, great blue heron, and great egret. The oak and bay woodlands and oak savannas include coast live oak, black oak, valley oak, blue oak, interior live oak, canyon live oak, California bay, California buckeye, and madrone.

Mixed deciduous riparian woodland occurs along perennial streams, including white alder, big-leaf maple, western sycamore, Fremont cottonwood, and black cottonwood that supports frogs, newts, and other amphibians; coast live oak, California bay, and willow woodlands on steep slopes along intermittent streams; and willow riparian scrub along perennial and intermittent streams (EBMUD 1999; EBRPD 1996, 2001). Along springs and seeps, the vegetation includes grasses, including rabbitsfoot grass, saltgrass, bentgrasses, rushes, tules, sedges, horsetails, and cattail; and forbs, including buttercup, watercress, stinging nettle, brass-buttons, mints, duckweed, and pondweed.

P.1.2 Special-Status Species

Species with special status are defined as species that are legally protected or otherwise considered sensitive by federal, state, or local resource agencies. Such species include the following:

- Species listed by the federal government as threatened or endangered.
- Species listed by the state of California as threatened, endangered, or rare (rare status is for plants only).
- Species that are formally proposed for federal listing or are candidates for federal listing as threatened or endangered.
- Species that are candidates for state listing as threatened or endangered.
- Species that meet the definitions of rare, threatened, or endangered under the California Environmental Quality Act.
- Species identified by USFWS as Birds of Conservation Concern.
- Species considered sensitive by BLM or U.S. Forest Service.
- Species identified by CDFW as species of special concern.
- Species designated by California statute as fully protected (e.g., California Fish and Game Code, sections 3511 [birds], 4700 [mammals], and 5050 [reptiles and amphibians] and 5515 [fish]).
- Species, subspecies, and varieties of plants considered by CDFW and California Native Plant Society (CNPS) to be rare, threatened, or endangered in California. The CNPS Inventory of Rare and Endangered Plants of California assigns California Rare Plant Ranks (CRPR) categories for plant species of concern. Only plant species in CRPR categories 1 and 2 are considered special-status plant species in this document.
    - CRPR 1A—Plants presumed to be extinct in California.
    - CRPR 1B—Plants that are rare, threatened, or endangered in California and elsewhere.
    - CRPR 2—Plants that are rare, threatened, or endangered in California but more common elsewhere.

Lists of wildlife and plant species with special status that occur or may occur in portions of the study area are provided in Tables P.1-1 and P.1-2. These resource lists were assembled from resources that include USFWS's IPaC online service, which was used to identify species federally listed as endangered or threatened that occur in or may be affected by projects in the study area. To supplement the IPaC list, the California Natural Diversity Database (CNDDB) was queried (CDFW 2019) for species that are not federally listed.

Table P.1-1 Special-Status Wildlife Species

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Lange's metalmark butterfly	*Apodemia mormo langei*	FE/–/–	Endemic to Antioch Sand Dunes. Restricted to sand dunes along the southern bank of the Sacramento–San Joaquin River and is currently found only at Antioch Dunes NWR. Found in close association with larval host plant, naked-stem buckwheat (*Eriogonum numdum* ssp. *auriculatum*).	Bay-Delta	None. The Antioch sand dunes will not be affected by project activities.	
Conservancy fairy shrimp	*Branchinecta conservatio*	FE/–/–	Large vernal pools and seasonal wetlands, ~ 1 acre in size. Known to occur in suitable habitat on the San Luis NWR Complex, Eastside Bypass, and along the San Joaquin River. Currently found in disjunct and fragmented habitats across the Central Valley of California from Tehama County to Merced County and at two southern California locations on the Los Padres National Forest in Ventura County.	Sacramento River, Feather River, Yolo Bypass, Sutter Bypass San Joaquin River, Bay-Delta	Moderate. Some activities could occur in the vicinity of vernal pools.	
Longhorn fairy shrimp	*Branchinecta longiantenna*	FE/–/–	Vernal pool/seasonal wetlands. Known distribution extends from Contra Costa and Alameda Counties to San Luis Obispo County and also includes Merced County. Within this geographic range, it is extremely rare in vernal pools and swales. Known to occur in suitable habitat on the San Luis NWR Complex.	Bay-Delta, San Joaquin River	Moderate. Some activities could occur in the vicinity of vernal pools.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Vernal pool fairy shrimp	*Branchinecta lynchi*	FT/–/–	Typically inhabits vernal pools and seasonal wetlands smaller than 2,153 square feet (200 square meters) and less than 2 inches deep; may also occur in larger, deeper pools. Known to occur in suitable habitat on the San Luis NWR.	Sacramento River, Feather River, Yolo Bypass, Sutter Bypass American River, Bay-Delta, San Joaquin River	Moderate. Some activities could occur in the vicinity of vernal pools.	X
Valley elderberry longhorn beetle	*Desmocerus californicus dimorphus*	FT/–/–	Found only in association with its host plant, blue elderberry (*Sambucus nigra* ssp. *caerulea*). In the Central Valley, the elderberry shrub is found primarily in riparian vegetation. Known to occur in elderberry shrubs present in the riparian woodland and expected to occur in suitable habitat in other locations along the San Joaquin River. Recorded at Caswell Memorial State Park and other locations along the Stanislaus River.	Trinity River, Sacramento River, Feather River, American River, San Joaquin River, Stanislaus River, Bay-Delta, San Luis Reservoir	High. Elderberry shrubs are present along drainages where restoration projects are proposed.	X
Delta green ground beetle	*Elaphrus viridis*	FT/–/–	Associated with vernal pool habitats—seasonally wet pools that accumulate in low areas with poor drainage—that occur throughout the Central Valley. Presently known to occur only in Solano County northeast of the San Francisco Bay Area.	Bay-Delta	None. Highly unlikely for the species to occur where restoration projects are proposed.	
Bay checkerspot butterfly	*Euphydryas editha bayensis*	FT/–/–	Associated with specific host plants that typically grow on serpentine soils.	Bay-Delta	None. Suitable habitat for this species would not be affected.	

Common Name	**Scientific Name**	**Status Federal/ State/ CDFW**	**Habitat/Distribution**	**Areas with Potential for Occurrence**	**Potential for Effect**	**Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)**
Vernal pool tadpole shrimp	*Lepidurus packardi*	FE/–/–	Vernal pool/seasonal wetlands. Endemic to the Central Valley, with most populations located in the Sacramento Valley. This species has also been reported from the Delta to the east side of San Francisco Bay. Known to occur in suitable habitat on the San Luis NWR Complex and at the Great Valley Grasslands State Park.	Sacramento River, Feather River, Yolo Bypass, Sutter Bypass Bay-Delta, San Joaquin River	Moderate. Some activities could occur in the vicinity of vernal pools.	
Trinity bristle snail	*Monadenia infumata setosa*	–/ST/–	Entire range of the species is within the southern Klamath Mountains and within the Shasta-Trinity National Forest. Occurs along riparian corridors and uplands within Klamath mixed conifer forests with a deciduous hardwood understory. Found in moist, well-drained, well-shaded canyons or streamside benches covered with a layer of leaf mold at least 4 inches deep.	Trinity River, Clear Creek, Shasta Lake	Moderate. Flow changes and restoration activities could occur in areas where this species is present.	
Mission blue butterfly	*Plebejus icarioides missionensis*	FE/–/–	Inhabits coastal chaparral and grasslands of the San Francisco peninsula (Twin Peaks), Marin Headlands, Fort Baker in Marin County, and Sun Bruno Mountain in San Mateo County. Three larval host plants: *Lupinus albifrons*, *L. varicolor*, and *L. formosus*.	Bay-Delta	None. No activities are proposed in habitat for this species.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Callippe silverspot butterfly	*Speyeria callippe*	FE/–/–	Limited to these sites in the Bay-Delta region: eastern shore of San Francisco Bay, inner coast range of northwestern Contra Costa County south to Castro Valley, Alameda County, west side of the Bay from San Francisco to La Honda, San Mateo County. Found in native grassland and adjacent habitats where the larval host plant, Johnny jump-up (*Viola pedunculata*), is found.	Bay-Delta	None. No activities are proposed in habitat for this species.	
Myrtle's silverspot butterfly	*Speyeria zerene myrtleae*	FE/–/–	Known from four populations in northwestern Marin County and southwestern Sonoma County. Found in coastal dune or prairie habitat. Known population inhabits coastal terrace prairie, costal bluff scrub, and associated nonnative grasslands. Usually found in wind-sheltered areas below 810 feet (250 meters) and within 3 miles of the coast. Larvae host plant is hookedspur violet (*Viola adunca*).	Bay-Delta	None. No activities are proposed in habitat for this species.	
California tiger salamander	*Ambystoma californiense*	FT/ST/–	Small ponds, lakes, or vernal pools in grasslands and oak woodlands for breeding; rodent burrows, rock crevices, or fallen logs for upland cover during dry season.	Sacramento River, Feather River, American River, San Joaquin River, Stanislaus River, Bay-Delta, San Luis Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration and facility improvements.	X

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Western spadefoot toad	*Spea hammondii*	-/-/SSC	Primarily a species of lowland habitats such as washes, floodplains of rivers, alluvial fans, playas, alkali flats (Stebbins 1985), vernal pools, and vernal swales. However, occurs in the foothills and mountains. Prefers areas of open vegetation and short grasses, where the soil is sandy or gravelly. Found in the valley and foothill grasslands, open chaparral, and pine-oak woodlands (USFWS 2005).	Sacramento River, Feather River, American River, San Joaquin River, Stanislaus River, San Luis Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration and facility improvements.	
Shasta salamander	*Hydromantes shastae*	-/ ST/-	Uncommon in limestone areas in vicinity of Shasta Reservoir in Shasta County. Distribution is discontinuous, with numerous, small isolated populations occurring in limestone areas in valley-foothill hardwood-conifer, ponderosa pine and mixed conifer habitat. Found from 1,100 feet (330 meters) to 2,550 feet (773 meters).	Shasta Lake	None. No activities are proposed in habitat for this species.	
Cascades frog	*Rana cascadae*	–/CE/SSC	In California, found in two locations: Siskiyou County and south near Lassen Peak. Elevational range is 750–8,200 feet (230–2,500 meters). Found in water and surrounding vegetation in mountain lakes, small streams, and ponds in meadows up to timber line. Closely restricted to water.	Trinity River, Shasta Lake, upper reaches of Battle Creek, Paynes Creek, Mill Creek	None. No activities are proposed in habitat for this species.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Foothill yellow-legged frog	*Rana boylii*	–/CT/SSC	Streams in woodland, forest, mixed chaparral, and wet meadow habitats with rock and gravel substrate and low overhanging vegetation along the edge; usually found near riffles with rocks and sunny banks nearby.	Trinity River, Shasta Lake, upper reaches of Battle Creek, Paynes Creek, Mill Creek, Stanislaus River, Sacramento River, Bay-Delta	High. Restoration is proposed in areas that support habitat for this species.	
California red-legged frog	*Rana draytonii*	FT/–/SSC	Permanent and semipermanent aquatic habitats such as creeks and cold water ponds, with emergent and submergent vegetation; may aestivate in rodent burrows or cracks during dry periods.	Trinity River, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, San Joaquin River, Stanislaus River, Bay-Delta, San Luis Reservoir	High. Restoration is proposed in areas that support habitat for this species.	X
Western pond turtle	*Emmys marmorata*	–/–/SSC	Inhabits slow-moving streams, sloughs, ponds, irrigation and drainage ditches, and adjacent upland areas. Potentially occurs near New Melones Reservoir. Recorded within Whiskeytown Lake and Clear Creek and near Lewiston Reservoir. Known to occur in suitable habitat on the San Luis NWR Complex, in the Mendota Wildlife Area, and at Mendota Pool; expected to occur in suitable habitat in other locations in the San Joaquin River Restoration Area.	Trinity River, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, San Joaquin River, Stanislaus River, Bay-Delta, San Luis Reservoir	High. Restoration is proposed in areas that support habitat for this species.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Blunt-nosed leopard lizard	*Gambelia sila*	FE/SE/FP	Resident of sparsely vegetated grasslands, alkali flats, and washes. Prefers flat areas with open space for running, avoiding densely vegetated areas. Seeks cover in mammal burrows, under shrubs or structures such as fence posts; does not excavate its own burrows. Semiarid grasslands, alkali flats, and washes.	San Joaquin River	None. No activities are proposed in habitat for this species.	
Alameda whipsnake	*Masticophis lateralis euryxanthus*	FT/ST/–	Valleys, foothills, and low mountains associated with northern coastal scrub or chaparral habitat; requires rock outcrops for cover and foraging.	Bay-Delta	None. No activities are proposed in habitat for this species.	
San Francisco garter snake	*Thamnophis sirtalis tetrataenia*	FE/SE/FP	Sloughs, canals, low gradient streams and freshwater marsh habitats where there is a prey base of small fish and amphibians; also found in irrigation ditches and rice fields; requires grassy banks and emergent vegetation for basking and areas of high ground protected from flooding during winter.	Bay-Delta	None. No activities are proposed in habitat for this species.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Giant garter snake	*Thamnophis gigas*	FT/ST/–	Marshes, ponds, sloughs, small lakes, low-gradient streams, and other waterways, and in agricultural wetlands, including irrigation and drainage canals, rice fields, and adjacent uplands. Current distribution extends from near Chico in Butte County south to the Mendota Wildlife Area in Fresno County. Known from White Slough/Caldoni Marsh and Yolo Basin/Willow Slough. Known to occur in suitable habitat on the San Luis NWR Complex and in the Mendota Wildlife Area; reported from Mendota Pool.	Sacramento River, Feather River, American River, Yolo Bypass, Sutter Bypass, Bay-Delta, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration and facility improvements.	X
Tricolored blackbird (nesting colony)	*Agelaius tricolor*	–/ST[1]/SSC	Nests colonially in tules, cattails, willows, thistles, blackberries, and other dense vegetation. Forages in grasslands and agricultural fields. Reclamation (2010) concluded this species occurs near New Melones Reservoir. Suitable nesting and foraging habitat is present in the upper Sacramento River area. Known to occur in suitable habitat on the San Luis NWR Complex and other sites in the Yolo Bypass.	Sacramento River, Feather River, Yolo Bypass, Sutter Bypass, American River, Bay-Delta, Stanislaus River	Moderate. Suitable habitat is present in areas proposed for restoration and facility improvements.	

[1] Emergency protection under CESA granted on December 3, 2014, by the California Fish and Game Commission (FGC). FGC voted to list as Threatened on April 19, 2018, official notice pending.

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Tule greater white-fronted goose (wintering)	*Anser albifrons elgasi*	–/–/SSC	Winters in California. Associated with dense tule–cattail marsh habitat. Has been documented near Sherman Island and at various locations in the Suisun Marsh. Winters at Sacramento Valley wildlife refuges and surrounding rice fields, Suisun Marsh, and Grizzly Island Wildlife Area.	Sacramento River, Bay-Delta	Moderate. Suitable habitat is present in areas proposed for restoration.	
Pallid bat	*Antrozous pallidus*	–/–/SSC	Occurs in a variety of habitats from desert to coniferous forest; most closely associated with oak, yellow pine, redwood, and giant sequoia habitats in northern California; relies heavily on trees for cavity roosts, but will use crevices in human-made structures including buildings.	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, Yolo Bypass, Stanislaus River, San Joaquin River, Bay-Delta, San Luis Reservoir, New Melones Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration.	
Long-eared owl	*Asio otis*	–/–/SSC	Conifer, oak, riparian, pinyon-juniper, and desert woodlands that are either open or are adjacent to grasslands, meadows, or shrublands (Shuford and Gardali 2008).	Sacramento River, Feather River, Yolo Bypass, Bay-Delta, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Oak titmouse	*Baeolophus inornatus*	BCC/–/–	Oak woodlands, including scrub oak woodland, from southwest Oregon to northwest Baja California (Cornell Lab of Ornithology 2017).	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, Yolo Bypass, Stanislaus River, San Joaquin River, Bay-Delta, San Luis Reservoir, New Melones Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration.	
Northern harrier	*Circus cyaneus*	–/–/SSC	Forages in marshes, grasslands, and ruderal habitats; nests in extensive marshes and wet fields.	Sacramento River, Feather River, Yolo Bypass, Bay-Delta, San Joaquin River	High. Suitable habitat is present in areas proposed for restoration.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Nuttall's woodpecker	*Picoides nuttalii*	BCC/–/–	Oak woodlands in California. Also uses wooded suburban areas and woodlands near streams farther south in its range where oak trees are scarcer.	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, Yolo Bypass, Stanislaus River, San Joaquin River, Bay-Delta, San Luis Reservoir, New Melones Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration.	
Short-eared owl (nesting)	*Asio flammeus*	–/–/SSC	Widespread winter migrant, found primarily in the Central Valley, in the western Sierra Nevada foothills, and along the coastline. Usually found in open areas with few trees, such as annual and perennial grasslands, prairies, dunes, meadows, irrigated lands, and saline and fresh emergent wetlands. Occasionally still breeds in northern California. Known to occur in suitable habitat on the San Luis NWR Complex, where it possibly also nests. Breeding range includes coastal areas in Del Norte and Humboldt Counties, the Bay-Delta, northeastern Modoc plateau, the east side of the Sierra from Lake Tahoe south to Inyo County, and the San Joaquin Valley.	Sacramento River, Feather River, Yolo Bypass, Sutter Bypass, Bay-Delta, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Burrowing owl (nesting and wintering sites)	*Athene cunicularia*	–/–/SSC	Nests and forages in grasslands, shrub lands, deserts, and agricultural fields, especially where ground squirrel burrows are present. Occurs near New Melones Reservoir. Unlikely to occur along the Sacramento River corridor due to a lack of suitable nesting habitat. Known to occur in suitable habitat in the Yolo Bypass, in the Chowchilla Bypass, on the San Luis NWR Complex, and at Mendota Pool.	Sacramento River, Feather River, American River, Yolo Bypass, Sutter Bypass, Stanislaus River, San Joaquin River, Bay-Delta, San Luis Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration and facility improvements.	
Marbled murrelet	*Brachyramphus marmoratus*	FT/SE/–	Pacific Ocean, but nesting occurs in old growth forest.	Bay-Delta	None. No activities are proposed in suitable habitat for this species.	
Swainson's hawk (nesting)	*Buteo swainsoni*	BCC/ST/–	Nests in riparian woodlands, roadside trees, tree rows, isolated trees, woodlots, and trees in farmyards and rural residences. Forages in grasslands and agricultural fields in Central Valley. Occurs near New Melones Reservoir. Known to nest in suitable habitat on the San Luis NWR Complex and Great Valley Grasslands State Park and other areas along the San Joaquin River. Suitable nesting and foraging habitat is present along Sacramento River.	Sacramento River, Feather River, American River, Yolo Bypass, Sutter Bypass, San Joaquin River, Stanislaus River, Bay-Delta, San Luis Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration and facility improvements.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Western snowy plover	*Charadrius alexandrines nivosus*	FT/–/SSC	Coastal beaches above the normal high tide limit in flat, open areas with sandy or saline substrates; vegetation and driftwood are usually sparse or absent.	Bay-Delta	None. No activities are proposed in suitable habitat for this species.	
Black tern	*Childonias niger*	–/–/SSC	Nests in freshwater marsh, forages for fish and insects in open water, rice fields, and marsh. Uncommon visitor in suitable habitat in the area of analysis; expected during the nonbreeding season along the San Joaquin River.	Sacramento River, Feather River, Yolo Bypass, Sutter Bypass, San Joaquin River, Bay-Delta	Moderate. Suitable habitat is present in areas proposed for restoration.	
Western yellow-billed cuckoo (nesting)	*Coccyzus americanus occidentalis*	BCC/FT/SE/–	Densely foliaged, deciduous trees and shrubs, especially willows, required for roosting sites. An uncommon to rare summer resident of valley foothill and desert riparian habitats in scattered locations in California. Breeding pairs known from Sacramento Valley. Reclamation (2010) concluded this species could potentially occur near New Melones Reservoir. Detected by BDCP surveys in 2009 near Walnut Grove. Likely to nest and forage in the upper Sacramento River area.	Trinity River, Clear Creek, Sacramento River, Feather River, Bay-Delta, New Melones Reservoir, San Joaquin Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration.	X

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Townsend's big-eared bat	*Corynorhinus townsendii*	–/–/SSC	Roosts in caves, tunnels, mines, and dark attics of abandoned buildings; very sensitive to disturbances and may abandon a roost after one onsite visit.	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, Yolo Bypass, Stanislaus River, San Joaquin River, Bay-Delta, San Luis Reservoir, New Melones Reservoir	Low. Suitable foraging habitat is present in areas proposed for restoration.	
Western mastiff bat	*Eumops perotis*	–/–/SSC	Primarily a cliff-dwelling species. Roosts generally under exfoliating rock slabs (e.g., granite, sandstone or columnar basalt). Also been found in similar crevices in large boulders and buildings. Forages in broad open areas, including desert washes, flood plains, chaparral, oak woodland, open ponderosa pine forest, grassland, and agricultural areas (Western Bat Working Group 2017).	Sacramento River, Feather River, American River, Yolo Bypass, Stanislaus River, San Joaquin River, Bay-Delta	Low. Suitable foraging habitat is present in areas	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Western red bat	*Lasiurus blossevillii*	–/–/SSC	Roosts in the foliage of trees or shrubs. Day roosts are commonly in edge habitats adjacent to streams or open fields, in orchards, and urban areas. May be associated with intact riparian habitat (particularly willows, cottonwoods, and sycamores). This species may also occasionally use caves (Western Bat Working Group 2017).	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, Yolo Bypass, Stanislaus River, San Joaquin River, Bay-Delta, San Luis Reservoir, New Melones Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration.	
Yellow warbler (nesting)	*Dendroica petechia brewsteri*	BCC/–/SSC	Nests in riparian woodland and riparian scrub habitats. Forages in a variety of wooded and shrub habitats during migration. Reclamation (2010) concluded this species occurs near New Melones Reservoir. No recent nesting records, but potential nesting habitat present; known to occur during migration in suitable habitat on the San Luis NWR. Could nest and forage in the upper Sacramento River area. Likely to use riparian woodlands during migration.	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, New Melones Reservoir, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
White-tailed kite (nesting)	*Elanus leucurus*	–/–/FP	Nests in woodlands and isolated trees; forages in grasslands, shrub lands, and agricultural fields. Common to uncommon and a year-round resident in the Central Valley, in other lowland valleys, and along the entire length of the coast. Recent surveys in Yolo and Sacramento Counties have documented active nest sites in riparian habitats in the Yolo Bypass and along Steamboat and Georgiana Sloughs and along the Sacramento River. Suitable nesting and foraging habitat is present along the upper Sacramento River. Expected to occur in suitable habitat along San Joaquin River and in Yolo Bypass.	Shasta River/Shasta Lake, Sacramento River, Feather River, Yolo Bypass, Sutter Bypass, American River, San Joaquin River, Bay-Delta, San Luis Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration.	
Saltmarsh common yellowthroat	*Geothlypis trichas sinuosa*	BCC/–/SSC	Primarily brackish marsh, but also brackish and fresh woody swamps and riparian areas. Ranges generally in the San Francisco Bay Area.	Bay-Delta	Moderate. Suitable habitat is present in areas proposed for restoration.	
Greater sandhill crane (nesting and wintering)	*Grus canadensis tabida*	–/ST/FP	Eight distinct wintering locations in the Central Valley from Chico/Butte Sink on the north to Pixley NWR near Delano on the south, with more than 95% occurring within the Sacramento Valley between Butte Sink and the Delta. Unlikely to breed in the upper Sacramento River area. Known to occur during winter in suitable habitat on the San Luis NWR Complex, along the San Joaquin River, and in the Delta.	Sacramento River, Feather River, Yolo Bypass, Sutter Bypass, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Bald eagle (nesting and wintering)	*Haliaeetus leucocephalus*	BCC/FD/SE/FP	Requires large bodies of water or free-flowing rivers with abundant fish and adjacent snags or other perches for foraging. Occurs near New Melones Reservoir, Whiskeytown Lake, Trinity Lake, and Lewiston Reservoir. Known to nest in suitable habitat around Lake Millerton and in the Chowchilla Bypass.	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, Yolo Bypass, Sutter Bypass, Stanislaus River, San Joaquin River, Bay-Delta, San Luis Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration.	
Least bittern (nesting)	*Ixobrychus exilis*	BCC/–/SSC	Rare to uncommon April to September nester in large, fresh emergent wetlands of cattails and tules in the Sacramento and San Joaquin Valleys. Occurs in fresh water marsh habitats in the Yolo Bypass, east of the Sacramento River, and in the western Delta. Uncommon but regular breeder in suitable habitat in the San Joaquin Valley.	Sacramento River, Feather River, Yolo Bypass, Sutter Bypass, Bay-Delta, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	
California black rail	*Laterallus jamaicensis coturniculus*	BCC/ST/FP	Tidal marshes in the northern San Francisco Bay estuary, Tomales Bay, Bolinas Lagoon, the Delta, Morro Bay, the Salton Sea, and the lower Colorado River. Found recently at several inland freshwater sites in the Sierra Nevada foothills in Butte, Yuba, and Nevada Counties, the Cosumnes River Preserve in south Sacramento County, and Bidwell Park in Chico, Butte County.	Bay-Delta	Moderate. Suitable habitat is present in areas proposed for restoration.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Least tern	*Sternula antillarum*	FE/SE/FP	Sandy or gravelly areas along bays, estuaries, lagoons, within the Bay-Delta.	Bay-Delta	Low. Suitable habitat is present in areas proposed for restoration.	X
Yellow-breasted Chat	*Icteria virens*	–/–/SSC	Breeds in areas with dense shrubbery, including agricultural areas, forest edges, swamps, and edges of streams and ponds. Breeding habitat is often blackberry bushes (Cornell Lab of Ornithology 2017).	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, American River, Yolo Bypass, Stanislaus River, San Joaquin River, Bay-Delta, San Luis Reservoir, New Melones Reservoir	Moderate. Suitable habitat is present in areas proposed for restoration.	
Suisun song sparrow	*Melospiza melodia maxillaris*	BCC/–/SSC	Brackish marshes around Suisun Bay.	Bay-Delta	Moderate. Suitable habitat is present in areas proposed for restoration.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Osprey (nesting)	*Pandion haliaetus*	–/–/WL	Nests on platform of sticks at the top of large snags, dead-topped trees, on cliffs, or on human-made structures. Requires open, clear waters for foraging. Uses rivers, lakes, reservoirs, bays, estuaries, and surf zones. Reclamation (2010) concluded this species occurs near New Melones Reservoir. Known to nest along the Sacramento River.	Trinity River, Clear Creek, Shasta River/Shasta Lake, Sacramento River, Feather River, Yolo Bypass, Sutter Bypass, American River, New Melones Reservoir	High. Suitable habitat is present in areas proposed for restoration.	
White-faced ibis (nesting colony)	*Plegadis chihi*	–/–/WL	Forages in wetlands and irrigated or flooded croplands and pastures. Breeds colonially in dense freshwater marsh. Known to occur in suitable habitat on the San Luis NWR Complex and other sites in the Restoration Area and Yolo Bypass.	Feather River, Yolo Bypass, Sutter Bypass, American River, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	
California Ridgway's rail	*Rallus obsoletus*	FE/SE/FP	Dense marshy areas of the Bay-Delta region.	Bay-Delta	Moderate. Suitable habitat is present in areas proposed for restoration.	X

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Bank swallow (nesting)	*Riparia*	–/ST/–	Neotropical migrant found primarily in riparian and other lowland habitats in California west of the deserts during the spring-fall period. In summer, restricted to riparian, lacustrine, and coastal areas with vertical banks, bluffs, and cliffs with fine-textured or sandy soils, into which it digs nesting holes. Approximately 75% of the current breeding population in California occurs along banks of the Sacramento and Feather Rivers in the northern Central Valley.	Trinity River, Clear Creek, Sacramento River, Feather River, American River, Yolo Bypass, Sutter Bypass, New Melones Reservoir, San Joaquin River, Bay-Delta	Moderate. Suitable habitat may be present in areas proposed for restoration. This species is also vulnerable to changes in flow regimes.	
Least bell's vireo (nesting)	*Vireo bellii pusillus*	FE/SE/–	Nests in dense, low, shrubby vegetation, generally early successional stages in riparian areas, particularly cottonwood-willow forest, but also brushy fields, young second-growth forest or woodland, scrub oak, coastal chaparral, and mesquite brush lands, often near water in arid regions. Observed in Yolo Bypass Wildlife Area. Successfully nested at the San Joaquin River NWR in 2005 and 2006.	Sacramento River, Yolo Bypass, Sutter Bypass, Bay-Delta, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	X
Nelson's antelope squirrel	*Ammospermophi lus nelsoni*	–/ST/–	Dry sparsely vegetated loam soils and needs widely scattered shrubs, forbs, and grasses in broken terrain with gullies and washes.	San Joaquin River	None. No activities are proposed in suitable habitat for this species.	

Common Name	**Scientific Name**	**Status Federal/ State/ CDFW**	**Habitat/Distribution**	**Areas with Potential for Occurrence**	**Potential for Effect**	**Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)**
Ring-tailed cat	*Bassariscus astutus*	–/–/FP	Wooded and brushy areas, especially near water courses. Species distribution not well known. Potentially suitable habitat is present along the Sacramento River corridor.	Shasta River/Shasta Lake, Sacramento River, Feather River, Bay-Delta, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	
Fresno kangaroo rat	*Dipodomys nitratoides exilis*	FE/SE/–	Nearly level, light, friable soils in chenopod scrub and grassland communities.	San Joaquin River	None. No activities are proposed in suitable habitat for this species.	
Southern sea otter	*Enhydra lutris nereis*	FT/–/FP	Found in nearshore marine environments with large giant kelp and bull kelp sea beds from Ano Nuevo, San Mateo County to Point Sal, Santa Barbara County. Uses nearshore waters adjacent to rock coasts, near points of land, or large bays for cover, sleeping, foraging. Also rafts in open water off sandy beaches.	Bay-Delta	None. No activities are proposed in suitable habitat for this species.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
California wolverine	*Gulo gulo*	PT/ST/FP	Scarce resident of North Coast mountains and Sierra Nevada. Ranges from Del Norte and Trinity Counties east through Siskiyou and Shasta Counties, and south through Tulare County. Utilizes Douglas-fir and mixed conifer habitats, red fir, lodgepole, wet meadow, and montane riparian habitats. Elevation in coastal ranges from 1,600 to 4,800 feet (500 to 1,500 meters), and elevation in the Sierra Nevada ranges from 4,300 to 7,300 feet (1,300–2,300 meters).	Trinity River, Shasta River/Shasta Lake, Battle Creek, Paynes Creek, Mill Creek, Butte Creek	None. No activities are proposed in suitable habitat for this species.	
Humboldt marten	*Martes caurina humboldtensis*	–/CE/SSC	Known from coastal northwestern California. Optimal habitats ae mixed evergreen forests with more than 40% crown closure, with large trees and snags. Important habitats include red fir, lodgepole pine, subalpine conifer, mixed conifer, Jeffrey pine, and eastside pine.	Trinity River	None. No activities are proposed in suitable habitat for this species.	
Riparian (= San Joaquin Valley) woodrat	*Neotoma fuscipes riparia*	FE/–/SSC	Historically found in riparian habitat along the San Joaquin, Stanislaus, and Tuolumne Rivers. Now known only from Caswell Memorial State Park on the Stanislaus River near its confluence with the San Joaquin River in very low gradient portion of river. No actions proposed that could affect this species in this area. Last reported at Caswell Memorial State Park in 2002. Likely still extant.	Bay-Delta, Stanislaus River, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	X

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Fisher	*Pekania pennanti*	–/ST/SSC	Resident of Sierra Nevada, Cascades, and Klamath Mountains. Also found in a few areas in North Coast Ranges. Occurs in intermediate to large-tree stages of coniferous forests and deciduous-riparian habitats with a high percentage of canopy closure.	Trinity River, tributaries to upper Sacramento, Battle, Paynes, Mill, and Deer Creeks	None. No activities are proposed in suitable habitat for this species.	
Salt marsh harvest mouse	*Reithrodontomys raviventris*	FE/SE/FP	Found only in saline emergent wetlands of San Francisco Bay and its tributaries. Pickleweed saline emergent wetland is preferred habitat, where it may be locally common. Grasslands adjacent to pickleweed marsh are used, but only when new grass growth affords suitable cover in spring and summer. Reported occurrences of the salt marsh harvest mouse from within the Delta are restricted to salt and brackish tidal marshes along the northern edge of the Sacramento River and the southern edge of the San Joaquin River as far east as the vicinity of Collinsville and Antioch, west of Sherman Island.	Bay-Delta	High. Suitable, occupied habitat is present in areas proposed for restoration.	X
Suisun shrew	*Sorex ornatus sinuosus*	–/–/SSC	Historically known from tidal wetlands of Solano, Napa, and eastern Sonoma Counties. Currently limited to the northern borders of San Pablo and Suisun Bays.	Bay-Delta	Moderate. Suitable habitat is present in areas proposed for restoration.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Riparian woodrat	*Neotoma fuscipes riparia*	FE/--/SSC	Historically found in riparian habitat along the San Joaquin, Stanislaus, and Tuolumne Rivers. Now known only from Caswell Memorial State Park on the Stanislaus River near its confluence with the San Joaquin River in very low gradient portion of river.	Bay-Delta, Stanislaus, San Joaquin	Moderate. Suitable habitat is present in areas proposed for restoration.	
Riparian brush rabbit	*Sylvilagus bachmani riparius*	FE/SE/–	Historical distribution may have extended along portions of the San Joaquin River and its tributaries on the valley floor from at least Stanislaus County to the Delta. Currently restricted to several populations at Caswell Memorial State Park, near Manteca in San Joaquin County, along the Stanislaus River, along Paradise Cut (a channel of the San Joaquin River in the southern part of the Delta), and a recent reintroduction on private lands adjacent to the San Joaquin River NWR.	Bay-Delta, Stanislaus River, San Joaquin River	Moderate. Suitable habitat is present in areas proposed for restoration.	X
San Joaquin kit fox	*Vulpies macrotis mutica*	FT/ST/–	Saltbush scrub, grassland, oak, savanna, and freshwater scrub.	Bay-Delta, San Joaquin River	None. No activities are proposed in suitable habitat for this species.	

Common Name	Scientific Name	Status Federal/ State/ CDFW	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation and in EIS (indicated with an X)
Sierra Nevada red fox	*Vulpes vulpes necator*	FC/ST/–	Range is throughout high elevations of the Sierra Nevada from Tulare County northward to Sierra County, and from Mount Shasta and Lassen Peak westward to the Trinity Mountains, Trinity County. Seldom seen below 5,000 feet (1,500 meters) and most often observed above 6,889 feet (2,100 meters). Occurs at low densities. Occupied habitat is a composite of high elevation barren, conifer and shrub habitat, montane meadows, subalpine woodlands, and fell-fields. Dens in natural cavities, earthen dens, boulder piles, and vacant space under human-made structures.	Upper reaches of Battle Creek, Paynes Creek, Mills Creek, Dear Creek, Butte Creek	None. No activities are proposed in suitable habitat for this species.

Table P.1-2. Special-Status Plant Species

Common Name	Scientific Name	Status Federal/State/ CRPR*	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation (indicated with an X)
Adobe sanicle	*Sanicula maritima*	–/SR/1B.1	Clay and serpentine soils in chaparral, coastal prairie, meadow and seeps, and annual grassland.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Beach layia	*Layia carnosa*	FE/SE/1B.1	Coastal dunes and coastal scrub on sandy soils.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Bensoniella	*Bensoniella oregona*	–/SR/1B.1	Bogs and fens, meadows and seeps, and mesic areas in lower montane coniferous forest.	Trinity River	None. No activities are proposed within suitable habitat in the known range of the species.	
Bogg's Lake hedge-hyssop	*Gratiola heterosepala*	–/SE/1B.2	Marshy and swampy lake margins, vernal pools. Known from north Delta and from the Sacramento and San Joaquin Valleys. CNDDB documents occurrences at Jepson Prairie, the Rio Linda area, and Mather County Park.	Sacramento River, Yolo Bypass, Sutter Bypass, Bay-Delta, San Joaquin River	None. No activities are proposed within suitable habitat in the known range of the species.	
Bolander's water hemlock	*Cicuta maculata* var. *bolanderi*	–/–/2.1	Coastal fresh or brackish marshes and swamps in Contra Costa, Sacramento, Marin, and Solano Counties. Present at north and central Delta and Suisun Marsh.	Sacramento River, Bay-Delta, Suisun Marsh	High. Restoration activities are proposed within suitable habitat in the known range of the species.	

Common Name	Scientific Name	Status Federal/State/ CRPR*	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation (indicated with an X)
Butte County meadowfoam	*Limnanthes floccosa* ssp.*californica*	FE/SE/1B.1	Vernal pools and swales in annual grassland.	Sacramento River and its tributaries in Butte County	None. No activities are proposed within suitable habitat in the known range of the species.	
Legenere	*Legenere limosa*	–/–/1B.1	Vernal pools and swales in annual grassland.	Sacramento River, Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Sandford's arrowhead	*Saggitaria sanfordii*	–/–/1B.2	Freshwater mashes and swamps	Sacramento River, Bay-Delta, San Joaquin River	Low. Some activities could occur near marshes and swamps for this species.	
California jewelflower	*Caulanthus californicus*	FE/SE/1B.1	Sandy soils on chenopod scrub, Pinyon and juniper woodland, and annual grassland.	San Joaquin River	None. No activities are proposed within suitable habitat in the known range of the species.	
California seablite	*Suaeda californica*	FE/–/1B.1	Margins of tidal salt marsh.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Chinese Camp brodiaea	*Brodiaea pallida*	FT/SE/1B.1	Ephemeral streams, often on serpentine, in cismontane woodland and annual grassland.	Stanislaus and Tuolumne Rivers	None. No activities are proposed within suitable habitat in the known range of the species.	
Colusa grass	*Neostapfia colusana*	FT/SE/1B.1	Adobe soils of vernal pools.	Sacramento River, Yolo Bypass, Sutter Bypass, Stanislaus River, San Joaquin River	None. No activities are proposed within suitable habitat in the known range of the species.	
Coulter's goldfields	*Lasthenia glabrata* ssp. *coulteri*	–/–/1B.1	Coastal salt marshes and swamps, playas, vernal pools	Sacramento River, San Joaquin River	None. No activities are proposed within suitable habitat in the known range of the species.	

Common Name	Scientific Name	Status Federal/State/ CRPR*	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation (indicated with an X)
Contra Costa goldfields	*Lasthenia conjugens*	FE/–/1B.1	Wet areas in cismontane woodland, valley and foothill grassland, vernal pools, alkaline playas, or saline vernal pools and swales.	Sacramento River, Bay-Delta	Low. Some activities could occur near vernal pools where this species occurs.	
Crystal Springs fountain thistle	*Cirsium fontinale* var. *fontinale*	FE/SE/1B.1	Serpentine seeps in chaparral openings and valley and foothill grassland.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Delta button-celery	*Eryngium racemosum*	–/SE/1B.1	Vernally mesic clay depressions in riparian scrub. Extant occurrences recorded along San Joaquin River in Merced County and in south Delta. Reclamation (2010) concluded this species could potentially occur near New Melones Reservoir.	Bay-Delta, Stanislaus River, New Melones Reservoir, San Joaquin River	Moderate. Potentially affected by floodplain restoration activities.	
Delta tule pea	*Lathyrus jepsonii* var. *jepsonii*	–/–/1B.2	Freshwater and brackish marshes and swamps in the Bay-Delta region. Known from north, central, and west Delta, and Suisun Marsh. CNDDB documents occurrences at Snodgrass, Barker, Lindsey, Hass, and Cache Sloughs; Delta Meadows Park; and Calhoun Cut.	Yolo Bypass, Sutter Bypass, Bay-Delta	High. Restoration activities are proposed within suitable habitat in the known range of the species.	
Franciscan manzanita	*Arctostaphylos hookeri* ssp. *franciscana*	FE/–/1B.1	Coastal scrub on serpentine soils. Known from only a single	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	

Common Name	Scientific Name	Status Federal/State/ CRPR*	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation (indicated with an X)
			occurrence in the Presidio of San Francisco.			
Greene's tuctoria	*Tuctoria greenei*	FE/SR/1B.1	Dry vernal pools.	Shasta River/Shasta Lake, Feather River, Sacramento River, American River, San Joaquin River	None. No activities are proposed within suitable habitat in the known range of the species.	
Hairy Orcutt grass	*Orcuttia pilosa*	FE/FE/1B.1	Vernal pools.	San Joaquin River, New Melones Reservoir	None. No activities are proposed within suitable habitat in the known range of the species.	
Hartweg's golden sunburst	*Pseudobahia bahiifolia*	FE/FE/1B.1	Predominantly on northern slopes of rocky, bare areas along rolling hills, shady creeks, adjacent to vernal pools and streams, on heavy clay soils in valley and foothill grasslands and cismontane woodland.	Stanislaus River, Tuolumne River, San Joaquin River.	None. No activities are proposed within suitable habitat in the known range of the species.	
Hoover's spurge	*Chamaesyce hooveri*	FT/–/1B.2	Below the high-water mark of large northern hardpan and volcanic vernal pools.	Sacramento River, Feather River, American River, San Joaquin River	None. No activities are proposed within suitable habitat in the known range of the species.	
Keck's checkerbloom	*Sidalcea keckii*	FE/–/1B.1	Serpentine clay soils in cismontane woodland, valley, and foothill grassland.	Sacramento River, Feather River, American River, Bay-Delta, San Joaquin River.	None. No activities are proposed within suitable habitat in the known range of the species.	
Large-flowered fiddleneck	*Amsinckia grandiflora*	FE/SE/1B.1	Cismontane woodland, valley, and foothill grassland slopes.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	

Common Name	Scientific Name	Status Federal/State/ CRPR*	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation (indicated with an X)
Livermore tarplant	*Deinandra bacigalupii*	–/SE/1B.2	Alkaline meadows and seeps.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Marin western flax	*Hesperolinon congestum*	FT/ST/1B.1	Serpentinite chaparral, serpentinite grassland.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Mason's lilaeopsis	*Lilaeopsis masonii*	–/SR/1B.1	Brackish or freshwater marshes and swamps, riparian scrub in Bay-Delta region. Known and locally common in certain regions of Delta and in Suisun Marsh. CNDDB documents occurrences of this species in Barker, Lindsey, Cache, and Snodgrass Sloughs as well as in Calhoun Cut.	Bay-Delta	High. Restoration activities are proposed within suitable habitat in the known range of the species.	
North Coast semaphore grass	*Pleuropogon hooverianus*	–/ST/1B.1	Open, mesic areas in broadleafed upland forest, meadows and seeps, and North Coast coniferous forest.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Pacific manzanita	*Arctostaphylos pacifica*	–/SE/1B.1	Chaparral and coastal scrub. Known only from San Bruno Mountain in San Mateo County.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Pallid manzanita	*Arctostaphylos pallida*	FT/SE/1B.1	Siliceous shale, sandy or gravelly soils in broadleafed upland forest, closed-cone coniferous forest, chaparral, cismontane woodland, and	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	

Common Name	Scientific Name	Status Federal/State/ CRPR*	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation (indicated with an X)
			coastal scrub habitats. Known only from the East Bay Hills.			
Palmate-bracted bird's-beak	*Cordylanthus palmatus*	FE/SE/1B.1	Alkaline sites in grassland and chenopod scrub.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Pitkin marsh lily	*Lilium pitkinense*	FE/SE/1B.1	Mesic, sandy soils in cismontane woodland, meadows and seeps, freshwater marshes, and swamps.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Presidio clarkia	*Clarkia franciscana*	FE/SE/1B.1	Coastal scrub and grassland, typically on serpentine soils. Known only in the cities of San Francisco and Oakland.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Presidio manzanita	*Arctostaphylos hookeri* ssp. *ravenii*	FE/SE/1B.1	Serpentine outcrops in chaparral, coastal prairie, and coastal scrub. Known only from the Presidio of San Francisco.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Red hills vervain	*Verbena californica*	FT/ST/1B.1	Mesic areas along serpentine seeps or creeks surrounded by cismontane woodland or grassland. Known only from the Red Hills.	Tuolumne River	None. No activities are proposed within suitable habitat in the known range of the species.	
Robust spineflower	*Chorizanthe robusta* var. *robusta*	FE/–/1B.1	Sandy or gravelly areas in coastal scrub, coastal dunes, and openings in cismontane woodland.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Sacramento Orcutt grass	*Orcuttia californica* var. *viscida*	FE/SE/1B.1	Vernal pools.	Sacramento River	None. No activities are proposed within suitable habitat in the known range of the species.	

Common Name	Scientific Name	Status Federal/State/ CRPR*	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation (indicated with an X)
San Bruno Mountain manzanita	*Arctostaphylos imbricata*	–/SE/1B.1	Rocky areas in chaparral and coastal scrub habitat.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
San Francisco lessingia	*Lessingia germanorum*	FE/SE/1B.1	Coastal scrub on remnant dunes.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
San Francisco popcornflower	*Plagiobothrys diffusus*	–/SE/1B.1	Coastal prairie and annual grassland.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
San Joaquin Valley Orcutt grass	*Orcuttia inaequalis*	FT/SE/1B.1	Vernal pools.	San Joaquin River	None. No activities are proposed within suitable habitat in the known range of the species.	
San Mateo thorn-mint	*Acanthomintha duttonii*	FE/SE/1B.1	Serpentine soils in valley and foothill grassland, open areas in chaparral and coastal scrub.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
San Mateo woolly sunflower	*Eriophyllum latilobum*	FE/SE/1B.1	Open areas in coast live oak woodland, often on roadsides, sometimes on serpentinite.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Santa Cruz tarplant	*Holocarpha macradenia*	FT/SE/1B.1	Coastal terrace grasslands, coastal scrub, often on light sandy to sandy clay soils.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Slender Orcutt grass	*Orcuttia tenuis*	FT/SE/1B.1	Vernal pools.	Sacramento River	None. No activities are proposed within suitable habitat in the known range of the species.	
Soft bird's-beak	*Chloropyron molle* ssp. *molle*	FE/SR/1B.2	Coastal salt marshes and swamps in Contra Costa, Napa, and Solano Counties.	Bay-Delta	High. Restoration activities are proposed within suitable habitat in the known range of the species.	X

Common Name	Scientific Name	Status Federal/State/ CRPR*	Habitat/Distribution	Areas with Potential for Occurrence	Potential for Effect	Species Addressed in Reinitiation of Consultation (indicated with an X)
Suisun marsh aster	*Symphyotrichum lentum*	–/–/1B.2	Endemic to Delta, generally occurs in marshes and swamps, often along sloughs, from 0 to 3 meters in elevation. Brackish and freshwater marshes and swamps in the Bay-Delta region. Known from many areas of Delta and from Suisun Marsh.	Yolo Bypass, Sutter Bypass, Bay-Delta, Suisun Marsh	High. Restoration activities are proposed within suitable habitat in the known range of the species.	
Suisun thistle	*Cirsium hydrophilum* var. *hydrophilum*	FE/–/1B.1	Salt marshes and swamps. Two known occurrences in Grizzly Island Wildlife Area and Peytonia Slough Ecological Reserve. Present at Suisun Marsh.	Bay-Delta	High. Restoration activities are proposed within suitable habitat in the known range of the species.	X
Tiburon jewelflower	*Streptanthus niger*	FE/SE/1B.1	Serpentine grasslands. Known from only two occurrences on the Tiburon Peninsula.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Tiburon mariposa lily	*Calochortus tiburonensis*	FT/ST/1B.1	Serpentine grasslands. Known only from one occurrence on Ring Mountain Preserve.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Tiburon paintbrush	*Castilleja affinis* var. *neglecta*	FE/ST/1B.2	Serpentine grasslands.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.	
Two-fork clover	*Trifolium amoenum*	FE/–/1B.1	Low elevation grasslands, including swales and disturbed areas, sometimes on serpentinite soils.	Bay-Delta	None. No activities are proposed within suitable habitat in the known range of the species.

CNDDB= California Natural Diversity Database
CRPR = California Rare Plant Rank

P.1.3 Critical Habitat

Critical habitat refers to areas designated by USFWS for the conservation of species listed as threatened or endangered under the Endangered Species Act (ESA) of 1973, as amended through the 108th Congress. When a species is proposed for listing under the ESA, USFWS considers whether there are certain areas essential to the conservation of the species. Critical habitat is defined in Section 3, Provision 5 of the ESA as follows.

(5)(A) The term "critical habitat" for a threatened or endangered species means -

(i) the specific areas within the geographical area occupied by a species at the time it is listed in accordance with the Act, on which are found those physical or biological features (I) essential to the conservation of the species, and (II) which may require special management considerations or protection; and

(ii) specific areas outside the geographical area occupied by a species at the time it is listed in accordance with the provisions of section 4 of this Act, upon a determination by the Secretary that such areas are essential for the conservation of the species.

Any federal action (permit, license, or funding) in critical habitat requires that federal agency to consult with USFWS where the action has potential to adversely modify the habitat for terrestrial species.

The federally listed wildlife and plant species considered in this EIS that have designated critical habitat areas that could be affected by the project are presented in Table P.1-3.

Table P.1-3. Critical Habitat for Terrestrial Species in the Study Area

Common Name	Scientific Name	Year Designated	Jurisdiction
Soft bird's-beak	*Cordylanthus mollis* ssp. *mollis*	2007	USFWS
Suisun thistle	*Cirsium hydrophilum* var. *hydrophilum*	2007	USFWS
Valley elderberry longhorn beetle	*Desmocerus californicus dimorphus*	1980	USFWS
Western yellow-billed cuckoo	*Coccyzus americanus*	2014 (proposed)	USFWS
California tiger salamander	*Ambystoma californiense*	2011 (Sonoma County DPS), 2005 (Central DPS)	USFWS

P.1.4 Wetlands and Waters of the United States

Wetlands and waters of the United States that occur in the study area are described below.

P.1.4.1 *Lake/Reservoir Communities*

Reservoirs that store CVP and SWP water supplies provide habitat used by some terrestrial species, either within the open water area of the reservoirs or along the margins and in drawdown areas.

P.1.4.1.1 Open Water Areas

Water surface elevations in reservoirs that store CVP and SWP water supplies change seasonally and annually due to hydrologic and operational variables. The open water areas of these reservoirs are used as foraging and resting sites by waterfowl and other birds and by semi-aquatic mammals such as river otter and beaver. Bald eagles and ospreys nest in forests at the margins of these reservoirs and frequently use the reservoirs to forage for fish.

Margins and Drawdown Areas

The CVP and SWP reservoirs in the Central Valley are generally located in canyons where the surrounding slopes are dominated by upland vegetation such as woodland, forest, and chaparral. Within the inundation area, the water surface elevations in these reservoirs fluctuate between maximum allowed storage elevations and minimum elevations defined by the lowest elevation on the intake structure. Along the water surface edge of the inundation area, the soils are usually shallow. Soil is frequently lost to wave action and periodic inundation, followed by severe desiccation when the water elevation declines, generally resulting in a barren drawdown zone around the perimeter of the reservoirs. Natural regeneration of vegetation within the drawdown zone is generally prevented by the timing of seed release when reservoir levels are high in the spring, lack of sediment replenishment necessary for seedling establishment in the spring, and high temperatures combined with low soil moisture levels of exposed soils in the summer.

Lack of vegetative cover within the drawdown zone can limit wildlife use of this area. Rapidly rising reservoir levels can potentially result in direct mortality of some sedentary wildlife species or life stages within the drawdown zone of reservoirs. As reservoir levels drop, energy expenditures can increase for piscivorous (fish-eating) birds foraging in the reservoirs as these species must travel greater distances to forage (DWR 2004).

P.1.4.2 *Riverine Communities*

The rivers and streams influenced by the long-term coordinated operation of the CVP and SWP support habitats for plants and wildlife. The primary components of the riverine environment that support plants and wildlife, including open water areas and adjacent riparian and floodplain communities (including bypasses that are inundated at high flows), are described below.

P.1.4.2.1 Open Water Areas

The riverine environment downstream of reservoirs is managed generally for water supply and flood control purposes. As such, the extent of open water in the rivers varies somewhat predictably, although not substantially, within and among years. In the wetter years when bypasses and floodplains are inundated, vast areas of open water become available during the flood season, generally in the late winter and early spring. Open water portions of riverine systems provide foraging habitat for fish-eating birds and waterfowl. Gulls, terns, ospreys, and bald eagles forage over open water. Near-shore and shoreline areas provide foraging habitat for birds such as waterfowl, herons, egrets, shorebirds, and belted kingfishers. Many species of insectivorous birds such as swallows, swifts, and flycatchers forage over open water areas of lakes and streams. Mammals known to associate with open water and shoreline habitats include river otters, American minks, muskrats, and beavers.

P.1.4.2.2 Riparian and Floodplain Areas

The riparian and floodplain communities that could be affected by CVP and SWP operations entail the vegetation and associated wildlife community supported and influenced by proximity to the waterway, including areas frequently flooded by rising water levels in the rivers (floodplains). The extent of riparian vegetation within the Central Valley has been reduced over time due to a variety of actions, including local, state, and federal construction and operation of flood control facilities on isolated historic floodplains; agricultural and land use development that occurred following development of flood control projects; regulation of flows from dams that has reduced the magnitude and frequency of larger flow events, increased recession rates, and increased summertime flows; and construction and maintenance of active ship channels by USACE (DWR 2012). Currently, levee and bank protection structures associated with the flood protection system are present along more than 2,600 miles of rivers in the Central Valley, including the Delta (DWR 2009).

Characteristic riparian tree species in the Central Valley include willows, cottonwoods, California sycamore, and valley oaks. Typical understory plants include elderberry, blackberries, and poison oak. On the valley floor in the deep alluvial soils, the structure and species composition of the plant communities change with distance from the river, with the denser stands of willow and cottonwood at the water's edge transitioning into stands of valley oaks on the less frequently inundated terraces. In other areas, the riparian zone does not support a canopy of large trees and instead is dominated by shrub species (sometimes referred to as *riparian scrub*).

Riparian and floodplain vegetation supports wildlife habitats because of its high floristic and structural diversity, high biomass and high food abundance, and proximity to water. In addition to providing breeding, foraging, and roosting habitat for an array of animals, riparian and floodplain vegetation also provides movement corridors for some species, connecting a variety of habitats throughout the region. The Sacramento and San Joaquin Valleys lack substantial areas of natural habitat that support native biodiversity or corridors between the areas of natural habitat; therefore, riparian and floodplain corridors play a critical role in connecting wildlife among the few remaining natural areas (California Department of Transportation and CDFG 2010).

River flows and associated hydrologic and geomorphic processes are important for maintaining riparian and floodplain ecosystems. Most aspects of a flow regime (e.g., the magnitude, frequency, timing, duration, and sediment load) affect a variety of riparian and floodplain habitat processes. Two processes that create riparian and floodplain ecosystems are disturbance and plant recruitment. The interaction of these processes across the landscape is primarily responsible for the pattern and distribution of riparian and floodplain habitat structure and condition, and for the composition and abundance of riparian-associated species.

High flow events and associated scour, deposition, and prolonged inundation can create exposed substrate for plant establishment or openings in existing riparian and floodplain communities. Early successional species, like cottonwoods and willows that recruit into these openings, become more abundant in the landscape as vegetation grows within disturbed areas. As a result, structural and species diversity within riparian and floodplain vegetation could increase, as could overall wildlife habitat values. Without disturbance, larger trees and species less tolerant of frequent disturbance begin to dominate riparian woodlands.

The recruitment of cottonwoods and willows especially depends on geomorphic processes that create bare mineral soil through erosion and deposition of sediment along river channels and on floodplains, and on flow events that result in floodplain inundation. Receding flood flows that expose moist mineral soil create ideal conditions for germination of cottonwood and willow seedlings. After germination occurs, the water surface must decline gradually to enable seedling establishment. Riparian and floodplain communities also undergo natural disturbance cycles when flood flows remove streamside vegetation and redistribute sediments and seeds, thereby maintaining habitat diversity for terrestrial species that associate with riparian and floodplain corridors.

Both prolonged drought and prolonged inundation, however, can lead to plant death and loss of riparian plants (Kozlowski and Pallardy 2002). Riparian plants have high moisture requirements during the active growing season (spring through fall), and dry soil conditions can reduce growth and injure or kill plants. On the other hand, prolonged inundation creates anaerobic conditions that, during the active growing season, also can reduce growth, injure, or kill plants.

The continuation of riparian and floodplain communities is anticipated to change along levees within the federally authorized levee systems that have maintenance agreements with the USACE (including Delta levees along the Sacramento and San Joaquin Rivers) and other levees that are eligible for the federal Rehabilitation and Inspection Program (Public Law 84-99). The vegetation management policies of the USACE were changed in 2009 and 2010. Historically, the USACE allowed brush and small trees to be located on the waterside of federal flood management project levees if the vegetation would preserve, protect, and/or enhance natural resources, and/or protect rights of Native Americans, while maintaining the safety, structural integrity, and functionality of the levee (DWR 2011). After Hurricane Katrina in 2005, the USACE issued a policy and draft policy guidance to remove substantial vegetation from these levees throughout the nation. In 2010, the USACE issued a draft policy guidance letter, *Draft Process for Requesting a Variance from Vegetation Standards for Levees and Floodwalls* (75 FR 6364-6368) that included procedures for state and local agencies to request variances on a site-specific basis. DWR has been in negotiations with USACE to remove vegetation on the upper third of the waterside slope, top, and landside of the levees, and continue to allow vegetation on the lower two-thirds of the waterside slope of the levee and along benches above the water surface.The effects of these changes have not become widespread at this time. Future conditions under these requirements are further described under the description of the No Action Alternative in this technical appendix.

P.1.4.3 *Wetlands, Marshes, and Wet Meadows*

Wetlands in the study area can be characterized as perennial or seasonal with perennial wetlands further classified as tidal or non-tidal. Natural, non-tidal perennial wetlands are scattered along the Sacramento and San Joaquin Rivers, typically in areas with slow moving backwaters. Management of wetlands, marshes, and wet meadows can include irrigating open areas to support native herbaceous plants or cultivated species; periodic or continuous flooding to provide feeding and roosting sites for many wetland-associated birds; and either limited tilling or no tilling or disturbance of the managed areas.

Managed seasonal wetlands on the west side of the Sacramento River generally occur between Willows and Dunnigan along the Colusa Basin Drain. Substantial portions of these managed wetland habitats occur at the flood bypasses, including the Yolo Bypass Wildlife Area and Fremont Weir, as a part of the Sacramento National Wildlife Refuge Complex, and around the Thermalito Afterbay. Both tidal and nontidal, perennial wetlands are found in the Delta and Suisun Marsh.

P.1.4.3.1 Perennial Non-Tidal (Freshwater) Wetlands and Marshes

In the Sacramento and San Joaquin Valleys and foothills, perennial non-tidal wetland habitats include freshwater emergent wetlands and wet meadows. Freshwater emergent wetlands, or marshes, are dominated by large, perennial herbaceous plants, particularly tules and cattails, which are generally restricted to shallow water. In marshes, vegetation structure and the number of species are strongly influenced by disturbance, changes in water levels, and the range of elevations present at a site. Wet meadows are similar to perennial freshwater wetlands in many regards; however, they are dominated by a greater variety of perennial plants such as rushes, sedges, and grasses than are found in freshwater wetlands. Perennial freshwater wetlands also provide ecological functions related to water quality and hydrology. These areas generally qualify as jurisdictional wetlands subject to USACE jurisdiction under Sections 401 and 404 of the federal Clean Water Act.

Perennial freshwater wetlands are among the most productive wildlife habitat in California (CDFG 1988). In the Sacramento and San Joaquin Valleys and foothills, these wetlands support several sensitive amphibians, reptiles, birds, and mammals. Perennial freshwater wetlands also provide food, cover, and water for numerous species of wildlife. Wetlands in the Sacramento and San Joaquin Valleys and foothills are especially important to migratory birds and wintering waterfowl.

P.1.4.3.2 Seasonal Wetlands

Natural seasonal wetlands occur in topographic depressions and swales that are seasonally saturated and exhibit hydric soils that support hydrophytic plant species. Natural seasonal wetlands are generally dominated by hydrophytic plants during the winter and spring months. Characteristic plant species in seasonal wetlands consist of both native and nonnative species. Native species include coyote thistle, toad rush, hyssop loosestrife, and foothill meadowfoam. Natural seasonal wetlands provide food, cover, and water for numerous common and special-status species of wildlife that rely on wetlands for all or part of their life cycle. Like perennial wetlands, seasonal wetlands have been substantially reduced from their historical extent.

Numerous managed seasonal wetlands occur within the Sacramento Colusa, Sutter, Tisdale, and Yolo Bypasses and around the Thermalito Afterbay.

Managed marsh areas are intentionally flooded and managed during specific seasonal periods to enhance habitat values for specific wildlife species (CALFED 2000). Managed marsh areas are distributed largely in the northern, central, and western portions of the Delta, as well as in Suisun Marsh and the Yolo Bypass, Stone Lakes NWR, Cosumnes River Preserve, and Suisun Marsh.

P.1.4.3.3 Perennial Tidal Wetlands and Open Water

In the study area tidal wetlands and open water are primarily found in the Delta and Suisun Marsh. Tidal wetlands are influenced by tidal movement of salt water from San Francisco Bay and inflow of freshwater from the Delta and smaller local watersheds. Salinity levels vary throughout the year and are influenced largely by inflow from the Delta (Reclamation et al. 2011). Tidal open water in the Delta is mainly freshwater habitat, with brackish and saline conditions occurring in the western Delta at times of high tides and low flows into the western Delta. It is freshwater in the Yolo Bypass and mainly brackish and saline in Suisun Marsh. Tidal mudflats occur as mostly unvegetated sediment deposits in the intertidal zone between the tidal wetland communities at its upper edge and the tidal perennial aquatic community at its lower edge. Tidal brackish wetlands exist from near Collinsville westward to the Carquinez Strait.

Suisun Marsh is the largest contiguous brackish water marsh remaining on the North America west coast (Reclamation et al. 2011). Tidal freshwater marshes occur at the shallow, slow-moving or stagnant edges of freshwater waterways in the intertidal zone and are subject to frequent, long duration flooding.

P.2 Evaluation of Alternatives

This section describes the technical background for the evaluation of environmental consequences associated with the Project alternatives and the No Action Alternative. This section also describes the results of the impact analysis for each Project alternative and the No Action Alternative. Most of the actions from the project that will affect terrestrial species are programmatic. The only effects from project-specific actions are from flow changes, discussed below. The remainder of the effects are associated with programmatic-level actions.

P.2.1 Technical Background

P.2.1.1 *Land Cover*

Reclamation used existing land cover data to assess effects on terrestrial biological resources. Data sources are listed below:

- Aerial Information Systems, Inc. 2011. Delta Vegetation and Land Use. Available: ftp://ftp.dfg.ca.gov/BDB/GIS/BIOS/Public_Datasets/200_299/ds292.zip. Accessed: December10, 2018.

P.2.1.2 *Federally Listed Species and Critical Habitat*

To identify federally listed as endangered and threatened species that may occur in the study area, Reclamation used the list generated by the IPaC online service. The species identified by the IPaC list are shown in Tables P.1-1 and P.1-2.

To determine which project components could affect the federally listed terrestrial species identified in Tables P.1-1 and Q-1.2, Reclamation reviewed species range maps to assess which project components overlap the species' ranges. All the range maps originated from the following data sources:

- California Department of Fish and Wildlife California Interagency Wildlife Task Group. 2016. California Tiger Salamander Range. Available: ftp://ftp.dfg.ca.gov/BDB/GIS/BIOS/Public_Datasets. Accessed: January 24, 2019.
- California Department of Fish and Wildlife California Interagency Wildlife Task Group. 2016. Clapper Rail Range. Available: ftp://ftp.dfg.ca.gov/BDB/GIS/BIOS/Public_Datasets. Accessed: January 2, 2019.
- California Department of Fish and Wildlife California Interagency Wildlife Task Group. 2016. Giant Garter Snake Range. Available: ftp://ftp.dfg.ca.gov/BDB/GIS/BIOS/Public_Datasets. Accessed: January 2, 2019.

- U.S. Fish and Wildlife. 2005. Vernal Pool Core Areas.

Reclamation used existing species habitat models where available to assess which project components would affect the habitat of federally listed species. Reclamation developed mitigation measures with the first goal being to avoid effects on federally listed species and the second goal being to minimize and compensate for unavoidable effects. Reclamation analyzed each project component to determine whether it could fully avoid effects on federally listed species. If effects were determined to be unavoidable, or potentially unavoidable, Reclamation developed measures to compensate for unavoidable effects. All effects on federally listed species are addressed at a programmatic level and are qualitatively described rather than quantified.

The analyses of potential effects on species' designated critical habitat follow the species analyses. Potential effects on primary constituent elements (PCEs)/physical and biological features (PBFs) of critical habitat are analyzed for western yellow-billed cuckoo and valley elderberry longhorn beetle. These analyses often draw on the foundation provided in the species analyses. Analysis of effects on critical habitat is guided by consideration of recent analyses by USFWS and National Marine Fisheries Service , which included refined interpretation of critical habitat PCEs/PBFs relative to the original descriptions at the time critical habitat was designated.

P.2.1.3 *Special-Status Species That Are Not Federally Listed*

To identify non-federally listed special-status species that may occur in the study area, Reclamation queried the CNDDB (CDFW 2019). These species are listed in Tables P.1-1 and P.1-2. Reclamation then evaluated each of these species based on the species' habitat and the distribution of land cover types in the study area that meet each species' habitat requirements.

For species with potential to be affected as identified in Tables P.1-1 and P.1-2, Reclamation developed mitigation measures with the first goal being to avoid effects on each special-status species, and the second goal being to minimize and compensate for unavoidable effects. Reclamation analyzed each project component to determine whether it could fully avoid effects on the special-status species. If effects were determined to be unavoidable, or potentially unavoidable, Reclamation developed measures to minimize and compensate for unavoidable effects. All effects on special-status species are addressed at a programmatic level and are qualitatively described rather than quantified.

P.2.1.4 *Wetlands and Waters of the United States*

Wetlands and waters of the United States in the study area that could be potentially affected have not been delineated, and the footprints of many of the project components are unknown; therefore, Reclamation addresses effects on wetlands and waters of the United States at a programmatic, qualitative level only. Based on land cover data described in Section P.2.1.1, *Land Cover*, Reclamation evaluated which wetland/waters land cover types may be affected by project components, developed measures for avoiding effects on these wetlands, and developed measures for minimizing and mitigating unavoidable effects.

P.2.2 No Action Alternative

The No Action Alternative for the project means that Reclamation and DWR would continue with current operations of the CVP and SWP. Under the No Action Alternative, no additional habitat restoration activities would occur other than the 8,000 acres of restoration required in the 2009 Biological Opinion. There would be no additional restoration in the Upper Sacramento, American River, Bay-Delta, Stanislaus, or Lower San Joaquin River Watersheds. Other than for 8,000 acres of restoration in the Bay-Delta area, habitat in these watersheds along rivers and tidal channels and in floodplains and marshes currently occupied by or suitable for terrestrial species would remain in the same condition as described in Section P.1.1, *Vegetation and Wildlife*, affected only by normal seasonal and annual variations and future climate change. Under the No Action Alternative, the existing UC Davis Fish Culture and Conservation Laboratory (FCCL) would be used to produce and release up to 50,000 adult Delta Smelt annually into the Bay-Delta to supplement the existing population. The proposed Delta Fish Species Conservation Hatchery (Conservation Hatchery) in Rio Vista would not be built nor constructed in areas that are occupied by or could potentially support terrestrial species such as burrowing owl, California tiger salamander, and vernal pool invertebrates.

P.2.3 Alternative 1

P.2.3.1 Project-Level Effects

Potential changes to wildlife and plant habitat on river banks

Compared to the No Action Alternative, operation of the CVP and SWP under Alternative 1 would change river flows and reservoir levels, which would change existing flow conditions. If river flows or reservoir levels have substantive declines or increases in areas with wildlife or plant habitat, the flows could adversely affect that habitat. Alternative 1, however, would have only minor changes to the water levels in reservoirs and along rivers. The flow changes are relatively small during each year type and would not result in substantive changes to riparian habitat.

For the purposes of the wildlife and plant species analyses, *flow changes* constitute the expected effects of implementing Alternative 1 in comparison with the No Action Alternative. Differences in flow management between Alternative 1 and the No Action Alternative would have the potential to affect a special-status wildlife or plant species if flow changes were to directly affect the species, directly alter habitat availability or quality, or result in vegetation changes that would alter habitat availability or quality. The great majority of stream channels within the study area are linear channels confined by levees or other engineered works that provide negligible habitat for special-status wildlife or plant species. There is, however, potential to affect such species at those sites where habitat has not been removed by channel alteration, or where habitat has been restored, or where habitat is expected to be restored during the proposed term of the proposed action. In the first two of these cases, existing habitat shows evidence of adaptation to anthropogenic modifications to the ecosystem that date back decades and, in many cases, over a century. These modifications include hydrologic changes associated with water manipulation; topographic changes associated with flood control, agriculture, restoration site construction, and other causes; and biological changes associated with the introduction of nonnative species. Implementation of Alternative 1 would generally result in very minor potential changes relative to the No Action Alternative, and these changes are small relative to normal month-to-month and year-to-year variability in the system.

Compared to the No Action Alternative, Alternative 1 is expected to have only minor effects on habitat along the banks of rivers and reservoirs; however, flow changes would have the potential to affect the amount of yellow-billed cuckoo riparian habitat. Alternative 1 may modify flows in a manner that would limit channel-forming flows, which could result in less riparian habitat establishment and expansion over time. If hydrologic modifications lead to too little or too much water during different times of the year, existing riparian habitat could be affected (79 FR 59991 60038); higher flows could result in erosion and potential loss of riparian vegetation while lower flows—especially in spring—could result in drought stress or less riparian vegetation recruitment, such as cottonwood seed dispersal. The hydrologic regime (stream flow pattern) and supply of (and interaction between) surface and subsurface water are driving factors in the long-term maintenance, growth, recycling, and regeneration of western yellow-billed cuckoo habitat (78 FR 61621 61666). Higher flows could also result in higher sedimentation along the channel banks that similarly result in the inability of riparian vegetation to establish or regenerate. Alternatively, lower flows could diminish the water table, leading to reduced groundwater availability and water stress in riparian trees. Physiological stress in native vegetation from prolonged lower flows or groundwater results in reduced growth rate, morphological change, or mortality of plants; altered species composition dominated by more drought-tolerant vegetation; and conversion to habitat dominated by nonnative species (Poff et al. 1997). These effects reduce and degrade habitat for the western yellow-billed cuckoo for foraging, nesting, and cover.

Flow change could adversely affect nesting habitat for bank swallows on the Sacramento and Feather Rivers. One of the primary threats to bank swallows is loss of nesting habitat from the placement of rock revetment for levee stabilization. Because of resulting limited available habitat and the reduction of natural river processes, the species is highly sensitive to 1) reductions in winter flows which are necessary to erode banks for habitat creation, and 2) high flows during the breeding season (generally April 1–August 31). The potential impacts of changes in upstream flows on bank swallows during the breeding season are the flooding of active burrows and destruction of colonies from increased bank sloughing.

Bank swallows arrive in California and begin to excavate their burrows in March, and peak egg-laying occurs between April and May (Bank Swallow Technical Advisory Committee 2013). Therefore, high-flow events on the Sacramento and Feather Rivers that occur after March when the swallows have nested and laid eggs in the burrows could adversely affect bank swallows and result in the loss of nests. On the Sacramento River, breeding season flows between 14,000 and 30,000 cubic feet per second (cfs) have been associated with localized bank collapses that resulted in partial or complete colony failure (Stillwater Sciences 2007).

Additionally, flows above 50,000 cfs on the Sacramento River could lead to multiple colony failures during the breeding season, but they may be beneficial during the non-breeding season because erosion can create new breeding habitat in the form of cut banks (Stillwater Sciences 2007).

Model results illustrate that, relative to the No Action Alternative, flows on the Sacramento River would be higher under Alternative 1 (due to spring pulses) during the bank swallow breeding season. Projected differences between the No Action Alternative and Alternative 1 would occur from mid-April to July; during this time period, average flows on the Sacramento River under Alternative 1 would be slightly greater than under the No Action Alternative but slightly lower than under Alternatives 2 and 3.

Average flows on the Sacramento River downstream of Keswick Reservoir, at Bend Bridge, and below Red Bluff Diversion Dam would increase under Alternative 1 during the bank swallow breeding season, with model results predicting flow staying below 15,000 cfs. Average flows on the Sacramento River at Hamilton City, at Wilkins Slough, and at Freeport under Alternative 1 would generally decrease during the bank swallow breeding season. Monthly flows are highest at Freeport during the bank swallow breeding season, with predicted monthly flows between 15,000 and 19,000 cfs under Alternative 1.

Model results illustrate that, relative to the No Action Alternative, flows on Feather River would be higher under Alternative 1 (due to spring pulses) during the bank swallow breeding season. Projected differences between the No Action Alternative and Alternative 1 would occur from mid-May to July. Average flows on Feather River downstream of Thermalito would increase under Alternative 1 during the bank swallow breeding season, with model results predicting peak flows of 7,000 cfs. However, average flows on the Feather River at the Sacramento River confluence would decrease under Alternative 1 during the bank swallow nesting season.

P.2.3.2 *Program-Level Effects*

Potential changes to existing marshes and associated special-status species in the Bay-Delta region

Alternative 1 would restore tidal wetlands, diked wetlands, and muted marsh habitat in the Bay-Delta region. Several sites including Dutch Slough, Winter Island, Hill Slough, Arnold Slough/Bradmoor Island, Chipps Island, and Lower Yolo Ranch are being restored to tidal habitat as mitigation for adverse impacts on Delta Smelt and its habitat. Tidal habitat restoration at each site would be achieved by conversion of currently leveed, cultivated land through breaching or setback of levees, thereby restoring tidal fluctuation to land parcels currently isolated behind those levees. Where appropriate, portions of restoration sites would be raised to elevations that would support tidal marsh vegetation following levee breaching. Depending on the degree of subsidence and location, lands may be elevated by grading higher elevations to fill subsided areas, importing clean dredged or fill material from other locations, or planting tules or other appropriate vegetation to raise elevations in shallowly subsided areas over time through organic material accumulation. Surface grading would create a shallow elevation gradient from the marsh plain to the upland transition habitat. Based on assessments of local hydrodynamic conditions, sediment transport, and topography, restoration activities may be designed and implemented in a manner that accelerates the development of tidal channels within restored marsh plains. Following reintroduction of tidal exchange, tidal marsh vegetation is expected to establish and maintain itself naturally at suitable elevations relative to the tidal range. Depending on site-specific conditions and monitoring results, patches of native emergent vegetation may be planted to accelerate the establishment of native marsh vegetation on restored marsh plain surfaces.

Habitat restoration activities and restoration of tidal inundation could have deleterious short-term effects on existing tidal, non-tidal, and managed marsh habitats and associated special-status species, including Suisun marsh aster, Mason's lilaeopsis, Bolander's water hemlock, soft bird's-beak, Suisun thistle, delta tule pea, western pond turtle, California black rail, California Ridgway's rail, Suisun song sparrow, saltmarsh common yellowthroat, short eared owl, Suisun shrew, and salt-marsh harvest mouse. The potential effects on tidal marsh habitat would include the conversion of mid- and high-marsh habitat types to low-marsh types; the conversion of low-marsh habitat to subtidal habitat; and the conversion of upland refugia habitat to tidal habitat. While it is expected that the habitat would persist after restoration of tidal action, the extent of mid- and high-marsh is expected to decrease in the near-term. In the longer-term, and with the implementation of remedial measures, the extent of habitat is expected to expand. The extent of habitat may not expand to pre-restoration conditions, although the habitat will be of great extent and more resilient to climate change because tidal habitat has potential to accrete sediment to keep up with sea level rise whereas diked wetlands do not. Furthermore, diked wetlands have the risk of breached dikes that cause excessive flooding of mid- and high-marsh habitats.

Tidal habitat restoration is not expected to occur in areas with occupied habitat for soft bird's-beak or Suisun thistle, and no negative effects would be expected from restoration activities. Over time, the restored and enhanced area is expected to be suitable and of higher long-term value for the species because it would be less vulnerable to sea level rise by including gradual slopes up from the current tidal region, potentially allowing introduction of the species into the restored areas. Thus, Alternative 1 is expected to have a wholly beneficial effect on special-status plant species.

Potential changes to existing riparian areas and associated special-status species

Habitat restoration under Alternative 1 could result in the loss of riparian habitat and associated special-status species. Riparian species potentially affected include valley elderberry longhorn beetle, western yellow-billed cuckoo, foothill yellow-legged frog, least Bell's vireo, yellow warbler, Swainson's hawk, white-tailed kite, yellow-breasted chat, osprey, bald eagle, ring-tailed cat, riparian brush rabbit, and riparian woodrat.

Alternative 1 includes creation of spawning habitat and side channels along rivers, floodplain restoration, or other aquatic habitat restoration in riparian areas. The construction of setback levees to restore seasonally inundated floodplain could permanently remove species habitat and would be expected to transition species habitat from areas that flood frequently (i.e., every 1–2 years) to areas that flood infrequently (i.e., every 10 years or more). Periodic inundation as a result of floodplain restoration is not expected to adversely affect nesting bird species because flooding is unlikely to occur during the breeding season, and the potential effects of inundation on existing riparian vegetation are expected to be minimal. While frequent flooding in the lower elevations of the floodplain may result in scouring of riparian vegetation, this is expected to have a beneficial rather than an adverse long-term effect on most riparian species because periodic scouring increases successional and structural diversity of the habitat.

Floodplain restoration may result in periodic flooding of habitat for riparian brush rabbit and riparian woodrat, which are primarily ground-dwelling species that are adversely affected by flooding if no upland refugia are available during flood events. In addition, the removal of oak trees in floodplains would remove nest building materials for riparian woodrats in floodplains. However, the mitigation measure for riparian brush rabbit and riparian woodrat (MM BIO-21) will avoid and minimize both of these impacts. MM BIO-21 requires floodplain restoration projects to include refugia habitat to provide shelter from flood events and avoidance of mature oak trees in areas identified by a qualified biologist as being occupied by riparian brush rabbit and riparian woodrat. MM BIO-21 also puts limits on the amount of habitat that can be impacted by restoration.

Potential changes to habitat for special-status reptiles

Alternative 1 includes creation of spawning habitat and side channels along rivers, channel margin restoration, floodplain restoration, and other aquatic habitat restoration on the banks of waterbodies that could result in loss of habitat for giant garter snake and western pond turtle. Aquatic habitat and floodplain restoration could result in directly mortality of these species.

Permanent effects on giant garter snake aquatic habitat are likely to occur when agricultural ditches are modified and flooded as part of the tidal habitat restoration process. Permanent effects on both giant garter snake and western pond turtle habitat could occur where channel margin restoration entails levee setback. For giant garter snake, the conversion of rice to tidal habitat would be a permanent loss; however, rice is not common in the areas where tidal restoration and channel margin restoration would likely be sited. Other aquatic features with potential to occur on restoration sites include natural channels and topographic depressions. Tidal aquatic edge habitat where open water meets the levee edge will also be permanently lost in those reaches where the levee is breached. Temporary effects on aquatic edge habitat are also likely to occur during the time of construction, though these effects would not be expected to last more than 2 years. Permanent effects on upland habitat will primarily occur where upland habitat is removed to create tidal connectivity.

Potential to injure or kill special-status species

Construction-related actions associated with habitat restoration and the installation/upgrade of facilities under Alternative 1 could injure or kill special-status species in occupied habitat. The operation of equipment for land clearing and restoration could result in injury or mortality of special-status species. This risk is highest for species with periods of dormancy, like California tiger salamander and giant garter snake. Increased vehicular traffic associated with construction activities could contribute to a higher incidence of road kill. However, construction monitoring and other mitigation measures have been identified to avoid and minimize injury or mortality of special-status species during construction.

In tidal marsh habitat, construction actions such as excavation of levees, construction of tidal control gates, movement and staging of large construction equipment, piling and storage of soils, dredging, and filling and grading of vegetated areas could cause the injury or mortality of special-status species that may be in the vicinity of the construction area. Tidal marsh species are especially vulnerable during periods of higher tides and peak flooding by storms; during these periods, these species move into upland marsh areas for protection. Tidal marsh species could drown or be preyed upon if construction activities or equipment isolate tidal marsh species from their refugia habitat or confuse or disturb them.

Equipment operation for the creation of side channels and levees in riparian habitat during periods of high seasonal activity, such as the nesting bird or bat maternity seasons, could also injure or kill special-status species. Risk is greatest to bird eggs and nestlings or bat pups that could be injured or killed through crushing by heavy equipment, nest abandonment, or increased exposure to the elements or to predators. Injury to adults and fledged juveniles is unlikely, as these individuals are expected to avoid contact with construction equipment.

Night construction could disrupt animal behavior and/or sleep cycles or adversely affect bat foraging activity in all impacted habitat types if special-status species are exposed to night lighting. For example, bird species are attracted to artificial lights, which may disrupt their behavioral patterns or cause collision-related fatalities (Gauthreaux and Belser 2006). Night lighting can also result in circadian/behavior disruptions which can cause bird species to molt and develop their reproductive system earlier than in dark nights. Night lighting can also influence the endocrine system of vertebrates, which can lead to health deterioration (Fonken and Nelson 2014; Ouyang et al. 2018).

Construction-related noise levels could cause additional behavioral modifications if special-status species are present in the general vicinity. Construction activities may create noise up to 60 dBA at no more than 1,200 feet from the edge of the noise generating activity. While 60 dBA is the standard noise threshold for birds (Dooling and Popper 2007), this standard is generally applied during the nesting season, when birds are more vulnerable to behavioral modifications that can cause nest failure. There is evidence, however, that migrating birds will avoid noisy areas during migration (McClure et al. 2013). Noise and visual disturbance outside the project footprint but within 200 feet of construction activities could temporarily affect the use of adjacent habitat by giant garter snake. These effects will be minimized by siting construction 200 feet away from the banks of giant garter snake aquatic habitat, where feasible, as described in MM BIO-5.

Contaminants could be introduced into species' habitats as a result of construction. Exhaust from construction and maintenance vehicles may result in deposition of particulates, heavy metals, and mineral nutrients that could influence the quality and quantity of vegetation and thereby affect presence and abundance of special-status species. The use of mechanical equipment during construction might cause the accidental release of petroleum or other contaminants that will affect occupied, suitable, or adjacent habitat. These accidental spills could also affect special-status species prey, resulting in less food availability. Increased runoff from impervious surfaces into wetland areas carries pollutants that are harmful to reptiles and amphibians, which are particularly sensitive to contaminants and other pollutants in the water.

Potential changes to vernal pools and associated special-status species

Tidal habitat restoration and the construction of the Conservation Hatchery under Alternative 1 could have direct and indirect effects on vernal pools and associated special-status species. Vernal pool species that could be affected include California tiger salamander, Contra Costa goldfields, and vernal pool invertebrates. Direct effects include loss of habitat and individual mortality as a result of construction. Tidal natural community restoration could result in the permanent loss of vernal pool crustacean habitat. It is anticipated that much of the existing vernal pool habitat that would be impacted by the project is already degraded. Vernal pools in the Sacramento and San Joaquin Valleys have already experienced significant disturbance due to agricultural development (e.g., plowing, disking, or leveling), which results in compacted soils, loss of hydrologic connections, and reductions in the size and extent of vernal pools.

Construction of the Conservation Hatchery could result in direct removal of vernal pools if it is constructed in an area that contains vernal pool complexes. Similarly, if these pools are occupied, vernal pool crustaceans could be destroyed. These effects will be avoided through the implementation of the identified/proposed mitigation measures.

Indirect conversion of vernal pool habitat could also occur due to hydrological changes as a result of tidal habitat restoration or construction of the hatchery. Construction restoration activities may result in the modification of hardpan and changes to the perched water table, which could lead to alterations in the rate, extent, and duration of inundation of nearby vernal pool crustacean habitat. USFWS typically considers construction within 250 feet of vernal pool crustacean habitat to constitute a possible conversion of crustacean habitat unless more detailed information is provided to further refine the limits of any such effects. Therefore, MM BIO-1 will ensure a buffer of 250 feet for construction or restoration near vernal pool habitat.

Potential to affect special-status bat species and their habitat

Special-status bat species with potential to occur in the study area employ varied roost strategies, from solitary roosting in foliage of trees to colonial roosting in trees and artificial structures such as tunnels, buildings, and bridges. Various roost strategies could include night roosts, maternity roosts, migration stopover, or hibernation. Special-status bat roosting habitats include riparian habitat, developed lands, and landscaped trees such as eucalyptus, palms, and orchards. Potential foraging habitat includes all riparian habitat types, cultivated lands, developed lands, grasslands, and wetlands.

Four California bat species of special concern could occur in the study area (Table P.1-1) as could several common bat species. Construction and restoration activities associated with Alternative 1 would result in both temporary and permanent losses of foraging and roosting habitat for special-status bat species. Tidal habitat restoration and floodplain restoration would result in permanent and temporary loss of riparian roosting habitat and conversion of foraging habitat from mostly cultivated lands and managed wetlands to tidal and nontidal wetlands. Development of the Conservation Hatchery could also result in the removal of roosting and foraging habitat. Noise and visual disturbances during implementation of riparian habitat restoration and other construction activities could result in temporary disturbances that, if bat roost sites are present, could cause temporary abandonment of roosts. Impacts on special-status bat species that occupy artificial structures are expected to be negligible in comparison to the amount of impacts on natural habitat types, but temporary and permanent impacts on special-status bat species occupying artificial structures could result in local adverse effects.

Despite having potential to result in some adverse effects, implementation of Alternative 1 would result in an overall benefit to special-status bats within the study area through restoration of their foraging and roosting habitats. The majority of affected habitat would be agricultural, and such land would be converted to natural communities with higher value foraging and roosting potential such as riparian land, tidal and nontidal wetlands, and periodically inundated lands. Restored habitats are expected to be of higher value because, compared to agricultural land, pesticide use would be lower and greater numbers of flying insect prey species would be available. In addition, any impact from construction, restoration, or periodic inundation on special-status bats and their habitat would be mitigated through implementation of MM BIO-24, which would ensure there is no significant impact on roosting special-status bats, either directly or through habitat modifications, and no substantial reduction in numbers nor a restriction in the range of special-status bats.

Potential changes to wetlands and waters of the United States

The restoration projects associated with Alternative 1 would likely require some fill of wetlands and waters of the United States. Fill could occur from dredging work, spoils areas, side channel construction, and installation of the Conservation Hatchery. The majority of the impacts on wetlands and waters of the United States are likely on tidal channels, emergent wetlands, and on wetlands and waters found within cultivated lands (agricultural ditches and seasonal wetlands). Reclamation will obtain and implement the conditions and requirements of state and federal permits that may be required prior to the construction of the proposed project.

Unavoidable impacts on waters of the United States would be offset such that the loss of acreage and functions due to construction activities are fully compensated. The restoration projects would ultimately result in a net increase of wetlands and waters of the United States, but restoration could result in short-term losses.

Restoration could also result in conversion from one wetland type to another. Wetland functions are defined as a process or series of processes that take place within a wetland. These include the storage of water, transformation of nutrients, growth of living matter, and diversity of wetland plants, and they have value for the wetland itself, for surrounding ecosystems, and for people. Functions can be grouped broadly as habitat, hydrologic/hydraulic, or water quality. Not all wetlands perform all functions nor do they perform all functions equally well. The location and size of a wetland may determine what functions it will perform. For example, the geographic location may determine its habitat functions, and the location of a wetland within a watershed may determine its hydrologic/hydraulic or water quality functions. Many factors determine how well a wetland will perform these functions: climatic conditions, quantity and quality of water entering the wetland, and disturbances or alteration within the wetland or the surrounding ecosystem. Wetland disturbances may be the result of natural conditions, such as an extended drought, or human activities, such as land clearing, dredging, or the introduction of nonnative species. Wetlands are among the most productive habitats in the world, providing food, water, and shelter for fish, shellfish, birds, and mammals, and serving as a breeding ground and nursery for numerous species. Many endangered plant and animal species are dependent on wetland habitats for their survival. Hydrologic and hydraulic functions are those related to the quantity of water that enters, is stored in, or leaves a wetland. These functions include such factors as the reduction of flow velocity, the role of wetlands as groundwater recharge or discharge areas, and the influence of wetlands on atmospheric processes. Water-quality functions include the trapping of sediment, pollution control, and the biochemical processes that take place as water enters, is stored in, or leaves a wetland.

The functions of the waters of the United States that would be temporarily or permanently impacted by Alternative 1 would vary, depending primarily on existing land uses and historical levels of disturbance. Generally, agricultural ditches and conveyance channels, which are regularly maintained and often devoid of vegetation, support only minimal hydraulic function (water conveyance), with virtually no water quality or habitat function. Some facilities that are regularly maintained can still support some hydrologic, hydraulic, and water quality functions (e.g., reduction of velocity, groundwater recharge, and trapping of sediment). Tidal channels affected by Alternative 1 support functions in all three categories, but the level at which these functions perform vary depending on setting, size, and level of disturbance. Alkaline wetlands and vernal pools exist in nonnative grasslands and have been subjected to some disturbance due to past land uses. Although these features likely support habitat, water quality, and hydrologic/hydraulic functions, the capacity of these features to perform such functions vary depending on the overall ecological setting and level of disturbance. Functions associated with emergent wetland, forest, and scrub-shrub depend primarily on the location of these habitat types. Where they exist as in-stream (in-channel) islands or as the thick band of habitat adjacent to a waterway, these features are expected to function at a high level. However, where these habitats exist as thin bands, or where they are situated in agricultural fields, their habitat functions would be considerably lower. All wetlands classified as seasonal wetlands occur in agricultural fields. As such, their habitat functions have been greatly compromised, but they retain some water quality and hydrologic/hydraulic function. Like seasonal wetlands, most depressions occur within agricultural areas; however, the depressions may support wetland vegetation at their edges.

Potential changes to terrestrial species' critical habitat

The restoration projects under Alternative 1 could result in loss of terrestrial species' critical habitat. Western yellow-billed cuckoo proposed critical habitat is present in Tisdale Bypass and Sutter Bypass. However, Alternative 1 does not propose to modify flows in the Tisdale or Sutter Bypasses. Changes in frequency of inundation in the Sacramento River would be minor, and within the current minimum and maximum flows. Alternative 1 could provide for some different riparian species that require year-round flows, as compared to the No Action Alternative, where low flows in the fall would stress invasive plants and encourage drought-tolerant native species to persist.

Critical habitat for valley elderberry longhorn beetle is present along the American River. However, under the action alternatives Reclamation will avoid valley elderberry longhorn critical habitat.

Critical habitat for vernal pool fairy shrimp and vernal pool tadpole shrimp is present in areas that Reclamation could potentially use for tidal habitat restoration. Reclamation will, however, avoid areas that would affect the primary constituent habitat elements for these species in the critical habitat units.

Critical habitat for California tiger salamander is present in areas that Reclamation could potentially use for tidal habitat restoration. Reclamation will, however, avoid areas that would affect the primary constituent habitat elements for this species in the critical habitat units.

Critical habitat for soft bird's-beak and Suisun thistle is present in areas that Reclamation could potentially use for tidal habitat restoration. Reclamation will, however, avoid areas that would affect the primary constituent habitat elements for these species in the critical habitat units.

P.2.4 Alternative 2

With respect to terrestrial species, Alternative 2 is nearly the same as the No Action Alternative described in Section P.2.2, *No Action Alternative*. Like the No Action Alternative, Alternative 2 proposes no additional restoration activities that would affect terrestrial species, and the existing FCCL would be used to produce and release Delta Smelt instead of constructing and using the new Conservation Hatchery. The only effects on terrestrial species under Alternative 2 would be from river flows, which would be slightly higher than under the No Action Alternative and Alternative 1, and from reservoir levels and inundation in the Yolo and Sutter Bypasses, which are discussed in Section P.2.3, *Alternative 1*, and Section P.2.5, *Alternative 3*.

Based on data indicating bank swallow colonies may be affected at 14,000 to 30,000 cfs, Alternative 2 would not have a significant effect on erosion of bank swallow colonies compared with the No Action Alternative.

P.2.5 Alternative 3

P.2.5.1 *Project-Level Effects*

Potential changes to wildlife and plant habitat on river banks.

Compared to the No Action Alternative, operation of the CVP and SWP under Alternative 3 would change river flows and reservoir levels, which would change existing flow conditions. If river flows or reservoir levels have substantive declines or increases in areas with riparian vegetation, the flows could adversely affect habitat. For example, higher flows could result in erosion and potential loss of riparian vegetation while lower flows, especially during the spring, could result in drought stress or less riparian vegetation recruitment, such as cottonwood seed dispersal. Alternative 3, however, would result in only minor changes to the water levels in reservoirs and along rivers. The flow changes are relatively small during each year type and would not result in substantive changes to riparian habitat.

For the purposes of the wildlife and plant species analyses, *flow changes* constitute the expected effects of implementing Alternative 3 in comparison with the No Action Alternative. Differences in flow management between Alternative 3 and the No Action Alternative would have the potential to affect a special-status wildlife or plant species if flow changes were to directly affect the species, directly alter habitat availability or quality, or result in vegetation changes that would alter habitat availability or quality. The great majority of stream channels within the study area are linear channels confined by levees or other engineered works that provide negligible habitat for special-status wildlife or plant species. There is, however, potential to affect such species at those sites where habitat has not been removed by channel alteration, or where habitat has been restored, or where habitat is expected to be restored during the proposed term of the proposed action. In the first two of these cases, existing habitat shows evidence of adaptation to anthropogenic modifications to the ecosystem that date back decades, and in many cases over a century. These modifications include hydrologic changes associated with water manipulation; topographic changes associated with flood control, agriculture, restoration site construction, and other causes; and biological changes associated with the introduction of nonnative species. Implementation of Alternative 3 would generally result in very minor potential changes relative to the No Action Alternative, and these changes are small relative to normal month-to-month and year-to-year variability in the system.

Compared to the No Action Alternative, Alternative 3 is expected to have only minor effects on habitat along the banks of rivers and reservoirs; however, flow changes would have the potential to affect the amount of yellow-billed cuckoo riparian habitat. Alternative 3 may modify flows in a manner that would limit channel-forming flows, which could result in less riparian habitat establishment and expansion over time. If hydrologic modifications lead to too little or too much water during different times of the year, existing riparian habitat could be affected (79 FR 59991–60038); higher flows could result in erosion and potential loss of riparian vegetation while lower flows—especially during the spring—could result in drought stress or less riparian vegetation recruitment, such as cottonwood seed dispersal. The hydrologic regime (stream flow pattern) and supply of (and interaction between) surface and subsurface water are driving factors in the long-term maintenance, growth, recycling, and regeneration of western yellow-billed cuckoo habitat (78 FR 61621 61666). Higher flows could also result in higher sedimentation along the channel banks that similarly result in the inability of riparian vegetation to establish or regenerate. Alternatively, lower flows could diminish the water table, leading to reduced groundwater availability and water stress in riparian trees. Physiological stress in native vegetation from prolonged lower flows or groundwater results in reduced growth rate, morphological change, or mortality of plants; altered species composition dominated by more drought-tolerant vegetation; and conversion to habitat dominated by nonnative species (Poff et al. 1997). These effects reduce and degrade habitat for the western yellow-billed cuckoo for foraging, nesting, and cover.

Flow changes could adversely affect nesting habitat for bank swallows. One the primary threats to bank swallows is loss of nesting habitat from the placement of rock revetment for levee stabilization. Because of this limited available habitat, and the reduction of natural river processes, the species is highly sensitive to 1) reductions in winter flows which are necessary to erode banks for habitat creation, and 2) high flows during the breeding season. The potential impacts of changes in upstream flows on bank swallows during the breeding season are the flooding of active burrows and destruction of burrows from increased bank sloughing. Bank swallows arrive in California and begin to excavate their burrows in March, and peak egg-laying occurs between April and May (Bank Swallow Technical Advisory Committee 2013). Therefore, increases in flows after March when the swallows have nested and laid eggs in the burrows could result in the loss of nests. On the Sacramento River, breeding season flows between 14,000 and 30,000 cfs have been associated with localized bank collapses which resulted in partial or complete colony failure (Stillwater Sciences 2007).

Additionally, flows above 50,000 cfs on the Sacramento River could lead to multiple colony failures during the breeding season, but they may be beneficial during the non-breeding season because erosion can create new breeding habitat in the form of cut banks (Stillwater Sciences 2007).

Model results illustrate that, relative to the No Action Alternative, flows on the Sacramento River would be higher under Alternative 3 during the bank swallow breeding season. Projected differences between the No Action Alternative and Alternative 3 occur from mid-April to July; during this time period, average flows under Alternative 3 would be slightly greater than under the No Action Alternative and Alternative 1.

Average flows on the Sacramento River downstream of Keswick Reservoir, at Bend Bridge, and below Red Bluff Diversion Dam would increase under Alternative 3 during the bank swallow breeding season, with model results predicting flow staying below 15,000 cfs. Average flows on the Sacramento River at Hamilton City, at Wilkins Slough, and at Freeport under Alternative 3 would generally decrease during the bank swallow breeding season. Monthly flows are highest at Freeport during the bank swallow breeding season, with predicted monthly flows between 15,000 and 19,000 cfs under Alternative 3.

Model results illustrate that, relative to the No Action Alternative, flows on Feather River would be higher under Alternative 3 during the bank swallow breeding season. Projected differences between the No Action Alternative and Alternative 3 would occur from mid-May to July. Average flows on Feather River downstream of Thermalito would increase under Alternative 3 during the bank swallow breeding season, with model results predicting peak flows of 7,000 cfs. However, average flows on the Feather River at the Sacramento River confluence would decrease under Alternative 3 during the bank swallow nesting season.

P.2.5.2 *Program-Level Effects*

Potential changes to existing marshes and associated special-status species in the Bay-Delta region

Alternative 3 would restore tidal wetlands, diked wetlands, and muted marsh habitat in the Bay-Delta region. Several sites including Dutch Slough, Winter Island, Hill Slough, Arnold Slough/Bradmoor Island, Chipps Island, and Lower Yolo Ranch are being restored to tidal habitat as mitigation for adverse impacts on Delta Smelt and its habitat. Tidal habitat restoration at each site would be achieved by conversion of currently leveed, cultivated land through breaching or setback of levees, thereby restoring tidal fluctuation to land parcels currently isolated behind those levees. Where appropriate, portions of restoration sites would be raised to elevations that would support tidal marsh vegetation following levee breaching. Depending on the degree of subsidence and location, lands may be elevated by grading higher elevations to fill subsided areas, importing clean dredged or fill material from other locations, or planting tules or other appropriate vegetation to raise elevations in shallowly subsided areas over time through organic material accumulation. Surface grading would create a shallow elevation gradient from the marsh plain to the upland transition habitat. Based on assessments of local hydrodynamic conditions, sediment transport, and topography, restoration activities may be designed and implemented in a manner that accelerates the development of tidal channels within restored marsh plains. Following reintroduction of tidal exchange, tidal marsh vegetation is expected to establish and maintain itself naturally at suitable elevations relative to the tidal range. Depending on site-specific conditions and monitoring results, patches of native emergent vegetation may be planted to accelerate the establishment of native marsh vegetation on restored marsh plain surfaces.

Habitat restoration activities and restoration of tidal inundation could have deleterious short-term effects on existing tidal, non-tidal, and managed marsh habitats and associated special-status species, including Suisun marsh aster, Mason’s lilaeopsis, Bolander’s water hemlock, soft bird’s-beak, Suisun thistle, delta tule pea, western pond turtle, California black rail, California Ridgway’s rail, Suisun song sparrow, saltmarsh common yellowthroat, short eared owl, Suisun shrew, and salt-marsh harvest mouse. The potential effects on tidal marsh habitat would include the conversion of mid- and high-marsh habitat types to low-marsh types; the conversion of low-marsh habitat to subtidal habitat; and the conversion of upland refugia habitat to tidal habitat. While it is expected that the habitat would persist after restoration of tidal action, the extent of mid- and high-marsh is expected to decrease in the near-term. In the longer-term, and with the implementation of remedial measures and adaptive management, the extent of habitat is expected to expand. The extent of habitat may not expand to pre-restoration conditions, although the habitat will be of great extent and more resilient to climate change because tidal habitat has potential to accrete sediment to keep up with sea level rise whereas diked wetlands do not. Furthermore, diked wetlands have the risk of breached dikes that cause excessive flooding of mid- and high-marsh habitats.

Tidal habitat restoration is not expected to occur in areas with occupied habitat for soft bird’s-beak or Suisun thistle, and no negative effects would be expected from restoration activities. Over time, the restored and enhanced area is expected to be suitable and of higher long-term value for the species because it would be less vulnerable to sea level rise by including gradual slopes up from the current tidal region, potentially allowing introduction of the species into the restored areas. Thus, Alternatives 1 and 3 are expected to have a wholly beneficial effect on special-status plant species.

The effect of tidal marsh restoration on special-status species in the Bay-Delta will be magnified under Alternative 3, as compared to the No Action Alternative and Alternative 1, given that Alternative 3 proposes 25,000 acres of habitat restoration within the Delta— more than triple the amount of habitat restoration under the No Action Alternative and Alternative 1. Although it is unknown at this time how much of the affected habitat is suitable for special-status species, it is likely that additional habitat for special-status species would be affected under Alternative 3. Additional habitat restoration would require a greater extent of permanent and temporary habitat loss, the latter of which would be expected to recover and restore over time. Habitat restoration will ultimately benefit special-status species by increasing the amount of available habitat and enhancing degraded habitat areas.

Potential changes to existing riparian areas and associated special-status species

Habitat restoration under Alternative 3 could result in the loss of riparian habitat and associated special-status species. Riparian species potentially affected include valley elderberry longhorn beetle, western yellow-billed cuckoo, foothill yellow-legged frog, least Bell's vireo, yellow warbler, Swainson's hawk, white-tailed kite, yellow-breasted chat, osprey, bald eagle, ring-tailed cat, riparian brush rabbit, and riparian woodrat.

Alternative 3 includes creation of spawning habitat and side channels along rivers, floodplain restoration, or other aquatic habitat restoration in riparian areas. The construction of setback levees to restore seasonally inundated floodplain could permanently remove species habitat and would be expected to transition species habitat from areas that flood frequently (i.e., every 1–2 years) to areas that flood infrequently (i.e., every 10 years or more). Periodic inundation as a result of floodplain restoration is not expected to adversely affect nesting bird species because flooding is unlikely to occur during the breeding season, and the potential effects of inundation on existing riparian vegetation are expected to be minimal. While frequent flooding in the lower elevations of the floodplain may result in scouring of riparian vegetation, this is expected to have a beneficial rather than an adverse long-term effect on most riparian species because periodic scouring increases successional and structural diversity of the habitat.

Floodplain restoration may result in periodic flooding of habitat for riparian brush rabbit and riparian woodrat, which are primarily ground-dwelling species that are adversely affected by flooding if no upland refugia are available during flood events. In addition, the removal of oak trees in floodplains would remove nest building materials for riparian woodrats in floodplains. However, the mitigation measure for riparian brush rabbit and riparian woodrat (MM BIO-21) will avoid and minimize both of these impacts. MM BIO-21 requires floodplain restoration projects to include refugia habitat to provide shelter from flood events and avoidance of mature oak trees in areas a qualified biologist has identified as being occupied by riparian brush rabbit and riparian woodrat. MM BIO-21 also puts limits on the amount of habitat that can be impacted by restoration.

The effect of aquatic habitat and floodplain restoration on special-status species in riparian areas would be magnified under Alternative 3, as compared to the No Action Alternative and Alternative 1, given that Alternative 3 proposes 25,000 acres of habitat restoration within the Delta. More than triple the amount of habitat will be restored under Alternative 3 than under the No Action Alternative and Alternative 1. Although it is unknown at this time how much of this habitat is suitable for special-status species in riparian areas, it is likely that additional habitat for special-status species would be affected under Alternative 3. Additional habitat restoration would result in a greater extent of permanent and temporary habitat loss, the latter of which would be expected to recover and restore over time. Habitat restoration would ultimately benefit special-status species in riparian areas by increasing the amount of available habitat and enhancing degraded habitat areas.

Potential changes to habitat for special-status reptiles

Alternative 3 includes creation of spawning habitat and side channels along rivers, channel margin restoration, floodplain restoration, and other aquatic habitat restoration on the banks of waterbodies that could result in loss of habitat for giant garter snake and western pond turtle. Aquatic habitat and floodplain restoration could result in directly mortality of these species.

Permanent effects on giant garter snake aquatic habitat are likely to occur when agricultural ditches are modified and flooded as part of the tidal habitat restoration process. Permanent effects on both giant garter snake and western pond turtle habitat could occur where channel margin restoration entail levee setback. For giant garter snake, the conversion of rice to tidal habitat would be a permanent loss, however, rice is not common in the areas where tidal restoration and channel margin restoration would likely be sited. Other aquatic features with potential to occur on restoration sites include natural channels and topographic depressions. Tidal aquatic edge habitat where open water meets the levee edge will also be permanently lost in those reaches where the levee is breached. Temporary effects on aquatic edge habitat are also likely to occur during the time of construction, though these effects would not be expected to last more than 2 years. Permanent effects on upland habitat will primarily occur where upland habitat is removed to create tidal connectivity.

The effect of aquatic habitat and floodplain restoration on special-status reptiles would be magnified under Alternative 3, as compared to the No Action Alternative and Alternative 1, given that Alternative 3 proposes 25,000 acres of habitat restoration within the Delta—more than triple the amount of habitat restored under the No Action Alternative and Alternative 1. Although it is unknown at this time how much of this habitat is suitable for special-status reptiles, it is likely that additional habitat for special-status reptiles will be affected. Additional habitat restoration will occur in a greater extent of permanent and temporary habitat loss, the latter of which would be expected to recover and restore. However, both western pond turtle and giant garter snake occur over a substantial range, which will reduce the magnitude of these effects. The giant garter snake range extends from Chico in Butte County to the Mendota Wildlife Area in Fresno County, and western pond turtle is found throughout Washington, Oregon, and California. Habitat restoration would ultimately benefit special-status reptiles by increasing the amount of available habitat and enhancing degraded habitat areas.

Potential to injure or kill special-status species

Construction-related actions associated with habitat restoration and the installation/upgrade of facilities under Alternative 3 could injure or kill special-status species in occupied habitat. The operation of equipment for land clearing and restoration could result in injury or mortality of special-status species. This risk is highest for species with periods of dormancy, like California tiger salamander and giant garter snake. Increased vehicular traffic associated with construction activities could contribute to a higher incidence of road kill. However, construction monitoring and other mitigation measures have been identified to avoid and minimize injury or mortality of special-status species during construction.

In tidal marsh habitat, construction actions such as excavation of levees, construction of tidal control gates, movement and staging of large construction equipment, piling and storage of soils, dredging, and filling and grading of vegetated areas, could cause the injury or mortality of special-status species that may be in the vicinity of the construction area. Tidal marsh species are especially vulnerable during periods of higher tides and peak flooding by storms; during these periods, these species move into upland marsh areas for protection. Tidal marsh species could drown or be preyed upon if construction activities or equipment isolate tidal marsh species from their refugia habitat or confuse or disturb them.

Equipment operation for the creation of side channels and levees in riparian habitat during periods of high seasonal activity, such as the nesting bird or bat maternity seasons, could also injure or kill special-status species. Risk is greatest to bird eggs and nestlings or bat pups that could be injured or killed through crushing by heavy equipment, nest abandonment, or increased exposure to the elements or to predators. Injury to adults and fledged juveniles is unlikely, as these individuals are expected to avoid contact with construction equipment.

Night construction could disrupt animal behavior and/or sleep cycles or adversely affect bat foraging activity in all impacted habitat types if special-status species are exposed to night lighting. For example, bird species are attracted to artificial lights, which may disrupt their behavioral patterns or cause collision-related fatalities (Gauthreaux and Belser 2006). Night lighting can also result in circadian/behavior disruptions which can cause bird species to molt and develop their reproductive system earlier than in dark nights. Night lighting can also influence the endocrine system of vertebrates, which can lead to health deterioration (Fonken and Nelson 2014; Ouyang et al. 2018).

Construction-related noise levels could cause additional behavioral modifications if special-status species are present in the general vicinity. Construction activities may create noise up to 60 dBA at no more than 1,200 feet from the edge of the noise generating activity. While 60 dBA is the standard noise threshold for birds (Dooling and Popper 2007), this standard is generally applied during the nesting season, when birds are more vulnerable to behavioral modifications that can cause nest failure. There is evidence, however, that migrating birds will avoid noisy areas during migration (McClure et al. 2013). Noise and visual disturbance outside the project footprint but within 200 feet of construction activities could temporarily affect the use of adjacent habitat by giant garter snake. These effects will be minimized by siting construction 200 feet away from the banks of giant garter snake aquatic habitat, where feasible, as described in MM BIO-5.

Contaminants could be introduced into species' habitats as a result of construction. Exhaust from construction and maintenance vehicles may result in deposition of particulates, heavy metals, and mineral nutrients that could influence the quality and quantity of vegetation and thereby affect presence and abundance of special-status species. The use of mechanical equipment during construction might cause the accidental release of petroleum or other contaminants that will affect occupied, suitable, or adjacent habitat. These accidental spills could also affect special-status species prey, resulting in less food availability. Increased runoff from impervious surfaces into wetland areas carries pollutants that are harmful to reptiles and amphibians, which are particularly sensitive to contaminants and other pollutants in the water.

Construction-related effects would be magnified under Alternative 3, as compared to the No Action Alternative and Alternative 1, given that Alternative 3 proposes 25,000 acres of habitat restoration within the Delta. Although the construction activities would be the same across Alternatives 1 and 3 (e.g., noise, lighting, equipment), Alternative 3 has a greater potential to occur in special-status species habitat and directly affect (i.e., injure or kill) a special-status species. Given that construction under Alternative 3 would occur in more than double the area that it will occur under Alternative 1, Alternative 3 has a greater potential to impact entire populations in the vicinity of the construction area or even an entire species, especially if that species has restrictive habitat requirements and a narrow range distribution. For example, Suisun shrew is only found in the northern borders of San Pablo and Suisun Bay, and Suisun thistle is known from only two occurrences and is present in Suisun March. However, if construction is properly cited and mitigation measures are in place, impacts on species with restrictive habitat requirements and range distribution can be avoided.

Potential changes to vernal pools and associated special-status species

Tidal habitat restoration and the construction of the Conservation Hatchery under the Alternative 3 could have direct and indirect effects on vernal pools and associated special-status species. Vernal pool species that could be affected include California tiger salamander, Contra Costa goldfields, and vernal pool invertebrates. Direct effects include loss of habitat and individual mortality as a result of construction. Tidal natural community restoration could result in the permanent loss of vernal pool crustacean habitat. It is anticipated that much of the existing vernal pool habitat that would be impacted by the project is already degraded. Vernal pools in the Sacramento and San Joaquin Valleys have already experienced significant disturbance due to agricultural development (e.g., plowing, disking, or leveling) which results in compacted soils, loss of hydrologic connections, and reductions in the size and extent of vernal pools.

Construction of the Conservation Hatchery could result in direct removal of vernal pools if it is constructed in an area that contains vernal pool complexes. Similarly, if these pools are occupied, vernal pool crustaceans could be destroyed. These effects will be avoided through the implementation of the identified/proposed mitigation measures.

Indirect conversion of vernal pool habitat could also occur due to hydrological changes as a result of tidal habitat restoration or construction of the hatchery. Construction restoration activities may result in the modification of hardpan and changes to the perched water table, which could lead to alterations in the rate, extent, and duration of inundation of nearby vernal pool crustacean habitat. USFWS typically considers construction within 250 feet of vernal pool crustacean habitat to constitute and a possible conversion of crustacean habitat unless more detailed information is provided to further refine the limits of any such effects. Therefore, MM BIO-1 will ensure a buffer of 250 feet for construction or restoration near vernal pool habitat.

The effect of the project on vernal pools and special-status species will be magnified under Alternative 3, as compared to Alternative 1, given that Alternative 3 proposes an additional 25,000 acres of habitat restoration. Although it is unknown at this time how much occupied and suitable vernal pool habitat will be impacted by each Action Alternative, additional habitat restoration is likely to impact a greater amount of vernal pool habitat. However, as stated above, MM1 requires full avoidance of vernal pools.

Potential to affect special-status bat species and their habitat

Special-status bat species with potential to occur in the study area employ varied roost strategies, from solitary roosting in foliage of trees to colonial roosting in trees and artificial structures, such as tunnels, buildings, and bridges. Various roost strategies could include night roosts, maternity roosts, migration stopover, or hibernation. Special-status bat roosting habitats include riparian habitat, developed lands, and landscaped trees such as eucalyptus, palms and orchards. Potential foraging habitat includes all riparian habitat types, cultivated lands, developed lands, grasslands, and wetlands.

Four California bat species of special concern could occur in the study area (Table P.1-1), as well as a number of common bat species. Construction and restoration activities associated with Alternative 3 would result in both temporary and permanent losses of foraging and roosting habitat for special-status bat species. Tidal habitat restoration and floodplain restoration would result in permanent and temporary loss of riparian roosting habitat and conversion of foraging habitat from mostly cultivated lands and managed wetlands to tidal and nontidal wetlands. Development of the Conservation Hatchery could also result in the removal of roosting and foraging habitat. Noise and visual disturbances during implementation of riparian habitat restoration and other construction activities could result in temporary disturbances that, if bat roost sites are present, could cause temporary abandonment of roosts. Impacts on special-status bat species that occupy artificial structures are expected to be negligible in comparison to the amount of impacts on natural habitat types, but temporary and permanent impacts on special-status bat species occupying artificial structures could result in local adverse effects.

Despite having potential to result in some adverse effects, implementation of Alternative 3 would result in an overall benefit to special-status bats within the study area through restoration of their foraging and roosting habitats. The majority of affected habitat would be agricultural, and such land would be converted to natural communities with higher value foraging and roosting potential such as riparian land, tidal and nontidal wetlands, and periodically inundated lands. Restored habitats are expected to be of higher value because, compared to agricultural land, pesticide use would be lower and greater numbers of flying insect prey species would be available. In addition, any impact from construction, restoration, or periodic inundation on special-status bats and their habitat would be mitigated through implementation of MM BIO-24, which would ensure there is no significant impact on roosting special-status bats, either directly or through habitat modifications, and no substantial reduction in numbers nor a restriction in the range of special-status bats.

Potential changes to wetlands and waters of the United States

The restoration projects associated with Alternative 3 would likely require some fill of wetlands and waters of the United States. Fill could occur from dredging work, spoils areas, side channel construction, and installation of the Conservation Hatchery. The majority of the impacts on wetlands and Waters of the United States are likely on tidal channels, emergent wetlands, and on wetlands and waters found within cultivated lands (agricultural ditches and seasonal wetlands). Reclamation will obtain and implement the conditions and requirements of state and federal permits that may be required prior to the construction of the proposed project.

Unavoidable impacts on waters of the United States would be the same as previously described for this impact under Section P.2.3, *Alternative 1*.

The functions of the Waters of the United States that would be temporarily or permanently impacted by Alternative 1 and Alternative 3 would vary, given that Alternative 3 proposes to restore 25,000 acres while Alternative 1 would restore 8,000 acres. The significance of the impact would depend primarily on existing land uses and historical levels of disturbance. Generally, agricultural ditches and conveyance channels, which are regularly maintained and often devoid of vegetation, support only minimal hydraulic function (water conveyance), with virtually no water quality or habitat function. Some facilities that are regularly maintained can still support some hydrologic, hydraulic, and water quality functions (e.g., reduction of velocity, groundwater recharge, and trapping of sediment). Tidal channels affected by this alternative support functions in all three categories, but the level at which these functions perform vary depending on setting, size, and level of disturbance. Alkaline wetlands and vernal pools exist in nonnative grasslands and have been subjected to some disturbance due to past land uses. Although these features likely support habitat, water quality, and hydrologic/hydraulic functions, the capacity of these features to perform such functions vary depending on the overall ecological setting and level of disturbance. Functions associated with emergent wetland, forest, and scrub-shrub depend primarily on the location of these habitat types. Where they exist as in-stream (in-channel islands) or as the thick band of habitat adjacent to a waterway, these features are expected to function at a high level. However, where these habitats exist as thin bands, or where they are situated in agricultural fields, their habitat functions would be considerably lower. All wetlands classified as seasonal wetlands occur in agricultural fields. As such, their habitat functions have been greatly compromised, but they retain some water quality and hydrologic/hydraulic function. Like seasonal wetlands, most depressions occur within agricultural areas; however the depressions may support wetland vegetation at their edges

Potential changes to terrestrial species' critical habitat

The restoration projects under Alternative 3 could result in loss of terrestrial species' critical habitat.

Western yellow-billed cuckoo proposed critical habitat is present in Tisdale Bypass and Sutter Bypass. However, Alternative 3 does not propose to modify flows in the Tisdale or Sutter Bypasses. Changes in frequency of inundation in the Sacramento River would be minor, and within the current minimum and maximum flows. The action alternatives could provide for some different riparian species that require year-round flows, as compared to the No Action Alternative, where low flows in the fall would stress invasive plants and encourage drought tolerant native species to persist.

Critical habitat for valley elderberry longhorn beetle is present along the American River. However, Reclamation will avoid valley elderberry longhorn critical habitat.

Critical habitat for vernal pool fairy shrimp and vernal pool tadpole shrimp is present in areas that Reclamation could potentially use for tidal habitat restoration. Reclamation will, however, avoid areas that would affect the primary constituent habitat elements for these species in the critical habitat units.

Critical habitat for California tiger salamander is present in areas that Reclamation could potentially use for tidal habitat restoration. Reclamation will, however, avoid areas that would affect the primary constituent habitat elements for this species in the critical habitat units.

Critical habitat for soft bird’s-beak and Suisun thistle is present in areas that Reclamation could potentially use for tidal habitat restoration. Reclamation will, however, avoid areas that would affect the primary constituent habitat elements for these species in the critical habitat units.

Therefore, Alternative 3 would have no effect on critical habitat for these species.

P.2.6 Alternative 4

P.2.6.1 *Project-Level Effects*

Potential changes to wildlife and plant habitat on river banks

Compared to the No Action Alternative, operation of the CVP and SWP under Alternative 4 would change river flows and reservoir levels, which would change existing flow conditions. Increases in peak flows are expected in the affected stream reaches for the Sacramento River, Clear Creek, Feather River, American River and Yolo Bypass under Alternative 4 compared to the No Action Alternative. If peak river flows or reservoir levels have substantive increases beyond the No Action Alternative, it could kill or injure special-status species and remove their habitat along rivers and reservoirs. However, evaluation of changes in peak flow indicates that increases would maintain higher flows generally from the months of February through June, where it is common for seasonal discharge to increase naturally. These flows are not expected to result in river bank overtopping/flooding or increased inundation in the Yolo Bypass, therefore flow increases under Alternative 4 would not result in any change to wildlife and plant habitat on river banks in comparison to the No Action Alternative.

P.2.6.2 *Program-Level Effects*

Potential changes to habitat for special-status reptiles

Alternative 4 components to increase water use efficiencies in agricultural areas may result in loss of habitat for giant garter snake . Permanent effects on giant garter snake aquatic habitat are likely to occur when agricultural ditches and canals are replaced with pipes to reduce water loss.. In addition, the conversion of rice to dryland farming or land uses would be a permanent loss of habitat for giant garter snake. Temporary effects on aquatic habitat for giant garter snake may also occur during the time of construction, though these effects would not be expected to last more than 2 years. Permanent effects on upland habitat would primarily occur where upland habitat is removed during construction of new on-farm irrigation or distribution systems or during alteration of existing on-farm distribution systems.

Potential to injure or kill special-status species

Construction-related actions associated with construction of new agricultural water use efficiency facilities under Alternative 4 could injure or kill giant garter snake and elderberry longhorn beetle in occupied habitat. The operation of equipment for land clearing could result in injury or mortality of special-status species. This risk is highest during the giant garter snake period of dormancy in the winter, where these snakes estivate in burrows adjacent to aquatic habitat, and when elderberry shrubs are removed along canals and ditches. Increased vehicular traffic associated with construction activities could contribute to a higher incidence of vehicle strikes. However, construction monitoring and other mitigation measures have been identified to avoid and minimize injury or mortality of giant garter snake and valley elderberry longhorn beetle during construction.

Construction-related noise levels could cause additional behavioral modifications if special-status species are present in the general vicinity. Construction activities may create noise up to 60 dBA at no more than 1,200 feet from the edge of the noise generating activity. While 60 dBA is the standard noise threshold for birds (Dooling and Popper 2007), this standard is generally applied during the nesting season, when birds are more vulnerable to behavioral modifications that can cause nest failure. There is evidence, however, that migrating birds will avoid noisy areas during migration (McClure et al. 2013). Noise and visual disturbance outside the project footprint but within 200 feet of construction activities could temporarily affect the use of adjacent habitat by giant garter snake. These effects will be minimized by siting construction 200 feet away from the banks of giant garter snake aquatic habitat, where feasible, as described in MM BIO-5.

Contaminants could be introduced into species' habitats as a result of construction. Exhaust from construction and maintenance vehicles may result in deposition of particulates, heavy metals, and mineral nutrients that could influence the quality and quantity of vegetation and thereby affect presence and abundance of special-status species. The use of mechanical equipment during construction might cause the accidental release of petroleum or other contaminants that will affect occupied, suitable, or adjacent habitat. These accidental spills could also affect special-status species prey, resulting in less food availability. Increased runoff from impervious surfaces into wetland areas carries pollutants that could contaminant the water.

Potential changes to wetlands and waters of the United States

The agricultural water use efficiency facilities associated with Alternative 4 would likely require some fill of wetlands and waters of the United States. The impacts on wetlands and waters of the United States. are waters found within cultivated lands (e.g., agricultural ditches, canals, seasonal wetlands). Reclamation will obtain and implement the conditions and requirements of state and federal permits that may be required prior to the construction of the proposed project.

Unavoidable impacts on waters of the United States would be offset such that the loss of acreage and functions due to construction activities are fully compensated. Unlike the alternatives described above which include restoration, construction would likely not result in a net increase of wetlands and waters of the United States. These losses may be short-term if construction results in conversion from one wetland type to another.

P.2.7 Mitigation Measures

Mitigation measures are included in this document to avoid, minimize, or compensate for adverse environmental effects of alternatives as compared to the No Action Alternative. The first set of mitigation measures described below are measures to avoid or minimize effects on special-status species, and to compensate for unavoidable effects (Section P.2.8, *Summary of Impacts*). A summary of how each of the measures will mitigate effects for each alternative is provided below.

P.2.7.1 *Species-Specific Mitigation Measures*

Reclamation will implement the following mitigation measures to avoid or minimize effects on special-status species and their habitat. Species-specific measures described below have been developed to avoid and minimize effects that could result from the proposed action on listed and nonlisted species addressed in this appendix. Table P.2-1 below briefly summarizes the species-specific measures.

Table P.2-1. Mitigation Measures for Terrestrial Species in the Study Area

Number	Title	Summary
BIO-1	Vernal Pool Fairy Shrimp, Vernal Pool Tadpole Shrimp, Conservancy Fairy Shrimp, Longhorn Fairy Shrimp	Avoidance of vernal pool habitat and critical habitat, regardless of occupancy, and maintain 250-foot nondisturbance buffer; conduct protocol-level surveys or assume presence.
BIO-2	Valley Elderberry Longhorn Beetle	Habitat avoidance where possible, preconstruction surveys, fencing, monitoring. Mitigate unavoidable impacts consistent with *Framework for Assessing Impacts to the Valley Elderberry Longhorn Beetle* (USFWS 2017).
BIO-3	California Tiger Salamander and Western Spadefoot Toad	Habitat avoidance (including critical habitat).
BIO-4	Foothill Yellow-Legged Frog	Preconstruction survey, timing, compensate for unavoidable effects
BIO-5	Giant Garter Snake	Habitat avoidance where possible, preconstruction survey, and biological monitoring. Unavoidable habitat loss will be offset through habitat protection and/or restoration at a 3:1 ratio.
BIO-6	Western Pond Turtle	Habitat assessment, preconstruction survey, and relocation.
BIO-7	California Black Rail	Protocol-level surveys, habitat avoidance, nondisturbance buffer, and timing of project activity.
BIO-8	California Ridgway’s Rail	Preconstruction protocol-level survey, timing, habitat avoidance.
BIO-9	Greater and Lesser Sandhill Crane	Timing of construction, habitat avoidance where possible. Preconstruction survey, avoid roosts where possible, directional lighting.
BIO-10	Least Bell’s Vireo	Habitat assessment, preconstruction survey, nondisturbance buffer, noise analysis, limit construction activity near nests. Mitigate unavoidable impacts through habitat creation at a 2:1 ratio.
BIO-11	Suisun Song Sparrow, Saltmarsh Common Yellowthroat, Yellow-Breasted Chat, Yellow Warbler	Preconstruction survey, nondisturbance buffer, biological monitoring of active nests, noise reduction, minimize construction traffic, directional lighting.
BIO-12	Swainson’s Hawk	Preconstruction survey, habitat avoidance where possible, nondisturbance buffer. Mitigate unavoidable loss of foraging

Number	Title	Summary
		habitat through foraging habitat protection at a 1:1 ratio and unavoidable loss of nesting habitat through riparian restoration at a 2:1 ratio.
BIO-13	Tricolored Blackbird	Preconstruction survey, habitat avoidance, biological monitoring. Mitigate unavoidable loss of foraging habitat at a 1:1 ratio and unavoidable loss of nesting habitat through restoration at a 2:1 ratio.
BIO-14	Western Burrowing Owl	Protocol-level survey, preconstruction survey, habitat avoidance, relocation during nonbreeding season, nondisturbance buffer, biological monitoring. Mitigate unavoidable loss of nesting, wintering, and satellite burrows, and burrowing owl habitat in comparable habitat at an approved mitigation ratio in consultation with the California Department of Fish and Wildlife.
BIO-15	Western Yellow-Billed Cuckoo	Habitat avoidance (including critical habitat), preconstruction surveys.
BIO-16	White-Tailed Kite	Preconstruction survey, nondisturbance buffer, work window restriction, biological monitoring. Mitigate unavoidable loss of foraging habitat through foraging habitat protection at a 1:1 ratio and unavoidable loss of nesting habitat through riparian restoration at a 2:1 ratio.
BIO-17	Bald Eagle	Nesting habitat avoidance, nondisturbance buffer, monitoring.
BIO-18	Bank Swallow	Preconstruction survey, nondisturbance buffer, monitoring, project design to avoid impacts.
BIO-19	California Least Tern	Habitat avoidance.
BIO-20	Migratory Nesting Birds	Preconstruction survey, nondisturbance buffer, monitoring.
BIO-21	Riparian Woodrat and Riparian Brush Rabbit	Habitat suitability assessment, protocol-level survey, habitat avoidance where possible. 3:1 compensation for unavoidable impacts.
BIO-22	Salt Marsh Harvest Mouse and Suisun Shrew	Preconstruction survey, biological monitoring, exclusion fence.
BIO-23	Ring-Tailed Cat	Avoid denning period, preconstruction survey, nondisturbance buffer, biological monitoring.
BIO-24	Special-Status Bats	Preconstruction surveys, monitoring, exclusion, timing, buffers.
BIO-25	Suisun Thistle and Soft Bird’s-Beak	Botanical survey, habitat avoidance (including critical habitat), minimize introduction of invasive plants. 1:1 compensation for unavoidable impacts.
BIO-26	Other Special-Status Plant Species	Botanical survey, habitat avoidance, prevent spread of invasive plant species. 1:1 compensation for unavoidable impacts.
BIO-27	Wetlands and Waters of the United States	Avoid fill of wetlands and waters of the United States. To the extent feasible, offset unavoidable effects through wetland creation, restoration, or enhancement.

Mitigation Measure BIO-1: Vernal Pool Fairy Shrimp, Vernal Pool Tadpole Shrimp, Conservancy Fairy Shrimp, Longhorn Fairy Shrimp

Reclamation will avoid vernal pool crustacean habitat, including habitat for vernal pool fairy shrimp, vernal pool tadpole shrimp, conservancy fairy shrimp, and longhorn fairy shrimp with a minimum

250-foot nondisturbance buffer. Reclamation will either conduct protocol-level surveys to assess whether habitat is occupied or will assume presence of the species.

Reclamation will avoid affecting any of the primary constituent elements of critical habitat for vernal pool fairy shrimp or vernal pool tadpole shrimp within designated critical habitat units.

Mitigation Measure BIO-2: Valley Elderberry Longhorn Beetle

Suitable Habitat

Valley elderberry longhorn beetle habitat is defined as elderberry shrubs within the study area. Elderberry shrubs in the study area could be found in riparian areas, along levee banks, grasslands, and in agricultural settings where vegetation is not being maintained (e.g., fence rows, fallow fields).

Avoidance and Minimization

Activities will be located to avoid or minimize disturbance of valley elderberry longhorn beetle suitable habitat within the species' range to the greatest extent practicable.

Reclamation will avoid valley elderberry longhorn beetle critical habitat during implementation of the project components.

Complete avoidance (i.e., no adverse effects) may be assumed when elderberry shrubs are not present or within a 165-foot buffer of the activity. USFWS will be consulted before any disturbances, including construction, within the 165-foot buffer area if it contains elderberry shrubs and/or riparian habitat.

Preconstruction surveys for elderberry shrubs will be conducted within all project construction footprints and areas within 165 feet by a biologist familiar with the appearance of valley elderberry longhorn beetle exit holes in elderberry shrubs. When possible, preconstruction surveys will be conducted in the calendar year prior to disturbance and will follow the guidance of USFWS's *Framework for Assessing Impacts to the Valley Elderberry Longhorn Beetle* (USFWS 2017), herein referred to as the 2017 VELB Framework.

For elderberry shrubs not directly affected by construction but that occur between 20 feet and 165 feet from ground-disturbing activities, the following measures will be implemented.

- All areas to be avoided during construction activities will be fenced and/or flagged as close to construction limits as feasible.
- Activities that may damage or kill an elderberry shrub (e.g., trenching, paving, etc.) may need an avoidance area of at least 20 feet (6 meters) from the drip-line, depending on the type of activity.
- A qualified biologist will provide training for all contractors, work crews, and any onsite personnel on the status of the valley elderberry longhorn beetle, its host plant and habitat, the need to avoid damaging the elderberry shrubs, and the possible penalties for noncompliance.
- A qualified biologist will monitor the work area at project-appropriate intervals to assure that all avoidance and minimization measures are implemented. The amount and duration of monitoring will depend on the project specifics and should be discussed with the USFWS biologist.
- As much as feasible, all activities that could occur within 165 feet (50 meters) of an elderberry shrub will be conducted outside of the flight season of the valley elderberry longhorn beetle (March to July).

- Trimming may remove or destroy valley elderberry longhorn beetle eggs and/or larvae and may reduce the health and vigor of the elderberry shrub. To avoid and minimize adverse effects to valley elderberry longhorn beetle, trimming will occur between November and February and will avoid the removal of any branches or stems that are greater than or equal to 1 inch in diameter. Measures to address regular and/or large-scale maintenance (trimming) should be established in consultation with the USFWS.
- Herbicides will not be used within the drip-line of the shrub. Insecticides will not be used within 98 feet (30 meters) of an elderberry shrub. All chemicals will be applied using a backpack sprayer or similar direct application method.
- Mechanical weed removal within the drip-line of the shrub will be limited to the season when adults are not active (August to February) and will avoid damaging the elderberry.
- Erosion control will be implemented, and the affected area will be revegetated with appropriate native plants.
- The potential effects of dust on valley elderberry longhorn beetle will be minimized by applying water during construction activities or by presoaking work areas that will occur within 100 feet of any potential elderberry shrub habitat. Elderberry shrubs with stems greater than 1 inch that are directly affected by construction should be transplanted under the following conditions:
  - If the elderberry shrub cannot be avoided.
  - If indirect effects will result in the death of stems or the entire shrub.

The removal of the elderberry shrub may either include the roots or just the removal of the aboveground portion of the plant. When possible, the entire root ball will be retained and the elderberry shrub will be transplanted as close as possible to its original location. Elderberry shrubs will be relocated adjacent to the project footprint if (1) the planting location is suitable for elderberry growth and reproduction; and (2) the project proponent is able to protect the shrub and ensure that the shrub becomes reestablished. If these criteria cannot be met, the shrub may be transplanted to an appropriate USFWS-approved mitigation site. Any elderberry shrub that is unlikely to survive transplanting because of poor condition or location, or a shrub that would be extremely difficult to move because of access problems, may not be appropriate for transplanting. The following transplanting guidelines may be used by agencies/applicants in developing their valley elderberry longhorn beetle conservation measures:

- A qualified biologist will be onsite for the duration of transplanting activities to ensure compliance with avoidance and minimization measures and other conservation measures.
- Exit-hole surveys will be completed immediately before transplanting. The number of exit holes found, GPS location of the plant to be relocated, and the GPS location of where the plant is transplanted will be reported to the USFWS and to the CNDDB.
- Elderberry shrubs will be transplanted when the shrubs are dormant (November through the first 2 weeks in February) and after they have lost their leaves. Transplanting during the nongrowing season will reduce shock to the shrub and increase transplantation success.
- Transplanting will follow the most current version of the ANSI A300 (Part 6) guidelines for transplanting (http://www.tcia.org/).

- Trimming will occur between November and February and should minimize the removal of branches or stems that exceed 1 inch in diameter.

Compensation for Unavoidable Effects

Reclamation will coordinate with the USFWS to offset unavoidable impacts on elderberry shrubs by either creating valley elderberry longhorn beetle habitat or by purchasing the equivalent credits at a USFWS-approved conservation bank with a service area that overlaps with the study area. Compensatory mitigation will be coordinated with the USFWS to determine the appropriate type and amount of compensatory mitigation and follow criteria in the 2017 VELB Framework. These guidelines recommend that the permanent loss of valley elderberry longhorn beetle habitat be replaced with habitat that is commensurate with the type (riparian or nonriparian) and amount of habitat lost. For plants in riparian areas, compensation may be appropriate for any impacts to valley elderberry longhorn beetle habitat. In nonriparian areas, compensation may be appropriate for occupied shrubs. Suitable riparian habitat may be replaced at a minimum ratio of 3:1 for all acres that will be permanently affected by the project. Suitable nonriparian habitat may be replaced at a minimum ratio of 1:1 for all acres that will be permanently affected by the project. Impacts on individual shrubs in riparian areas may be replaced by the purchase of two credits (one credit = 1,800 square feet) at a USFWS-approved bank for each shrub that will be trimmed regardless of the presence of exit holes. If the shrub will be completely removed by the activity, the entire shrub may be transplanted to a USFWS-approved location in addition to the credit purchase. Impacts on individual shrubs in nonriparian areas be replaced through a purchase of 1 credit at a USFWS-approved bank for each shrub that will be trimmed if exit holes have been found in any shrub on or within 165 feet of the project. If the shrub will be completely removed by the activity, the entire shrub will be transplanted to a USFWS-approved location in addition to a credit purchase. These ratios may apply if compensation occurs prior to or concurrent with the impacts. If compensation occurs after the impacts, a higher ratio may be required by USFWS. Appropriate compensatory mitigation may include purchasing credits at a USFWS-approved conservation bank, providing onsite mitigation, or establishing and/or protecting habitat for valley elderberry longhorn beetle.

Mitigation Measure BIO-3: California Tiger Salamander and Western Spadefoot Toad

For restoration projects and construction of the Conservation Hatchery, Reclamation will avoid California tiger salamander and western spadefoot toad upland and aquatic habitat. Reclamation will avoid affecting any of the primary constituent elements of critical habitat for California tiger salamander within designated critical habitat units.

Mitigation Measure BIO-4: Foothill Yellow-Legged Frog

Species-specific mitigation for foothill yellow-legged frog will only be required for projects occurring within or adjacent to suitable habitat as identified by assessments conducted during the project component planning phase. A qualified biologist will conduct a field evaluation for foothill yellow-legged frog for all project activities that occur within suitable habitat.

Prior to any ground-disturbing activity scheduled to occur during the dry season (June 1–October 15), a qualified biologist will survey potential breeding habitat for the presence of foothill yellow-legged frogs using methods from the *Draft Visual Encounter Survey Protocol for* Rana boylii *in Lotic Environments* (Peek et al. 2017) or other more recent guidelines, if available. Surveys will be conducted no more than 30 days before the start of ground-disturbing activities and will be spatially phased to precede construction activities. Avoidance and minimization measures, including moving individuals to nearby ponds or other appropriate measures, will be implemented with authorizations issued under the California Endangered Species Act (CESA).

Compensation for Unavoidable Effects

Reclamation will provide compensatory mitigation for unavoidable permanent impacts on habitat for foothill yellow-legged frog. Impacts on occupied or presumed occupied aquatic habitat will be compensated for at a ratio of 3:1 for breeding and foraging habitat.

Mitigation Measure BIO-5: Giant Garter Snake

Avoidance and Minimization Measures

Species-specific mitigation for giant garter snake will be required only for projects occurring within or adjacent to suitable habitat, as identified by assessments conducted during the project component planning phase. A qualified biologist will conduct a field evaluation of suitable upland or aquatic habitat for giant garter snake for all covered activities that occur within suitable giant garter snake habitat.

If the project does not fully avoid effects on suitable habitat, the following measures will be required:

- Initiate construction between May 1 and October 1 within suitable giant garter snake upland habitat, which corresponds with the snake’s active period. Work in giant garter snake upland habitat may also occur between October 2 and November 1 or between April 1 and May 1 if ambient temperatures exceed 75 degrees Fahrenheit (°F) during construction activities and maximum daily temperatures have exceeded 75°F for a least 3 consecutive days immediately preceding work. During these periods, giant garter snakes are more likely to be active in aquatic habitats and less likely to be found in upland habitats. To the extent practicable, conduct all activities within paved roads, farm roads, road shoulders, and similarly disturbed and compacted areas; confine ground disturbance and habitat removal to the minimum area necessary to facilitate construction activities. For construction activities and any conveyance facility maintenance involving heavy equipment, giant garter snake aquatic and upland habitat that can be avoided will be clearly delineated on the work site, with high-visibility fencing and signage identifying these areas as sensitive. The fencing will be installed before equipment is moved onsite and before any ground-disturbing activities begin. The purpose of the fencing is to prevent construction activities from encroaching into sensitive habitat areas and not intended to exclude animals. To minimize the potential for snakes and other ground-dwelling animals to be caught in the construction fencing, the fencing will be placed with at least a 6-inch gap between the ground and the bottom of the fencing to allow animals to pass under.
- All construction personnel and personnel involved in operations and maintenance in or near giant garter snake habitat will attend worker environmental awareness training (as described in Appendix O, *Aquatic Resources Technical Appendix*). This training will include instructions to workers on how to recognize giant garter snakes, their habitat(s), and the nature and purpose of protection measures.
- Within 24 hours prior to construction activities or maintenance activities requiring heavy equipment within giant garter snake habitat, a USFWS-approved biologist will survey all areas planned for disturbance and at least 50 feet outside the disturbance area where giant garter snake

could be present. The surveyor will inspect all burrows, soil cracks, and crevices that could be used by giant garter snake. To the extent that these habitat features can be avoided within the work area, they will be flagged, and the locations will be provided to the biological monitor. This survey of the work area will be repeated if a lapse in construction activity of 2 weeks or greater occurs during the giant garter snake inactive period (October 1 to May 1) or if the lapse in construction activity is more than 12 hours during the active period (May 1 to October 1). If a giant garter snake is encountered during surveys or construction, activities will cease until appropriate corrective measures have been completed, it has been determined that the giant garter snake will not be harmed, or the giant garter snake has left the work area.

- For all construction activities that occur in giant garter snake habitat that could result in injury or mortality of snakes (e.g., movement of heavy equipment; excavation of soil, rock, or existing structures; grading; vegetation removal), a USFWS-approved biologist will be present to monitor these activities. As work is performed, the biologist will visually scan work areas, under equipment, and excavated materials for giant garter snakes. The biologist will also help guide access and construction work around wetlands, active rice fields, and other sensitive habitats capable of supporting giant garter snake to minimize habitat disturbance and risk of injuring or killing giant garter snakes.
- Report all observations of giant garter snakes to the USFWS-approved biological monitor. If a giant garter snake is observed in the work area, the monitor will have the authority to stop work in the immediate vicinity of the snake. If possible, the snake will be allowed to leave the work area on its own volition and the monitor will remain in the area until the snake is safely out of harm's way. A giant garter snake may be captured and relocated out of the work area with prior authorization from USFWS and by an individual with the appropriate handling permit. The snake will be relocated to suitable habitat at least 200 feet from the work area.
- Maintain all construction and operations and maintenance equipment to prevent leaks of fuel, lubricants, and other fluids and use extreme caution when handling and or storing chemicals (such as fuel and hydraulic fluid) near waterways, and abide by all applicable laws and regulations. Follow all applicable hazardous waste BMPs and keep appropriate materials onsite to contain, manage, and clean up any spills.
- Conduct service and refueling procedures in uplands in staging areas and at least 200 feet away from waterways when practicable.
- During construction and operation and maintenance activities in and near giant garter snake habitat, employ erosion (non-monofilament silt fence), sediment, material stockpile, and dust control BMPs. Avoid using fill or allowing runoff into wetland areas or waterways to the extent practicable.
- Return temporary work areas to pre-existing contours and conditions upon completion of work. Where revegetation and soil stabilization are necessary in nonagricultural habitats, revegetate with appropriate noninvasive native plants at a density and structure similar to that of preconstruction conditions. Restoration of aquatic vegetation in giant garter snake aquatic habitat and annual grassland within giant garter snake upland habitat will be detailed in a mitigation and monitoring plan that will be reviewed and approved by USFWS prior to the start of construction. Habitat will be restored within one season (defined as May 1 to October 1).

- Properly contain and remove from the worksite all trash and waste items generated by construction and crew activities to prevent the encouragement of predators such as raccoons and coyotes from occupying the site.
- Permit no pets, campfires, or firearms at the worksite.
- Store equipment in designated staging area areas at least 200 feet away from giant garter snake aquatic habitat to the extent practicable.
- Confine any vegetation clearing to the minimum area necessary to facilitate construction activities.
- Limit vehicle speed to 10 miles per hour (mph) on access routes (except for public roads and highways) and within work areas that are within 200 feet of giant garter snake aquatic habitat but not protected by exclusion fencing to avoid running over giant garter snakes.
- Visually check for giant garter snake under vehicles and equipment prior to moving them. Cap all onsite materials (conduits, pipe, etc.), precluding wildlife from becoming entrapped. Check any crevices or cavities in the work area where individuals may be present including stockpiles that have been left for more than 24 hours where cracks or crevices may have formed.
- For proposed activities that will occur within suitable aquatic giant garter snake habitat during the active giant garter snake season (May 1 through October 1), prior to proposed construction activities that will commence during the inactive period, and when unavoidable, all aquatic giant garter snake habitat will be dewatered for at least 14 days prior to excavating or filling the dewatered habitat. Dewatering is necessary because aquatic habitat provides prey and cover for giant garter snake; dewatering serves to remove the attractant and increase the likelihood that giant garter snake will move to other available habitat. Any deviation from this measure will be done in coordination with, and with approval of, the USFWS.
- Following dewatering of aquatic habitat, all potential affected areas that provide suitable aquatic or upland giant garter snake habitat will be surveyed for giant garter snake by the USFWS-approved biologist. If giant garter snakes are observed, they will be passively allowed to leave the area, or the USFWS will be consulted to determine the appropriate course of action for removing giant garter snake from the area.

Maintenance activities such as vegetation and rodent control, embankment repair, and channel maintenance will occur at conveyance facilities with permanent structures and at conveyance facility and restoration sites with flexible locations (e.g., transmission line right of ways, restoration locations, etc.). The following avoidance and minimization measures will be applied to maintenance activities in suitable aquatic habitat and uplands within 200 feet of suitable aquatic habitat, to minimize effects on the giant garter snake:

- Vegetation control will take place during the active period (May 1 through October 1) when snakes are able to move out of areas of activity.
- Trapping or hunting methods will be used for rodent control rather than poison bait. All rodent control methods will be approved by USFWS. If trapping or other nonpoison methods are ineffective, the USFWS will be consulted to determine the best course of action.

- Movement of heavy equipment will be confined to outside 200 feet of the banks of giant garter snake aquatic habitat to minimize habitat disturbance.
- All construction personnel and personnel involved in operations and maintenance in or near giant garter snake habitat will attend worker awareness training (as described in Appendix O, *Aquatic Resources Technical Appendix*). This training will include instructions to workers on how to recognize giant garter snakes, their habitat, and the nature and purpose of protection measures.

Compensation for Unavoidable Effects

Where giant garter snake habitat cannot be avoided, compensation for the permanent loss of the habitat will occur at a rate of 3:1 for aquatic and upland habitat.

Mitigation Measure BIO-6: Western Pond Turtle

Species-specific mitigation for western pond turtle will only be required for projects occurring within or adjacent to suitable habitat as identified by assessments conducted during the project component planning phase. A qualified biologist will conduct a field evaluation of suitable upland or aquatic habitat for western pond turtles for all covered activities that occur within suitable pond turtle habitat.

If the project does not fully avoid effects on suitable habitat, the following measures will be required.

- The project proponent will retain a qualified wildlife biologist to conduct a preconstruction survey within 48 hours of disturbance in aquatic and riparian habitats to determine presence or absence of pond turtles in the construction work area.
- If possible, the surveys will be timed to coincide with the time of day and year when turtles are most likely to be basking and visible (during the cooler part of the day, 8:00 a.m. to 12:00 p.m., during spring, summer, and late summer). Prior to conducting presence/absence surveys the biologist will locate the microhabitats for turtle basking (logs, rocks, brush thickets) and determine a location to quietly observe turtles.
- Each survey will include a 30-minute wait time after arriving at the site to allow startled turtles to return to open basking areas. The survey will consist of a minimum 15-minute observation time per area where turtles could be observed.
- If turtles are observed during a survey, they will be relocated outside of the construction area to appropriate aquatic habitat by a biologist.

Mitigation Measure BIO-7: California Black Rail

Preconstruction surveys for California black rail will be conducted where potentially suitable habitat for this species occurs within 500 feet of work areas where access is available. Potentially suitable habitat includes tidal and nontidal seasonal or perennial wetlands at least 2 acres in size with any kind of vegetation types consistent with black rail use in the Delta, as determined by field evaluations conducted by a qualified biologist with experience surveying for black rail, over 10 inches high, whether or not the patch in question was mapped as modeled habitat. Surveys will be initiated sometime between January 15 and February 1. A minimum of four surveys will be conducted. The survey dates will be spaced at least 2 to 3 weeks apart and will be scheduled so that the last survey is conducted no more than 2 weeks before April 15. This will allow the surveys to encompass the time period when the highest frequency of calls is likely to occur. These surveys will involve the following protocols (based on Evens et al. 1991), or other approved survey methodologies that may be developed using new information and best-available science, and will be conducted by biologists with the qualifications stipulated in the approved methodologies.

- Listening stations will be established at 300-foot intervals throughout potential black rail habitat that will be affected by covered activities. Listening stations will be placed along roads, trails, and levees to avoid trampling.
- California black rail vocalization recordings will be played at each station, and playing will cease immediately once a response is detected.
- Each listening station will be occupied for 6 minutes, including 1 minute of passive listening, 1 minute of "grr" calls followed by 30 seconds of "ki-ki-krrr" calls, then followed by another 3.5 minutes of passive listening.
- Each survey will include a survey at sunrise and a survey at sunset.
- Sunrise surveys will begin 60 minutes before sunrise and conclude 75 minutes after sunrise (or until presence is detected).
- Sunset surveys will begin 75 minutes before sunset and conclude 60 minutes after sunset (or until presence is detected).
- Surveys will not be conducted when tides are greater than National Geodetic Vertical Datum or when sloughs and marshes are more than bank-full.
- California black rail vocalizations will be recorded on a data sheet. A GPS receiver and compass will be used to identify surveys stations, angles to call locations, and call locations and distances. The call type, location, distance from listening station, and time will be recorded on a data sheet.

The project will be implemented in a manner that will not result in take of California black rail, as defined by Section 86 of the California Fish and Game Code. If California black rail is present in the immediate construction area, the following measures will apply during construction activities:

- To avoid the loss of individual California black rails, activities within 500 feet of potential habitat will not occur within 2 hours before or after extreme high tides (6.5 feet or above, as measured at the Golden Gate Bridge). During high tide, protective cover for California black rail is sometimes limited, and activities could prevent them from reaching available cover.
- To avoid the loss of individual California black rails, activities within 500 feet of tidal marsh areas and managed wetlands will be avoided during the rail breeding season (February 1 to August 31), unless surveys are conducted to determine that no rails are present within the 500-foot buffer.
- If breeding California black rail is determined to be present, activities will not occur within 500 feet of an identified calling center (unless a qualified biologist determines that a smaller distance will not result in the take of the state-listed species). If the intervening distance between the rail calling center and any activity area is greater than 200 feet and across a major slough channel or substantial barrier (e.g., constructed noise barrier) it may proceed at that location within the breeding season.
- If California black rail are determined to be present in habitat that must be disturbed, vegetation will be removed during the nonbreeding season (September 1 to January 31) to encourage them to

leave the area. Vegetation removal will be completed carefully using hand tools or vegetation removal equipment that is approved by a biologist. The biologist will search vegetation immediately in front of the removal equipment, and will stop removal if rails are detected. Vegetation removal will resume when the black rail leaves the area.

- If construction activities require removal of potential California black rail habitat, whether or not black rails have been detected there, vegetation will be removed during the nonbreeding season (September 1 to January 31). Vegetation removal will be completed carefully using hand tools or vegetation removal equipment that is approved by an biologist. The biologist will search vegetation immediately in front of the removal equipment, and will stop removal if rails are detected. Vegetation removal will resume when the rail leaves the area.
- Exception: Inspection, maintenance, or nonconstruction monitoring activities may be performed during the California black rail breeding season (February 1 to August 31) in areas within or adjacent to breeding habitat (within 500 feet) with CDFW approval and under the supervision of a permitted, approved biologist.
- If the construction footprint is within 500 feet of a known calling center, noise reduction structures such as temporary noise reducing walls, will be installed at the edge of construction footprint, as determined by an onsite biologist. Noise-causing construction will begin during the nonbreeding season (September 1 to January 31) so that rails can acclimate to noise and activity prior to initiating nests.

Mitigation Measure BIO-8: California Ridgway's Rail

If construction or restoration activities are necessary during the breeding season, preconstruction surveys for California Ridgway's rail will be conducted where suitable habitat for these species occurs within or adjacent to work areas. Surveys will be initiated sometime between January 15 and February 1. A minimum of four surveys will be conducted. The survey dates will be spaced at least 2 to 3 weeks apart and will cover the time period from the date of the first survey through the end of March and mid-April. This will allow the surveys to encompass the time period when the highest frequency of calls is likely to occur. These surveys will involve the following protocols (based on USFWS 2015 and Evens et al. 1991), or other approved survey methodologies that may be developed based on new information and evolving science, and will be conducted by biologists with the qualifications stipulated in the approved methodologies.

- Listening stations will be established at 200-meter intervals along roads, trails, and levees that will be affected by covered activities.
- California Ridgway's rail vocalization recordings will be played at each station, and playing will cease immediately once a response is detected.
- For California Ridgway's rail, each listening station will be occupied for a period of 10 minutes, followed by 1 minute of playing California Ridgway's rail vocalization recordings, then followed by an additional minute of listening.
- Sunrise surveys will begin 60 minutes before sunrise and conclude 75 minutes after sunrise (or until presence is detected).
- Sunset surveys will begin 75 minutes before sunset and conclude 60 minutes after sunset (or until presence is detected).

- Surveys will not be conducted when tides are greater than 4.5 National Geodetic Vertical Datum or when sloughs and marshes are more than bank-full.
- California Ridgway's rail vocalizations will be recorded on a data sheet. A GPS receiver and compass will be used to identify surveys stations, angles to call locations, and call locations and distances. The call type, location, distance, and time will be recorded on a data sheet.

If California Ridgway's rail is present in the immediate construction area, the following measures will apply during construction activities.

- To avoid the loss of individual California Ridgway's rails, activities within or adjacent to the species' habitat will not occur within 2 hours before or after extreme high tides (6.5 feet or above, as measured at the Golden Gate Bridge), when the marsh plain is inundated. During high tide, protective cover for California Ridgway's rail is sometimes limited, and activities could prevent them from reaching available cover.
- To avoid the loss of individual California Ridgway's rails, activities within or adjacent to tidal marsh areas will be avoided during the rail breeding season (February 1 through August 31), unless surveys are conducted to determine rail locations and territories can be avoided.
- If breeding California Ridgway's rail are determined to be present, activities will not occur within 500 feet of an identified calling center (unless a qualified biologist determines that a smaller distance will not result in the take of the state-listed species). If the intervening distance is across a major slough channel or across a substantial barrier between the rail calling center and any activity area is greater than 200 feet, it may proceed at that location within the breeding season.
- Exception: Inspection, maintenance, or nonconstruction monitoring activities may be performed during the California Ridgway's breeding season in areas within or adjacent to breeding habitat (within 500 or 200 feet, as specified above) as long as a qualified biologist determines the action will not result in take. These activities will be conducted under the supervision of a qualified, permitted biologist.

Mitigation Measure BIO-9: Greater and Lesser Sandhill Crane

If construction and restoration activities are to occur during sandhill crane wintering season (September 15 through March 15) in a greater sandhill crane winter use area or within suitable lesser sandhill crane wintering habitat, the following avoidance and minimization measures will be implemented.

- Construction will be minimized during the sandhill crane wintering season to the extent practicable in light of project schedule and cost and logistical considerations.
- To the extent feasible, construction that cannot be completed prior to commencement of the wintering season will be started before September 15 or after March 15, such that no new sources of noise or other major disturbance that could affect cranes will be introduced after the cranes arrive at their wintering grounds.
- Preconstruction surveys will be conducted for sandhill crane temporary and permanent roost sites within 0.75 mile of the construction area boundary where access is available. Surveys will be conducted during the winter prior to project implementation, over multiple days within the survey area by a qualified biologist with experience observing the species. Alternatively, roost sites

within 0.75 mile of the construction area boundary can be identified by a qualified sandhill crane biologist familiar with roost sites. If a sandhill crane roost site is located within 0.75 mile of the construction area boundary, then to the extent practicable, nighttime (1 hour before sunset to 1 hour after sunrise) project activities will be relocated to maintain a 0.75-mile nondisturbance buffer.

- Route truck traffic to reduce headlight impacts in roosting habitat.
- Install light barriers to block the line-of-sight between the nearest roosting areas and the primary nighttime construction light source areas.
- Operate portable lights near roosting habitat at the lowest allowable wattage and height, while in accordance with the National Cooperative Highway Research Program's (NCHRP's) *Report 498: Illumination Guidelines for Nighttime Highway Work*.
- Screen all lights and direct them down toward work activities and away from the night sky and nearby roost sites. A biological construction monitor will ensure that lights are properly directed at all times.
- Limit the number of nighttime lights used to the greatest extent practicable in light of worker safety requirements.
- If restoration takes place near Stone Lake NWR, install a vegetation screen or other noise and visual barrier along the south side of Hood Franklin Road along the length of Stone Lake NWR's property to reduce disturbance to sandhill cranes. The noise and visual barrier will be a minimum of 5 feet high (above the adjacent elevated road, if applicable) and will provide a continuous surface impenetrable by light. This height may be obtained by installing a temporary structure, such as fencing (e.g., chain link with privacy slats) or a semipermanent structure, such as a concrete barrier (e.g., a roadway median barrier or architectural concrete wall system) retrofitted with an approved visual screen, if necessary, to meet the required height. This barrier will not be installed immediately adjacent to crane foraging habitat, and placement will be coordinated with a qualified crane biologist.

Mitigation Measure BIO-10: Least Bell's Vireo

Species-specific mitigation measures for least Bell's vireo will be required for activities occurring within suitable habitat within the species' range. Prior to disturbing an area potentially supporting habitat for the species, a USFWS approved biologist will evaluate the area to identify suitable habitat.

Activities will be located to avoid or minimize disturbance of least Bell's vireo suitable habitat within the species' range. The following measures will be required for project components unable to avoid least Bell's vireo habitat:

- Prior to construction, all suitable least Bell's vireo habitat within the species' range in the construction area will be surveyed.
- At least five surveys will be conducted in suitable habitats within 30 days of the onset of construction, with the last survey conducted within 3 days of the onset of construction, by a qualified biologist with experience surveying and observing these species and familiar with their vocalizations.

- If an active nest site is present, a 500-foot nondisturbance buffer will be established around nest sites during the breeding season (generally, late February through late August).
- Disturbance to previous least Bell's vireo nesting sites (for up to 3 years since known nest activity) will also be avoided during the breeding season unless the disturbance is to maintain public safety. Least Bell's vireo uses previous nesting sites, and disturbance during the breeding season may preclude birds from using existing unoccupied nest sites.
- The required buffer may be reduced in areas where barriers or topographic relief are sufficient to protect the nest from excessive noise or other disturbance, as determeined by a the qualified biologist on a case-by-case basis.
- If occupied nests are identified, a qualified biologist will monitor construction activities in the vicinity of all active least Bell's vireo nests to ensure that covered activities do not affect nest success.
- If surveys find least Bell's vireos in the area where vegetation will be removed, vegetation removal will be done when the birds are not present.
- If an activity is to occur within 1,200 feet of least Bell's vireo habitat (or within 2,000 feet if pile driving will occur) during the breeding period for least Bell's vireos, the following measures will be implemented to avoid noise effects on least Bell's vireo.
    - Prior to the construction, a noise expert will create a noise contour map showing the 60 A-weighted decibel noise contour specific to the type and location of construction to occur in the area.
    - During the breeding period for least Bell's vireo, a USFWS-approved biologist will survey any suitable habitat for least Bell's vireo within the 60 dBA noise contour daily during a 2-week period prior to construction. While construction is occurring within this work window, the USFWS-approved biologist will conduct daily surveys in any suitable habitat where construction related noise levels could exceed 60 dBA L_{eq} (1 hour). If a least Bell's vireo is found, sound will be limited to 60 dBA in the habitat being used until the USFWS-approved biologist has confirmed that the bird has left the area.
    - Limit pile driving to daytime hours (7:00 a.m. to 7:00 p.m.).
    - Locate, store, and maintain portable and stationary equipment as far as possible from suitable least Bell's vireo habitat.
    - Employ preventive maintenance including practicable methods and devices to control, prevent, and minimize noise.
    - Route truck traffic to reduce construction noise impacts and traffic noise levels within 1,200 feet of suitable least Bell's vireo habitat during migration periods.
    - Limit trucking activities (e.g., deliveries, export of materials) to the hours of 7:00 a.m. to 10:00 p.m.
    - Screen all lights and direct them down toward work activities away from migratory habitat. A biological construction monitor will ensure that lights are properly directed at all times.
    - Operate portable lights at the lowest allowable wattage and height, while in accordance with NCHRP's *Report 498: Illumination Guidelines for Nighttime Highway Work* (Transportation Research Board 2003).

Compensation to Offset Effects

Reclamation will offset the loss of least Bell's vireo habitat through habitat creation or restoration at a 2:1 ratio. Reclamation will develop a riparian restoration plan that will identify the location and methods for riparian creation or restoration, and this plan will be subject to USFWS approval.

Mitigation Measure BIO-11: Suisun Song Sparrow, Saltmarsh Common Yellowthroat, Yellow-Breasted Chat, Yellow Warbler

Preconstruction surveys of potential breeding habitat for the Suisun song sparrow, saltmarsh common yellowthroat, yellow-breasted chat, and yellow warbler will be conducted within 500 feet project activities where access is available. At least five surveys will be conducted in suitable habitats within 30 days of the onset of construction, with the last survey conducted within 3 days of the onset of construction, by a qualified biologist with experience surveying and observing these species and familiar with their vocalizations.

If an active nest site is present, a 250-foot nondisturbance buffer will be established around nest sites during the breeding season (generally, late February through late August for yellow-breasted chat, early April through mid-July for saltmarsh common yellowthroat and yellow warbler, and early April through late August for Suisun song sparrow).

The required buffer may be reduced in areas where barriers or topographic relief are sufficient to protect the nest from excessive noise or other disturbance, as determined by a qualified biologist on a case-by-case basis.

If occupied nests are identified, a qualified biologist will monitor construction activities in the vicinity of all active nests to ensure that covered activities do not affect nest success.

To the extent feasible, the contractor will employ the following best practices to reduce construction noise during daytime and evening hours (7:00 a.m. to 10:00 p.m.) such that construction noise levels do not exceed 60 dBA Leq (1 hour) during migration periods:

- Limit construction during nighttime hours (10:00 p.m. to 7:00 a.m.) such that construction noise levels do not exceed 50 dBA L_{max} (1 hour) at the nearest residential land uses.
- Limit construction activities to daytime hours (7:00 a.m. to 7:00 p.m.), where feasible.
- Locate, store, and maintain portable and stationary equipment 300 feet away from suitable nesting habitat during migration periods, and 300 feet from active breeding sites.
- Employ preventive maintenance including practicable methods and devices to control, prevent, and minimize noise.
- Except where equipment must cross through riparian zones, route truck traffic to at least 300 feet from suitable avian migratory habitat during migration periods.
- Limit trucking activities (e.g., deliveries, export of materials) to the hours of 7:00 a.m. to 10:00 p.m. within 300 feet of migration habitat during migration periods.
- Screen all lights and direct them down toward work activities away from migratory habitat. A biological construction monitor will ensure that lights are properly directed at all times.
- Operate portable lights at the lowest allowable wattage and height, while in accordance with the NCHRP *Report 498: Illumination Guidelines for Nighttime Highway Work* (Transportation Research Board 2003).

Mitigation Measure BIO-12: Swainson's Hawk

Preconstruction surveys will be conducted to identify the presence of active nest sites of tree-nesting raptors within 0.25 mile of project sites, staging and storage areas, construction access roads, work areas, and soil stockpile areas where accessible by a qualified biologist with experience identifying Swainson's hawk. Transportation routes along public roads (roads leading to and from work areas) are considered disturbed, and no surveys or monitoring are required for nests along those roadways unless they are within 0.25 mile of work areas. Surveys for nesting Swainson's hawks will be conducted to ensure nesting activity is documented prior to the onset of construction activity. Swainson's hawks nest in the study area between approximately March 15 and September 15. While many nest sites are traditionally used for multiple years, new nest sites can be established in any year. Therefore, construction activity that is planned after March 15 of any year will require surveys during the year of the construction. If construction is planned before March 15 of any year, surveys will be conducted the year immediately prior to the year of construction. If construction is planned before March 15 of any year and subject to prior-year surveys, but is later postponed to after March 15, surveys will also be conducted during the year of construction.

The survey protocol shown in Table P.2-2 is modified from the recommended timing and methodology for Swainson's hawk nesting surveys in the Central Valley (Swainson's Hawk Technical Advisory Committee 2000). This protocol will be used to detect active nests for Swainson's hawk. If active nests are found, appropriate avoidance and minimization measures will be implemented as described. If no activity is found, then construction can proceed with no restrictions until the following breeding season. Survey results will be documented in a memo no less than 5 days prior to commencement of construction activities, and provided to the Program Environmental Manager and Construction Supervisor. The designated biologist will include the location of any known nest trees (occupied within 1 or more of the last 5 years) present within 0.25 mile of the construction footprint.

Removal of known nest trees (defined as a tree that has been used for nesting at least once in the last 3 years) will be avoided to the maximum extent feasible. No trees with occupied nests will be removed until the nest is vacated.

The designated biologist will survey potential Swainson's hawk nest trees and monitor occupied Swainson's hawk nests as described below. When proposed construction will occur within 0.25 mile of known nest trees, construction activities will be limited to outside the breeding season if feasible, or until the tree site is determined to be inactive.

Where construction activities cannot be restricted to more than 0.25 mile of an occupied nest site, activities will be restricted during the period of egg-laying to post-hatching to the extent feasible. If construction activities must occur in that time frame, construction will be initiated prior to egg-laying to the extent feasible. This will allow time for Swainson's hawks to acclimate to disturbance before eggs are laid, reducing the potential for abandonment. If construction activities must begin after egg-laying is initiated, a 650-foot-radius nondisturbance buffer will be established at least until eggs have hatched.

When construction activities will occur within 0.25 mile of an occupied Swainson's hawk nest, a 650-foot-radius nondisturbance buffer will be established around each occupied hawk nest tree. To the greatest extent feasible, no construction activity will be allowed to occur within the buffer while a Swainson's hawk nest is occupied. A nest is considered occupied from the time the nest is being constructed until the young leave the nest, or until the nesting attempt fails and the nest is abandoned. Occupied nests will be monitored to track progress of nesting activities. The buffer will be clearly delineated with fencing or other conspicuous marking.

Where construction will occur within 0.25 mile of an occupied Swainson's hawk nest tree, the following monitoring plan will be implemented. If a project nesting bird monitoring and management plan is prepared by a designated biologist, it will prevail where it differs from the measures below.

- A designated biologist will observe any nest site that is within 0.25 mile of construction activities for at least 1 hour and until normal nesting behavior can be determined 5 days and 3 days prior to the initiation of construction. The biologist will determine nest status and document normal nesting behaviors, which may be used to compare to the hawks' activities once construction begins. The results of preconstruction monitoring will be reported in a memo and provided to the Program Environmental Manager and Construction Supervisor.
- Where a Swainson's hawk occupied nest occurs less than 325 feet from construction activities, the designated biologist will observe the nest periodically throughout the day where covered activities occur to ensure the hawks are engaged in normal nesting behavior.
- Where a Swainson's hawk occupied nest occurs between 325 and 650 feet from construction, the designated biologist will observe the nest for at least 2 hours per construction day where covered activities occur to ensure the hawks are engaged in normal nesting behavior.
- Where a Swainson's hawk occupied nest occurs between 650 and 1,300 feet from construction, the designated biologist will observe the nest for at least 3 days per construction week to ensure the hawks are engaged in normal nesting behavior and to check the status of the nest.

Physical contact with an active nest tree will be prohibited from the time of egg laying to fledging. Construction personnel outside of vehicles must remain at least 650 feet, unless the biologist determines that a smaller buffer will not result in take of this state-listed species, from the nest tree unless construction activities require them to be closer.

All personnel will be out of the line of sight of an occupied nest during breaks if within 650 feet of the nest (as stated above, activities will only occur within 650 feet of a nest with approval by the designated biologist).

If during construction the designated biologist determines that a nesting Swainson's hawk within 0.25 mile of the project is disturbed by project activities, to the point where their reproductive failure could occur, the designated biologist will immediately notify the Construction Supervisor and Program Environmental Manager. The Program Environmental Manager will contact CDFW, and it will be determined by the parties whether additional protection measures can be implemented.

Potential nest abandonment and failure may be indicated if Swainson's hawk exhibits distress and/or abnormal nesting behavior such as swooping/stooping at construction equipment or personnel, excessive vocalization (distress calls) or agitation directed at construction equipment or personnel, failure to remain on nest, or failure to deliver prey items for an extended time period. Additional protection measures will remain in place until the Swainson's hawk behavior has normalized. The designated biologist will notify CDFW if nests or nestlings are abandoned and if the nestlings are still alive to determine appropriate actions for salvaging the eggs or returning nestlings to the wild.

In addition to the measures described above, the following measures will also be implemented for activities for which the extent and location of the activity have not yet been fully planned.

- Restoration exploration activities will fully avoid Swainson's hawk nesting habitat.
- Restoration exploration will not be conducted within 0.25 mile of an occupied Swainson's hawk nest.

Table P.2-2. Timing and Methodology for Swainson's Hawk Nesting Surveys

Survey Dates	Survey Time	Number of Surveys	Methodology
First week of April	Sunrise to 12:00 p.m.; 4:00 p.m. to sunset	1	Position the surveyor at 50 to 200 feet from suitable nesting habitat with a clear view of trees and surrounding area. Scan all trees for a minimum of 2 hours within 0.25 mile of the project boundary. Observe perching, nest building, mating, courtship, and other prenesting behaviors to identify a nest or nesting activity area.
Second week of April	Sunrise to 12:00 p.m.; 4:00 p.m. to sunset	1	Repeat the above survey in areas not determined to be occupied during the first survey. Attempt to confirm nest locations within nesting activity areas.
Third week of April	Sunrise to 12:00 p.m.; 4:00 p.m. to sunset	1	Repeat the above survey in areas not determined to be occupied during the first and second survey. In cases where a nest site was not identified within a nesting activity area during the first two surveys, approach the nesting activity area carefully to locate nests. If a nest is not found where there is reasonable certainty of nesting activity, rely on observations of courtship, mating, nest building, and other behaviors to define a nesting area and establish a buffer.
June 10 through July 15	Sunrise to 12:00 p.m.; 4:00 p.m. to sunset	3 surveys spaced at least 3 days apart	Inspect all previously identified nests for activity status. Walk and scan all other suitable nest trees within 0.25 mile of the project boundary for nests not found during the initial survey.

Mitigation Measure BIO-13: Tricolored Blackbird

Prior to implementation of project activities, a qualified biologist with experience surveying for and observing tricolored blackbird will conduct a preconstruction survey to establish use of suitable habitat by tricolored blackbird colonies. Surveys will be conducted in suitable habitat within 1,300 feet of proposed construction areas, where access allows, during the nesting season (generally March 15 to July 31) 1 year prior to, and then again the year of, construction. During each year, surveys will be conducted monthly in March, April, May, June, and July. If construction is initiated at a site during the nesting season, three surveys will be conducted within 15 days of construction with one of the surveys within 5 days of the start of construction. The CDFW Suisun Marsh Unit tracks tricolored blackbird colonies yearly in Suisun Marsh as part of the University of California, Davis/USFWS tricolored blackbird portal project; these records will also be searched and staff at the portal project consulted for recent colony information. If active tricolored blackbird nesting colonies are identified, minimization requirements and construction monitoring will be required.

- Project activities will avoid active tricolored blackbird nesting colonies and associated habitat during the breeding season (generally March 15 to July 31). Avoidance measures will include relocating covered activities away from the nesting colonies and associated habitat to the maximum extent practicable.
- Projects (construction and restoration) will be designed to avoid construction activity to the maximum extent practicable up to 1,300 feet, but not less than a minimum of 300 feet, from an active tricolored blackbird nesting colony. This minimum buffer may be reduced in areas with

dense forest, buildings, or other habitat features between the construction activities and the active nest colony, or where there is sufficient topographic relief to protect the colony from excessive noise or visual disturbance as determined by a biologist experienced with tricolored blackbird.

- Project activities potentially affecting a nesting colony will be monitored by a qualified biologist to verify that the activity is not disrupting the colony. If it is, the activity will be modified, as practicable, by either delaying construction until the colony abandons the site or until the end of the breeding season, whichever occurs first; temporarily relocating staging areas; or temporarily rerouting access to the construction site. Reclamation technical staff will consult with the fish and wildlife agencies and evaluate exceptions to the minimum nondisturbance buffer distance on a case-by-case basis.
- Prior to initiation of construction within 300 feet of suitable roosting habitat, a biologist with experience surveying for and observing tricolored blackbirds will conduct preconstruction surveys to establish use of roosting habitat by tricolored blackbird colonies. Surveys will be conducted in suitable habitat where access is available within 300 feet of proposed construction areas during the nonbreeding season (generally August 1 to March 14) 1 year prior to, and then again the year of, construction. If construction is initiated at a site during the nonbreeding season, three surveys will be conducted within 15 days prior to construction with one of the surveys within 5 days prior to the start of construction.
- Construction and restoration projects will also be designed to avoid construction activity within at least 300 feet from occupied active tricolored blackbird roosting habitat. This minimum buffer may be reduced in areas with dense forest, buildings, or other habitat features between the construction activities and the active roosting site, or where there is sufficient topographic relief to protect the roosting site from excessive noise or visual disturbance, or where sound curtains are used, as determined by a biologist experienced with tricolored blackbird.
- Construction activities that are within 300 feet of occupied roosting habitat will be monitored by a biologist familiar with tricolored blackbird behavior patterns to verify that the activity is not disrupting the roosting birds. If it is, the activity will be modified, as practicable, by delaying construction until the blackbirds are no longer using the roosting site, temporarily relocating staging areas, temporarily rerouting access to the construction site, or use of sound curtains. The biologist will evaluate the nondisturbance buffer distance on a case-by-case basis.

Unavoidable loss of foraging habitat will be mitigated through foraging habitat protection at a 1:1 ratio, and unavoidable loss of nesting habitat through riparian restoration at a 2:1 ratio.

Mitigation Measure BIO-14: Western Burrowing Owl

Species-specific measures for western burrowing owl will only be required for water conveyance construction, restoration, and operations and maintenance activities occurring within suitable habitat as identified from habitat assessments conducted in advance of initiating ground-disturbing and staging activities. This measure incorporates survey, avoidance, and minimization guidelines taken primarily from the *Staff Report on Burrowing Owl Mitigation* (CDFG 2012).

Preconstruction Surveys

Western burrowing owl surveys will be required within and adjacent to (within 500 feet) water conveyance work areas and restoration sites where suitable habitat has been identified during habitat assessment surveys where access is available. Surveys will be conducted during the breeding season that precedes construction.

Four survey visits will be conducted with at least one site visit between February 15 and April 15 and a minimum of three survey visits, at least 3 weeks apart, between April 15 and July 15, with at least one visit after June 15. Surveys will be conducted between 10:00 a.m. and 2 hours before sunset. A qualified biologist will survey the study area and record and map all burrowing owl observations and burrows that may be occupied (as indicated by tracks, feathers, egg shell fragments, pellets, prey remains, cast pellets, whitewash, or decoration) on the project site. The surveys will be conducted while walking transects throughout the entire project footprint, plus all accessible areas within a 500-foot radius of the project footprint. The centerlines of these transects will be spaced 15 to 60 feet apart and will vary in width to account for changes in terrain and vegetation that can preclude complete visual coverage of the area. For example, in hilly terrain with patches of tall grass, transects will be closer together, while in open areas with little vegetation they can be 60 feet apart. Surveyors will stop at least every 300 feet along each transect to scan the entire visible area for presence of burrowing owls. Adjacent parcels under different land ownership will be surveyed only if access is granted or if the parcels are visible from authorized areas.

In addition, preconstruction surveys will be conducted with one occurring 14 days prior to ground breaking and/or staging activities and another within 24 hours of these activities. These surveys will confirm whether owls identified during the breeding season surveys are still present or whether the site has since become occupied by burrowing owls.

Avoidance and Minimization

To the extent feasible, burrowing owls will be avoided by relocating work areas with flexible locations, such as geotechnical exploration sites and restoration sites. Within the construction footprint where ground disturbance cannot avoid burrowing owls, owls will be relocated during the nonbreeding season and burrows will be excavated.

If an active burrow is identified near a work area and work cannot be conducted outside of the nesting season (February 1 to August 31), a qualified biologist will establish a nondisturbance buffer that extends a minimum of 250 feet around the burrow. If burrowing owls are present at the site during the nonbreeding season (September 1 through January 31), a qualified biologist will establish a nondisturbance buffer that extends a minimum of 150 feet around the burrow.

If the appropriate nondisturbance buffer for breeding or nonbreeding burrowing owls cannot be established, a wildlife biologist experienced in burrowing owl behavior will evaluate site-specific conditions and recommend a smaller buffer that still minimizes the potential to disturb the owls (and still allows reproductive success during the breeding season), if possible. The site-specific buffer will be established by taking into consideration the type and extent of the proposed activity occurring near the occupied burrow, the duration and timing of the activity, the sensitivity and habituation of the owls to existing conditions, and the dissimilarity of the proposed activity to background activities. If an appropriate buffer cannot be established around the active owl burrows, actions will be taken to exclude the owls from the site per the requirements below.

A biological monitor will be present during all construction activities occurring within any reduced buffers. If during the breeding season there is any change in owl nesting and foraging behavior as a result of construction activities, the biological monitor will work with construction personnel and the Environmental Manager to provide additional protections to reduce disturbance, such as adding visual and sound curtains; any modifications to the standard protections will be approved by a qualified biologist.

If monitoring indicates that the nest is abandoned prior to the end of nesting season and the burrow is no longer in use by owls, the nondisturbance buffer may be removed. If necessary because the burrow cannot be avoided by construction activity, the biologist will excavate and collapse the burrow to prevent reoccupation.

Relocation

No exclusion of burrowing owls will occur during the breeding season. If burrowing owls are present within the construction footprint and cannot be avoided during the nonbreeding season (generally September 1 through January 31), they will be relocated through passive relocation, with or without burrow exclusion. Passive relocation will be used when (1) there is a sufficient amount of suitable habitat adjacent to the work area to support nesting and foraging, (2) there are compatible land use practices in the area and 3) the area is preferably currently under or proposed for conservation.

Passive relocation will be conducted during the nonbreeding season; however passive relocation techniques may be used during the breeding season (February 1 through August 30) if a qualified biologist determines through site surveillance that the burrow is not occupied by a breeding pair, young, or eggs. To the extent feasible, passive relocation will first be considered without the use of exclusion devices to avoid and minimize harassment of owls.

Passive Relocation without Exclusion

Prior to relocating owls, all potential burrowing owl burrows in suitable nesting habitat and within the project footprint and 75 feet around the footprint, will be surveyed for owl use, and excavated if no owls are found. If occupied burrows are found, two natural or artificial burrows will be provided for each occupied burrow in the above defined survey area, at least 250 feet from the construction footprint. Artificial burrows will be installed following the methods in Barclay (2008) and Johnson et al. (2010). Sites used for artificial burrows will either be properties currently used for or proposed for conservation. After constructing the artificial burrows, the owls will be given 60 days to relocate on their own. The study area will be monitored weekly for up to 60 days to determine whether the owls have left the burrow and to attempting to confirm occupancy at the artificial or other nearby burrows. The formerly occupied burrows will then be excavated. Whenever possible, burrows will be excavated using hand tools and refilled to prevent reoccupation. Sections of flexible plastic pipe (at least 3 inches in diameter) will be inserted into burrows during excavation to maintain an escape route for any animals inside the burrow.

Passive Relocation with Exclusion

If the burrowing owls found in the above survey area do not relocate on their own through the above methodology, passive relocation will be accomplished by installing one-way doors (e.g., modified dryer vents). The one-way doors will be left in place for a minimum of 48 hours and be monitored twice daily to ensure that the owls have left the burrow. The burrow will be excavated using hand tools, and a section of flexible plastic pipe (at least 3 inches in diameter) will be inserted into the burrow tunnel during excavation to maintain an escape route for any animals that may be inside the burrow.

Compensation for Unavoidable Effects

Mitigate unavoidable loss of nesting, wintering, and satellite burrows, and burrowing owl habitat in comparable habitat at an approved mitigation ratio in consultation with CDFW. The mitigation strategy will be consistent with the mitigation guidance in the *Staff Report on Burrowing Owl Mitigation* (CDFG 2012).

Mitigation Measure BIO-15: Western Yellow-Billed Cuckoo

This measure for western yellow-billed cuckoo will be required for activities occurring within suitable habitat, or in the vicinity of suitable habitat. Prior to disturbing an area potentially supporting habitat for the species, a USFWS-approved biologist will evaluate the area to identify suitable habitat.

Project activities will be located to avoid or minimize disturbance of western yellow-billed cuckoo suitable habitat within the species' range. The following measures will be required for project components unable to avoid western yellow-billed cuckoo habitat.

- Permanent or temporary loss of all suitable migratory habitat will be minimized by all activities associated with the proposed action through project design.
- Prior to construction, all suitable western yellow-billed cuckoo habitat in the construction area will be surveyed.
- At least five surveys will be conducted in suitable habitats within 30 days of the onset of construction, with the last within 3 days of the onset of construction, by a qualified biologist with experience surveying and observing this species and familiar with its vocalizations.
- If an active nest site is present, a 500-foot nondisturbance buffer will be established around nest sites during the breeding season (generally, late February through late August).
- The required buffer may be reduced in areas where barriers or topographic relief are sufficient protect the nest from excessive noise or other disturbance, as determined by a qualified biologist on a case-by-case basis.
- If occupied nests are identified, a qualified biologist will monitor construction activities in the vicinity of all active western yellow-billed cuckoo nests to ensure that covered activities do not affect nest success.
- If surveys find western yellow-billed cuckoos in the area where vegetation will be removed, vegetation removal will be done when cuckoos are not present.
- If an activity is to occur within 1,200 feet of western yellow-billed cuckoo habitat (or within 2,000 feet if pile driving will occur) during the period of from June 15 through September 1 (the period in which yellow-billed cuckoos have been observed in the legal Delta) the following measures will be implemented to avoid noise effects on migrating western yellow- billed cuckoos.
    - Prior to the construction, a noise expert will create a noise contour map showing the 60 dBA noise contour specific to the type and location of construction to occur in the area.
    - During the period between June 15 and September 1, a qualified biologist will survey any suitable migratory habitat for yellow-billed cuckoos within the 60 dBA noise contour on a daily basis during a two-week period prior to construction. While construction is occurring within this work window, the USFWS-approved biologist will conduct daily surveys in any suitable habitat where construction related noise levels could exceed 60 dBA L_{eq} (1 hour). If a yellow-billed cuckoo is found, sound will be limited to 60 dBA in the habitat being used until the USFWS-approved biologist has confirmed that the bird has left the area.
    - Locate, store, and maintain portable and stationary equipment as far as possible from suitable western yellow-billed cuckoo habitat.

- Employ preventive maintenance including practicable methods and devices to control, prevent, and minimize noise.
- Route truck traffic to reduce construction noise impacts and traffic noise levels within 1,200 feet of suitable western yellow-billed cuckoo migratory habitat during migration periods.
- Limit trucking activities (e.g., deliveries, export of materials) to the hours of 7:00 a.m. to 10:00 p.m.
- Screen all lights and direct them down toward work activities away from migratory habitat. A biological construction monitor will ensure that lights are properly directed at all times.
- Operate portable lights at the lowest allowable wattage and height, while in accordance with the NCHRP *Report 498: Illumination Guidelines for Nighttime Highway Work* (Transportation Research Board 2003).

Compensation to Offset Effects

Reclamation will offset the loss of western yellow-billed cuckoo migratory habitat through the creation or restoration at a 3:1 ratio, for a total of [to be determined] acres of migratory riparian habitat creation or restoration in USFWS-approved location. For restoration, Reclamation will develop a riparian restoration plan that will identify the location and methods for riparian creation or restoration, and this plan will be subject to USFWS approval.

Mitigation Measure BIO-16: White-Tailed Kite

Preconstruction surveys will be conducted to identify the presence of active nest sites of tree nesting raptors within 0.25 mile of project sites, staging and storage areas, construction access roads, work areas, and soil stockpile areas where accessible, by a qualified biologist with experience identifying white-tailed kite nests. Transportation routes along public roads (roads leading to and from work areas) are considered disturbed, and no surveys or monitoring are required for nests along those roadways unless they are within ¼ mile of work areas. Surveys for nesting white-tailed kites will be conducted within 30 days prior to construction to ensure nesting activity is documented prior to the onset of construction activity during the nesting season. White-tailed kites nest in the study area between approximately March 15 and September 15. While many nest sites are traditionally used for multiple years, new nest sites can be established in any year. Therefore, construction activity that is planned after March 15 of any year will require surveys during the year of the construction. If construction is planned before March 15 of any year, surveys will be conducted the year immediately prior to the year of construction. If construction is planned before March 15 of any year and subject to prior-year surveys, but is later postposed to after March 15, surveys will also be conducted during the year of construction.

Construction will be restricted to the greatest extent possible during the nesting season where nest sites occur within 0.25 mile of construction activities, unless an already existing suitable buffer between the construction activity and the nest site is identified by a biologist. Surveys for white-tailed kite nests and nesting activity will occur in conjunction with the surveys for bald eagles under MM BIO-17 and follow the same protocol. If active nests are found or nesting activity is identified within 0.25 mile of construction activities appropriate avoidance and minimization measures will be implemented as described. Results of the surveys will be summarized in a memo(s) and provided to the Program Environmental Manager and Construction Supervisor prior to the commencement of construction.

Removal of known nest trees will be avoided to the maximum extent feasible. No trees with occupied nests will be removed until the nest is vacated.

The biologist will conduct a second survey of potential nesting trees and active nests, and monitor white-tailed kite nests no more than 72 hours prior to construction. If no nesting activity is found, then construction can proceed with no restrictions.

Where construction activities within 0.25 mile of an active nest cannot feasibly be avoided, construction will be initiated prior to egg-laying to the extent possible. If eggs and or young are present in the nest, work will be restricted until a biologist determines that white-tailed kites have acclimated to disturbance and exhibit normal nesting behavior.

A 650-foot-radius nondisturbance buffer will be established around each active white-tailed kite nest site. No construction activity will be allowed to occur in the buffer while a nest site is occupied by white-tailed kite during the breeding season. The buffer size may be modified based on the field examination and determination by the biologist of conditions that may minimize disturbance effects, including line-of-sight, topography, land use, type of disturbance, existing ambient noise and disturbance levels, and other relevant factors. The buffer will be clearly delineated with fencing or other conspicuous marking. Active nests will be monitored to track progress of nesting activities. Entry into the buffer will be granted when the biologist determines that the young have fledged and are capable of independent survival or the nest has failed and the nest site is no longer active.

Where it is infeasible to avoid construction within 0.25 mile of an active white-tailed kite nest identified in preconstruction surveys, at a minimum the following measures will be implemented as part of a nesting bird monitoring and management plan. The final plan may include additional measures that are specific to site conditions.

- A designated biologist will observe any nest site that is within 0.25 mile of construction activities for at least 1 hour and until normal nesting behavior can be determined 5 days and 3 days prior to the initiation of construction. The biologist will determine nest status and observe normal nesting behaviors, which may be used to compare to the nesting activities once construction begins. The results of preconstruction monitoring will be reported in a memo and provided to the Program Environmental Manager and Construction Supervisor.
- Where pre-project surveys have identified an occupied white-tailed kite nest less than 325 feet from construction, the designated biologist will observe the nest periodically throughout the day where covered activities occur to ensure the white-tailed kites demonstrate normal nesting behavior.
- Where pre-project surveys have identified an occupied white-tailed kite nest between 325 to 650 feet from construction, the designated biologist will observe the nest for at least 2 hours per construction day where covered activities occur to ensure the white-tailed kites are engaged in normal nesting behavior.
- Where pre-project surveys have identified an occupied white-tailed kite nest between 650 to 1,300 feet from construction, the Biological Monitor will observe the nest for at least 3 days per construction week to ensure the white-tailed kites are engaged in normal nesting behavior and to check the status of the nest.

During construction or ongoing operation and maintenance activities, physical contact with an active nest tree is prohibited from the time of egg laying to fledging, unless approved by CDFW. Construction personnel outside of vehicles must remain at least 650 feet, or the length of a buffer approved by a qualified biologist which will not result in take, from the nest tree unless construction activities require them to be closer.

All personnel will remain out of the line of sight of an occupied white-tailed kite nest during breaks if within 650 feet of the nest (as stated above, activities will only occur within 650 feet of a nest with approval by the designated biologist).

The project will be implemented in a manner that will not result in take of white-tailed kite as defined by Section 86 of the California Fish and Game Code. If during construction monitoring, the designated biologist determines that a nesting white-tailed kite within 650 feet of construction is disturbed by construction activities, to the point where reproductive failure could occur, the designated biologist will immediately notify the Construction Supervisor and Program Environmental Manager. The Program Environmental Manager will contact CDFW, and it will be determined by the parties whether additional protection measures can be implemented.

Potential nest abandonment and failure may be indicated if white-tailed kite exhibits distress and/or abnormal nesting behavior such as swooping/stooping at construction equipment or personnel, excessive vocalization (distress calls) or agitation directed at construction equipment or personnel, failure to remain on nest or failure to deliver prey items for an extended time period. Additional protection measures will remain in place until the white-tailed kite behavior has normalized.

Mitigate unavoidable loss of foraging habitat through foraging habitat protection at a 1:1 ratio, and unavoidable loss of nesting habitat through riparian restoration at a 2:1 ratio.

Mitigation Measure BIO-17: Bald Eagle

The following measures will be implemented to avoid and minimize impacts on bald eagle during Reclamation project activities.

- If restoration activities, including helicopter flights, need to take place during the nesting season and within 0.5 mile of potential bald eagle nesting habitat, qualified agency-approved biologists will conduct a preconstruction survey for occupied bald eagle nest in and within 0.5 mile of the work areas. An *occupied nest* is a “nest used for breeding in the current year by a [bald or golden eagle] pair” (Pagel et al. 2010). Survey procedures, including required surveyor qualifications, will follow the USFWS’ *Interim Golden Eagle Inventory and Monitoring Protocols; and Other Recommendations* (Pagel et al. 2010) or other more recent guidelines, if available.
- Reclamation will implement, at a minimum, the following measures to avoid disturbance of active eagle nests (i.e., “a golden eagle [or bald eagle] nest characterized by the presence of any adult, egg, or dependent young at the nest in the past 10 consecutive days immediately prior to, and including, at present” [Pagel et al. 2010]):
    - No activities involving loud noise (>90 decibels) or helicopter flight paths will be permitted within 0.5 mile of any active eagle nest found during preconstruction surveys. This restriction will be in effect from January to August 31 unless nest monitoring by a qualified agency-approved biologist reveals that the nest is no longer active (e.g., adults did not nest that year, nest failure from natural causes, young fledged).
    - Activities that do not involve loud noise will maintain an exclusion zone of 0.25 mile around all active eagle nests found during preconstruction surveys. This restriction will be in effect from January to August 31 unless nest monitoring by a qualified agency-approved biologist reveals that the nest is no longer active.

- Eagle nest exclusion zones may be removed if monitoring reveals the nest to be inactive, and considered to be an "alternate nest" under current regulations under the Bald and Golden Eagle Protection Act. An alternate nest is "one of potentially several nests within a nesting territory that is not an in-use nest at the current time" (USFWS 2016). Monitoring to demonstrate that nests are not in-use will follow observational procedures described by Pagel et al. (2010).

Mitigation Measure BIO-18: Bank Swallow

The following measures will be implemented to avoid and minimize impacts on bank swallow individuals, colonies, current and potential habitat (i.e., natural banks), and, if feasible, to river processes. This applies to activities year-round, whether bank swallows are present or not.

Preconstruction Surveys

Prior to beginning project activities within 500 feet of the Sacramento River, Feather River, and lower American River during the bank swallow nesting season (April 1 through August 31), a preconstruction survey for bank swallow colonies will be conducted where bank swallow habitat is present within 500 feet of work areas. If no active nesting colonies are present, no further measures are required.

If an active colony is found and work must occur during the nesting season (April 1 through August 31), Reclamation will establish a nondisturbance buffer (in consultation with a biologist) around the colony during the breeding season. In addition, the biologist will monitor any active colony within 500 feet of work areas to ensure that activities do not affect nest success. No project activities will take place within the disturbance buffer.

Avoidance and Minimization

Prevent Impacts on Individuals, Colonies, and Habitat

To the extent feasible, where proposed water management or land-use projects (i.e., restoration activities) projects would impact bank swallows or river processes, alternatives such as setback levees can be used to avoid those impacts.

Consult with a biologist when planning projects within the floodplain of the Sacramento River and its tributaries to ensure projects do not affect colonies or current or potential habitat.

Develop flow criteria that avoid impacts of high water flows by limiting frequency and duration of peak flows over 14,000 cfs (Sacramento River) or rapid draw-downs to nesting bank swallow habitat during the breeding season (April 1 through August 31); this includes downstream tributary flows when timing water releases (Bank Swallow Technical Advisory Committee 2013).

Prevent Impacts on River Processes

To the extent feasible, where restoration activities would impact river processes, alternatives to bank stabilization, such as setback and adjacent levees, should be used to preserve dynamic river processes.

Maintain flow regimes during the nonbreeding season (September 1 through March 31) that promote natural river processes and create bank swallow habitat by providing annual flows that cause local bank erosion and a minimum of one bankfull flood event every 3 years to promote bank erosion, meander migration, and channel cutoff. (Bank Swallow Technical Advisory Committee 2013).

Mitigation Measure BIO-19: California Least Tern

For restoration projects, Reclamation will avoid California least tern nesting colony sites.

Mitigation Measure BIO-20: Migratory Birds (Osprey, Short-Eared Owl, Tule Greater White-fronted Goose, Black Tern, Least Bittern, White-Faced Ibis)

The following measures will be implemented to avoid and minimize impacts on nesting migratory birds, including special-status birds, during Reclamation restoration activities.

- A qualified wildlife biologist with experience with nesting birds will conduct nesting surveys before the start of restoration activities. A minimum of three separate surveys will be conducted within 30 days prior to the initiation of work, with the last survey within 3 days prior to work beginning in a given work area. Surveys will include a search of all suitable nesting habitat in the work area. In addition, a 500-foot radius around the work area, where accessible, will be surveyed for nesting raptors, and an area within 50 feet of the work area will be surveyed for other nesting birds protected by the MBTA. If no active nests are detected during these surveys, no additional measures are required.

If active nests are found in the survey area, nondisturbance buffers will be established around the nest sites to avoid disturbance or destruction of the nest site until the end of the breeding season (approximately September 1) or until a qualified wildlife biologist determines that the young have fledged and moved out of the study area. The end of the breeding season varies by species and the stage of the nesting effort (i.e., nest building, egg laying, incubation, feeding nestling, feathered young, fledged young, etc.) as determined by the qualified wildlife biologist. A qualified wildlife biologist will monitor activities in the vicinity of the nests to ensure that activities do not affect nest success. The extent of the buffers will be determined by the biologist and will depend on the level of noise or disturbance, line-of-sight between the nest and the disturbance, ambient levels of noise and other disturbances, and other topographical or artificial barriers. Suitable buffer distances may vary between species.

Mitigation Measure BIO-21: Riparian Woodrat and Riparian Brush Rabbit

The measures for riparian woodrat and riparian brush rabbit will be implemented for projects occurring within suitable habitat. Within the study area, based on the known distribution of the species, suitable habitat is defined to include the areas within the legal Delta along San Joaquin and Stanislaus Rivers south of State Route 4 and Old River Pipeline. Within this area, suitable riparian habitat includes the vegetation types that make up a dense, brushy understory shrub layer with a minimum patch size of 0.05 acres. Riparian brush rabbit grassland habitat includes grasslands with a minimum patch size of 0.05 acres that are adjacent to riparian brush rabbit riparian habitat.

A qualified biologist will conduct a field evaluation of suitable habitat for both species for all covered activities that occur within the defined area for these species' habitat as described above. If the project cannot fully avoid effects on suitable habitat, the following measures will be required.

- A qualified biologist will assess habitat suitability for both species. If the qualified biologist determines the habitat to be suitable for the species, then Reclamation will avoid disturbing suitable habitat while accessing restoration sites (i.e., access to enhancement sites for in-stream activities such as gravel placement).

- If a habitat or floodplain restoration component would disturb suitable habitat, Reclamation will assume presence or conduct protocol-level surveys according to the USFWS *Draft Habitat*

Assessment Guidelines and Survey Protocol for the Riparian Brush Rabbit and the Riparian Woodrat (USFWS n.d.).

- If occupied riparian woodrat or riparian brush rabbit habitat is present, or the habitat is assumed to be occupied, Reclamation will redesign the project to avoid occupied habitat. Avoidance requires the following buffers and avoidance measures:
  - Establish minimum 250-foot nondisturbance buffers between project activities and suitable riparian habitat that is occupied or assumed to be occupied. The nondisturbance buffer is not necessary for access to restoration sites provided existing access roads are used.
  - Establish a 1,400-foot buffer between any lighting and suitable riparian habitat that is occupied or assumed to be occupied.
  - Screen all lights and direct them down toward work activities away from riparian habitat that is occupied or assumed to be occupied. A biological construction monitor will ensure that lights are properly directed at all times.
  - Operate portable lights at the lowest allowable wattage and height, while in accordance with the NCHRP *Report 498: Illumination Guidelines for Nighttime Highway Work* (Transportation Research Board 2003).
- If the suitable habitat is determined through surveys to be unoccupied, Reclamation will implement the following measures to minimize long-term effects on the habitat so that it may provide for the recovery of the species. No more than 45 acres of suitable, unoccupied riparian habitat and 30 acres of adjacent grasslands may be permanently removed by levee construction in the San Joaquin River watershed. No more than 35 acres of suitable riparian habitat and 20 acres of adjacent grassland habitat may be temporarily removed for levee construction in the San Joaquin watershed. No more than 10 acres of suitable, unoccupied riparian habitat may be affected in the Stanislaus River watershed.
  - Floodplain restoration projects will be designed to minimize the removal of mature oaks in areas providing suitable habitat for the riparian woodrat.
  - Include refugia within the restored floodplains to provide shelter from flood events for any individuals of these species that may come to occupy the area.
- Reclamation will additionally implement the following measures to avoid and minimize noise and lighting-related effects on riparian brush rabbit:
  - Establish a 1,200-foot nondisturbance buffer between any project activities and suitable riparian habitat.
- Offset any unavoidable loss of suitable riparian habitat through restoration at a 3:1 ratio, using the following restoration design measures:
- Restoration must meet specific ecological requirements for the species.
- Restoration is adjacent to, or facilitates connectivity with, existing occupied or potentially occupied habitat.

Mitigation Measure BIO-22: Salt Marsh Harvest Mouse and Suisun Shrew

Where suitable salt marsh harvest mouse and Suisun shrew habitat has been identified within a tidal restoration work area or within 100 feet of a tidal restoration work area where ground-disturbing activities will occur (e.g., at a levee breach or grading location) a biologist will conduct preconstruction surveys for the mouse or shrew prior to ground disturbance. If a mouse or shrew is discovered, tidal restoration activities near the mouse or shrew will cease until wildlife staff can be contacted and a relocation plan can be developed. Prior to tidal restoration ground-disturbing activities, vegetation will first be removed with nonmechanized hand tools (e.g., goat or sheep grazing, or, in limited cases where the biological monitor can confirm that there is no risk of harming salt marsh harvest mouse or Suisun shrew, hoes, rakes, and shovels may be used) to allow salt marsh harvest mouse and Suisun shrew to passively move out of the location. Vegetation must be cleared to bare ground and removed from the work area, including roads. The upper 6 inches of soil excavated within salt marsh harvest mouse and Suisun shrew habitat will be stockpiled and replaced on top of backfilled material. Vegetation will be removed under supervision of a biological monitor familiar with salt marsh harvest mouse and Suisun shrew. Vegetation removal will start at the edge farthest from the salt marsh and work its way toward the salt marsh. This method of removal provides cover for salt marsh harvest mouse and Suisun shrew and allows them to move toward the salt marsh as vegetation is being removed.

Temporary exclusion fencing will be placed around a defined tidal restoration work area before construction activities start and immediately after vegetation removal. The fence should be made of material that does not allow a salt marsh harvest mouse or Suisun shrew to pass through and should be buried to a depth of 2 inches so that mice cannot crawl under the fence. Supports for the fence must be placed on the inside of the exclusion area. Prior to the start of daily activities during initial ground disturbance, the biologist will inspect the salt marsh harvest mouse-proof boundary for holes or rips. The work area will also be inspected to ensure no mice are trapped inside. Any mice or shrews found along or outside the fence will be closely monitored until they move away from the construction site. Tidal restoration work will be scheduled to avoid extreme high tides (6.5 feet or above, as measured at the Golden Gate Bridge) to allow for salt marsh harvest mouse to more easily move to higher grounds.

The biologist with previous salt marsh harvest mouse and Suisun shrew experience will be onsite during construction activities related to tidal restoration in suitable habitat. The biologist will document compliance with the project permit conditions and avoidance and conservation measures. The approved biologist will have the authority to stop tidal restoration activities if any of the requirements associated with these measures are not being fulfilled. If the biologist requests work stoppage because of take of any listed species, CDFW and USFWS staff will be notified within 1 day by email or telephone.

Mitigation Measure BIO-23: Ring-Tailed Cat

Because ring-tailed cats maintain multiple dens, the loss of one den would be a negligible impact. However, the loss of a natal or maternity den would be significant. Reclamation will implement the following measure for ring-tailed cat:

- A qualified biologist familiar with ring-tailed cat biology will conduct a habitat assessment of the proposed construction area. If highly suitable denning habitat is present, the area will be designated as an Environmental Sensitive Area and marked on project maps.
- When possible, the removal of vegetation and construction activities will be conducted outside of the breeding season for ring-tailed cat (February 1 through May 1).

- If the denning season cannot be completely avoided, a qualified biologist will conduct a preconstruction survey within 2 weeks prior to commencement of construction for potential natal or maternity den trees. If an active den is found, a qualified biologist, will determine a construction-free buffer zone to be establish around the den until the young have left the den.
- A biological monitor will be present when construction activities take place when active ring-tailed cat dens are identified within the construction work area and work takes place within 150 feet of the den.

Mitigation Measure BIO-24: Special-Status Bats

The following measure was designed to avoid and minimize adverse direct and indirect effects on special-status bats. Baseline data are not available or are limited on how bats use the study area and on individual numbers of bats and how they vary seasonally. Accordingly, it is difficult to determine if there would be a substantial reduction in species numbers. Bat species with potential to occur in the study area employ varied roost strategies, from solitary roosting in foliage of trees to colonial roosting in trees and artificial structures, such as buildings and bridges. Daily and seasonal variations in habitat use are common. To obtain the highest likelihood of detection, preconstruction bat surveys will be conducted by Reclamation and will include these components:

- Identification of potential roosting habitat within project footprint.
- Daytime search for bats and bat sign in and around identified habitat.
- Evening emergence surveys at potential day-roost sites, using night-vision goggles and/or active full-spectrum acoustic monitoring where species identification is sought.
- Passive full-spectrum acoustic monitoring and analysis to detect bat use of the area from dusk to dawn over multiple nights.
- Additional onsite night surveys as needed following passive acoustic detection of special-status bats to determine nature of bat use of the structure in question (e.g., use of structure as night roost between foraging bouts).
- Qualified biologists will have knowledge of the natural history of the species that could occur in the study area and experience using full-spectrum acoustic equipment. During surveys, biologists will avoid unnecessary disturbance of occupied roosts.

Preconstruction Bridge and Other Structure Surveys

Before work begins on the bridge/structure, qualified biologists will conduct a daytime search for bat sign and evening emergence surveys to determine if the bridge/structure is being used as a roost. Biologists conducting daytime surveys would listen for audible bat calls and would use naked eye, binoculars, and a high-powered spotlight to inspect expansion joints, weep holes, and other bridge features that could house bats. Bridge surfaces and the ground around the bridge/structure would be surveyed for bat sign, such as guano, staining, and prey remains.

Evening emergence surveys will consist of at least one biologist stationed on each side of the bridge/structure watching for emerging bats from a half hour before sunset to 1–2 hours after sunset for a minimum of 2 nights within the season that construction would be taking place. Night-vision goggles and/or full-spectrum acoustic detectors shall be used during emergence surveys to assist in species identification. All emergence surveys would be conducted during favorable weather conditions (calm nights with temperatures conducive to bat activity and no precipitation predicted).

Additionally, passive monitoring with full-spectrum bat detectors will be used to assist in determining species present. A minimum of 4 nights of acoustic monitoring surveys will be conducted within the season that the construction would be taking place. If site security allows, detectors should be set to record bat calls for the duration of each night. To the extent possible, all monitoring will be conducted during favorable weather conditions (calm nights with temperatures conducive to bat activity and no precipitation predicted). The biologists will analyze the bat call data using appropriate software and prepare a report with the results of the surveys. If acoustic data suggest that bats may be using the bridge/structure as a night roost, biologists will conduct a night survey from 1 to 2 hours past sunset up to 6 hours past sunset to determine if the bridge is serving as a colonial night roost.

If suitable roost structures will be removed, additional surveys may be required to determine how the structure is used by bats, whether it is as a night roost, maternity roosts, migration stopover, or for hibernation.

Preconstruction Tree Surveys

If tree removal or trimming is necessary, qualified biologists will examine trees to be removed or trimmed for suitable bat roosting habitat. High-value habitat features (large tree cavities, basal hollows, loose or peeling bark, larger snags, palm trees with intact thatch, etc.) will be identified and the area around these features searched for bats and bat sign (guano, culled insect parts, staining, etc.). Riparian woodland, orchards, and stands of mature broadleaf trees should be considered potential habitat for solitary foliage roosting bat species.

If bat sign is detected, biologists will conduct evening visual emergence surveys of the source habitat feature from a half hour before sunset to 1–2 hours after sunset for a minimum of 2 nights within the season that construction would be taking place. Methodology should follow that described above for the bridge emergence survey.

Additionally, if suitable tree roosting habitat is present, acoustic monitoring with a bat detector will be used to assist in determining species present. These surveys would be conducted in coordination with the acoustic monitoring conducted for the bridge structure.

Protective Measures for Bats using Bridges/Structures and Trees

Avoidance and minimization measures shall be necessary if it is determined that bats are using the bridge/structure or trees as roost sites and/or sensitive bats species are detected during acoustic monitoring. Appropriate measures shall include, as applicable, the measures listed below.

- Ensure that bats are protected from noise, vibrations, and light that result from construction activities associated with water conveyance facilities, conservation components, and ongoing habitat enhancement, as well as operations and maintenance of above-ground water conveyance facilities, including the transmission facilities. This would be accomplished by either directing noise barriers and lights inward from the disturbance or ensuring that the disturbances do not extend more than 300 feet from the point source.
- Disturbance of the bridge will be avoided between March 1 and October 31 (the maternity period) to avoid impacts on reproductively active females and dependent young.

- Installation of exclusion devices from March 1 through October 31 to preclude bats from occupying the bridge during construction. Exclusionary devices will only be installed by or under the supervision of an experienced bat biologist.
- Tree removal will be avoided between April 15 and September 15 (the maternity period for bat species that use trees) to avoid impacts on pregnant females and active maternity roosts (whether colonial or solitary).
- Tree removal will be conducted between September 15 and October 31 to the maximum extent feasible, which corresponds to a time period when bats would not likely have entered winter hibernation and would not be caring for flightless young.
- Trees will be removed in pieces, rather than felling the entire tree.
- If a maternity roost is located, whether solitary or colonial, that roost will remain undisturbed with a buffer as determined in by a qualified biologist until September 15 or until the qualified biologist has determined the roost is no longer active.
- If a non-maternity roost is found, that roost will be avoided to the maximum extent feasible and an appropriate buffer established in consultation with a qualified biologist. Every effort would be made to avoid the roost to the maximum extent feasible, as methods to evict bats from trees are largely untested. However, if the roost cannot be avoided, eviction will be attempted and procedures designed in consultation with the qualified biologist will be employed to reduce the likelihood of mortality of evicted bats. In all cases:
  - Eviction would not occur before September 15.
  - Qualified biologists would carry out or oversee the eviction tasks and would monitor the tree trimming/removal.
  - Eviction would take place late in the day or in the evening to reduce the likelihood of evicted bats falling prey to diurnal predators.
  - Eviction would take place during weather and temperature conditions conducive to bat activity.
  - Special-status bat roosts would not be disturbed.
- Eviction procedures shall include but are not limited to the following:
  - Pre-eviction surveys to obtain data to inform the eviction approach and subsequent mitigation requirements. Relevant data may include the species, sex, reproductive status and/or number of bats using the roost, and roost conditions themselves such as temperature and dimensions. Surveys may include visual emergence, night vision, acoustic, and/or capture.
  - If needed, structural changes to the roost, performed without harming bats, such that the conditions in the roost are undesirable to roosting bats and the bats leave on their own (e.g., open additional portals so that temperature, wind, light and precipitation regime in the roost change).
  - Non-injurious harassment at the roost site to encourage bats to leave on their own, such as ultrasound deterrents or other sensory irritants.
- Prior to removal/trimming, after other eviction efforts have been attempted, any confirmed roost tree would be shaken, repeatedly struck with a heavy implement such as an axe and several

minutes should pass before felling trees or trimming limbs to allow bats time to arouse and leave the tree. The biologists should search downed vegetation for dead and injured bats. The presence of dead or injured bats would be reported to CDFW.

Compensatory mitigation for the loss of roosting habitat will include the construction and installation of suitable replacement habitat onsite. Depending on the species and type of roost lost, various roost replacement habitats have met with some success (e.g., bat houses, “bat bark,” planting cottonwood trees, leaving palm thatch in place rather than trimming). Creating natural habitat onsite is generally preferable to artificial habitat.

Artificial roosts are often unsuccessful, and care must be taken to determine as closely as possible the conditions in the natural roost to be replaced. Even with such care, artificial habitat may fail. Several artificial roosts have been highly successful in replacing bridge roost habitat when incorporated into new bridge designs. “Bat bark” has been successfully used by the Arizona Department of Game and Fish to create artificial crevice-roosting bat habitat mounted on pine trees (Mering and Chambers 2012:765). Bat houses have at best an inconsistent track record but information is mounting on how to create successful houses. There is no single protocol or recipe for bat-house success. Careful study of the roost requirements of the species in question; the particular conditions at the lost roost site including temperature, orientation of the openings, airflow, internal dimensions and structures (cavity vs. crevice, etc.) should increase the chances of designing a successful replacement.

Restoring riparian woodland with plantings shows signs of success in Colorado. Western red bat activity has been positively correlated with increased vegetation and tree growth, canopy complexity and restoration acreage at cottonwood-willow restoration sites along the Lower Colorado River (Broderick 2010). These complex woodland areas would ultimately provide a wider range of bat species with preferred roost types, including both foliage-roosting and crevice-/cavity-roosting bats.

Mitigation Measure BIO-25: Suisun Thistle and Soft Bird’s-Beak

A complete botanical survey of project sites will be completed using *Guidelines for Conducting and Reporting Botanical Inventories for Federally Listed, Proposed and Candidate Plants* (USFWS 1996) and *Protocols for Surveying and Evaluating Impacts to Special Status Native Plant Populations and Sensitive Natural Communities* (CDFW 2018). The surveys will be floristic in nature and conducted in a manner that maximizes the likelihood of locating Suisun thistle and soft bird’s-beak (i.e., during the appropriate season and at an appropriate level of ground coverage).

Special-status plant surveys required for project-specific permit compliance will be conducted early in the planning process to allow design of the individual restoration projects to avoid adverse modification of habitat for specified covered plants. The purpose of these surveys will be to verify that the locations of Suisun thistle and soft bird’s-beak identified in previous record searches or surveys are extant, identify any new occurrences, and cover any portions of the study area not previously identified. The extent of compensation for direct loss of or indirect effects on Suisun thistle and soft bird’s-beak will be based on these survey results. Locations of the plants in proposed construction areas will be recorded using a GPS unit and flagged.

The following measures will be implemented:

- Design restoration projects to avoid the direct, temporary loss of occupied habitat from construction activities for Suisun thistle. In tidal restoration areas, Suisun thistle occurrences may experience the indirect effect of tidal damping. This effect will be monitored and adaptively managed to ensure the occurrence is protected from loss.

- If a soft bird's-beak occurrence has more than 10 individuals, no more than 5% of the total number of individuals in the occurrence will be removed. If an occurrence has 10 or fewer individuals, all individuals may be removed. Loss of individuals for all occurrences will be offset through replacement of occupied habitat at a ratio of at least 1:1, to achieve no net loss of occupied habitat.
- To minimize the spread of nonnative, invasive plant species from restoration sites, Reclamation will retain a qualified botanist or weed scientist prior to clearing operations to determine if affected areas contain invasive plants. If areas to be cleared contain invasive plants, then chipped vegetation material from those areas will not be used for erosion control; in these cases, the material will be disposed of to minimize the spread of invasive plant propagules (e.g., by burning, composting). All revegetation materials (such as mulches and seed mixtures used during restoration) shall be certified weed-free and come from locally adapted native plant materials.
- To minimize the introduction of invasive plant species, construction vehicles and construction machinery will be cleaned prior to entering construction sites that are in or adjacent to natural communities other than cultivated lands and prior to entering any restoration sites or conservation lands other than cultivated lands. Vehicles travelling off paved roads in areas with infestations of invasive plant species will be cleaned before travelling to other parts of the study area. Cleaning stations will be established at the perimeter of covered activities along construction routes as well as at the entrance to reserve system lands. Biological monitoring will include locating and mapping locations of invasive plant species within the construction areas during the construction phase and the restoration phase. Infestations of invasive plant species will be targeted for control or eradication as part of the restoration and revegetation of temporarily disturbed construction areas.
- Reclamation will ensure that covered activities in designated critical habitat areas for Suisun thistle or soft bird's-beak, if any, will not result in the adverse modification of any of the primary constituent elements for Suisun thistle or soft bird's-beak critical habitat. The CDFW Suisun Marsh Unit tracks both of these species (GIS-mapped) in Suisun Marsh. No covered activities will take place within designated Suisun thistle or soft bird's-beak critical habitat areas without prior written concurrence from USFWS that such activities will not adversely modify any primary constituent elements of Suisun thistle or soft bird's-beak critical habitat. Primary constituent elements for Suisun thistle are defined as follows.
  - Persistent emergent, intertidal, estuarine wetland at or above the mean high water mark as extended directly across any intersecting channels).
  - Open channels that periodically contain moving water with ocean-derived salts in excess of 0.5%.
  - Gaps in surrounding vegetation to allow for seed germination and growth.
- Primary constituent elements for soft bird's-beak are defined as follows.
  - Persistent emergent, intertidal, estuarine wetland at or above the mean high water mark (as extended directly across any intersecting channels).
  - Rarity or absence of plants that naturally die in late spring (winter annuals).

- Partially open spring canopy cover at ground level, with many small openings to facilitate seedling germination.

Mitigation Measure BIO-26: Other Special-Status Plant Species (Contra Costa Goldfields, Delta Button-Celery, Delta Tule Pea, Mason's Lilaeopsis, Suisun Marsh Aster, Bolander's Water Hemlock, Sanford's Arrowhead)

A complete botanical survey of project sites in areas of suitable habitat for special-status plants will be completed using *Protocols for Surveying and Evaluating Impacts to Special Status Native Plant Populations and Sensitive Natural Communities* (CDFW 2018). The surveys will be floristic in nature and conducted in a manner that maximizes the likelihood of locating special-status plant species or special-status natural communities that may be present (i.e., during the appropriate season and at an appropriate level of ground coverage).

Special-status plant surveys required for project-specific permit compliance will be conducted during the planning phase to allow design of the individual project activities to avoid or minimize adverse impacts to habitat for specified covered plants. The purpose of these surveys will be to verify that the locations of special-status plants identified in previous record searches or surveys are extant, identify any new special-status plant occurrences, and cover any portions of the study area not previously identified. The extent of mitigation of direct loss of or indirect effects on special-status plants will be based on these survey results. Locations of special-status plants in proposed construction areas will be recorded using a GPS unit and flagged.

The following measures will be implemented.

- Design restoration projects to avoid the direct, temporary loss of occupied habitat from construction activities for other special-status plant species. If other special-status plant species occur in a floodplain restoration area, restoration projects may be designed to include occupied habitat in the restored floodplain provided ground disturbance is avoided in the occupied habitat and the restoration is designed such that the anticipated level of flooding and scouring is compatible with the life-history needs of the covered plant species. In tidal restoration areas, occurrences may experience the indirect effect of tidal damping. This effect will be monitored and adaptively managed to ensure the occurrence is protected from loss.
- Avoid modeled habitat for vernal pool plants to the maximum extent practicable. Where practicable, no ground-disturbing activities or alterations to hydrology will occur within 250 feet of vernal pools. Reclamation will ensure that there will be no adverse modification of critical habitat for vernal pool plants.
- Avoid the loss of extant occurrences of all other special-status plant species.
- If an occurrence has more than 10 individuals, no more than 5% of the total number of individuals in the occurrence will be removed. If an occurrence has 10 or fewer individuals, all individuals may be removed. Loss of individuals for all occurrences will be offset through replacement of occupied habitat at a ratio of at least 1:1, to achieve no net loss of occupied habitat.
- To minimize the spread of nonnative, invasive plant species from restoration sites, Reclamation will retain a qualified botanist or weed scientist prior to clearing operations to determine if affected areas contain invasive plants. If areas to be cleared contain invasive plants, then chipped vegetation material from those areas will not be used for erosion control; in these cases, the

material will be disposed of to minimize the spread of invasive plant propagules (e.g., by burning, composting). All revegetation materials (such as mulches and seed mixtures used during restoration) shall be certified weed-free and come from locally adapted native plant materials.

- To minimize the introduction of invasive plant species, construction vehicles and construction machinery will be cleaned prior to entering construction sites that are in or adjacent to natural communities other than cultivated lands, and prior to entering any project restoration sites or conservation lands other than cultivated lands. Vehicles travelling off paved roads in areas with infestations of invasive plant species will be cleaned before travelling to other parts of the project. Cleaning stations will be established at the perimeter of covered activities along construction routes as well as at the entrance to conservation lands. Biological monitoring will include locating and mapping locations of invasive plant species within the construction areas during the construction phase and the restoration phase. Infestations of invasive plant species will be targeted for control or eradication as part of the restoration and revegetation of temporarily disturbed construction areas.
- This mitigation measure does not apply to the routine management and maintenance activities of Reclamation. Reclamation will determine during implementation the most effective and cost-efficient means to minimize the unintentional spread of invasive plants through vehicle travel.

P.2.7.2 *Mitigation Measures for Wetlands and Waters of the United States*

Mitigation Measure BIO-27: Wetlands and Waters of the United States

Reclamation will avoid fill of wetlands and waters of the United States to the extent feasible, and will offset unavoidable effects through wetland creation, restoration, or enhancement with the goal of achieving no net loss of wetland acres and functions.

P.2.8 Summary of Impacts

Table P.2-3 includes a summary of impacts, the magnitude and direction of those impacts, and potential mitigation measures for consideration.

Table P.2-3. Impact Summary

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
Potential changes to wildlife and plant habitat on river banks (Project-Level)	No Action	No effect	–
	1	Changes in flows compared with the No Action Alternative are expected to result in very minor effects on plants and wildlife along stream and reservoir banks but could result in substantial adverse effects on bank swallow colonies.	MM BIO-18 Bank Swallow

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	2	Changes in flows compared with the No Action Alternative are expected to result in very minor effects on plants and wildlife along stream and reservoir banks but could result in substantial adverse effects on bank swallow colonies.	MM BIO-18 Bank Swallow
	3	Changes in flows compared with the No Action Alternative are expected to result in very minor effects on plants and wildlife along stream and reservoir banks, but could result in substantial adverse effects on bank swallow colonies.	MM BIO-18 Bank Swallow
	4	Changes in flows compared with the No Action Alternative are expected to result in very minor effects on plants and wildlife along stream and reservoir banks, but could result in substantial adverse effects on bank swallow colonies.	MM BIO-18 Bank Swallow
Potential changes to existing marshes and associated special-status species in the Bay-Delta region (Program-Level)	No Action	No effect	–
	1	Habitat restoration may result in short-term loss of tidal marsh habitat.	MM BIO-7 California Black Rail, MM BIO-8 California Ridgway's Rail, MM BIO-22, Salt Marsh Harvest Mouse and Suisun Shrew, MM BIO-25 Suisun Thistle and Soft Bird's-Beak, MM BIO-26 Other Special-Status Plant Species
	2	No effect	–
	3	Habitat restoration may result in short-term loss of tidal marsh habitat.	MM BIO-7 California Black Rail, MM BIO-8 California Ridgway's Rail, MM BIO-22, Salt Marsh Harvest Mouse and Suisun Shrew, MM BIO-25 Suisun Thistle and Soft Bird's-Beak, MM BIO-26 Other Special-Status Plant Species

Impact	Alternative	Magnitude and Direction of Impacts	Potential Mitigation Measures
	4	No effect	–
Potential changes to existing riparian areas and associated special-status species (Program-Level)	No Action	No effect	–
	1	Habitat restoration may result in the loss of riparian habitat.	MM BIO-2 Valley Elderberry Longhorn Beetle, MM BIO-4 Foothill Yellow-Legged Frog, MM BIO-15 Western Yellow-Billed Cuckoo, MM BIO-10 Least Bell's Vireo, MM BIO-12 Swainson's Hawk, MM BIO-16 White-Tailed Kite, MM BIO-11 Suisun Song Sparrow, Saltmarsh Common Yellowthroat, Yellow-Breasted Chat, Yellow Warbler, MM BIO-20 Migratory Nesting Birds, MM BIO-17 Bald Eagle, MM BIO-23 Ring-Tailed Cat, MM BIO-21 Riparian Woodrat and Riparian Brush Rabbit

	4	Potential short term decrease or long-term conversion of wetland types and waters of the United States.	MM BIO-27 Wetlands and Waters of the United States

P.2.9 Cumulative Effects

The cumulative effects analysis for terrestrial biological resources addresses the potential for the project alternatives to act in combination with other past, present, and reasonably foreseeable future projects, programs, or conditions to create a cumulatively adverse impact. The analysis also considers whether any incremental effect of the alternative is cumulatively considerable.

The projects and programs that have been considered as part of the cumulative analysis have been compiled in Appendix Y, *Cumulative Methodology*. The list of past, present, and reasonably foreseeable future projects and programs has been evaluated to determine which of these activities may have effects on terrestrial habitats and terrestrial species that are known to occur within the study area.

In addition, the effects of climate change have been considered in addressing the cumulative effects of alternatives on terrestrial biological resources. Changes that might occur within the study area related to climate change are considered reasonably foreseeable and part of the cumulative condition that might combine with the effects of the implementation of project alternatives.

To assess whether implementation of the alternatives would contribute to an adverse cumulative effect on the terrestrial biological resources of the study area, a judgment must first be made regarding potential adverse effects of the alternatives. Where adverse effects are anticipated, a determination must be made as to whether these effects would contribute to a cumulative adverse effect on a terrestrial biological resource. If there is a contribution to a cumulative adverse effect, a final judgment must be made as to whether the effect of the alternative represents a considerable contribution to the cumulative effect.

P.2.9.1 *Cumulative Effects of the No Action Alternative*

P.2.9.1.1 Effects of Past, Present, and Reasonably Foreseeable Projects and Programs

The current conditions of study area biological resources are the byproduct of past and ongoing human activity, including declining acreages of natural habitat due to agricultural, urban development, and flood control and water management activities. The various projects and programs listed in Appendix Y will have cumulative effects on the existing biological resources of the study area through the early long-term (year 15) and over the next 50 years. The most relevant elements of these projects and programs are their abilities to modify land use patterns, modify land management practices, and change the patterns of hydrology and vegetation in the study area. Most of the local, state, and federal land use and land management programs that are affecting or will affect the study area are designed to preserve open space and agricultural lands, and to manage the resources of the area for multiple uses, including agriculture, recreation, fish and wildlife habitat, flood protection, and water management. The restoration programs would increase primarily wetland and riparian natural communities by converting agricultural land or managed wetland. The special-status and common plants and wildlife that rely on wetland and riparian habitats for some stage of their life would benefit from these changes over time. Other species that rely on agricultural land and managed wetland but do not benefit from wetland and riparian expansion may decline in the study area. On the upland fringes of the Bay-Delta, plans exist for small expansions of urban development that would remove primarily agricultural land uses. The management of state- and federally owned wildlife areas, including Grizzly Island, Sherman Island, and Yolo Bypass State Wildlife Areas and Stone Lakes NWR, would continue to focus on multiple uses, including wildlife habitat improvement, public access for wildlife viewing, wildlife friendly agricultural production, and hunting opportunities. Natural habitat would be improved and expanded. The principal changes that are likely to result from the various habitat conservation plans that overlap with the study area would be expected to include the restoration and protection of the habitats that support the same special-status species in the study area. These changes would be expected to result in increases of wetland, grassland, and riparian habitats and a decrease in agricultural lands, and possibly managed wetlands in the study area.

Implementation of the water management strategies associated with the programs listed in Appendix Y would not modify the principal species habitat in the study area. These management strategies are designed, in part, to improve aquatic habitat conditions in the study area for the benefit of special-status fish species. Periodic levee and channel maintenance activities associated with the flood management programs identified in Appendix Y would result in localized disturbances to valley/foothill riparian, grassland, and tidal perennial aquatic natural communities, and to a lesser extent to tidal brackish and tidal freshwater emergent wetlands. To the extent that ongoing levee repair and replacement involves use of reinforcing rock and discouragement of replanting streamside vegetation, there could be a gradual decline in the extent and value of valley/foothill riparian habitat and grassland along minor and major waterways. Several of the water management and transportation projects listed in Appendix Y require localized removal of natural communities and agricultural land for expanding infrastructure.

The overall direction of these existing and ongoing programs and policies that influence land conversion and land management in the study area would continue to be toward maintaining the mix of agricultural, recreational, water management, and wildlife uses in the study area. However, given that the No Action Alternative would not change CVP and SWP operations and would not change flow rates or increase land conversion or land management activities, the No Action Alternative would have no effect on terrestrial biological resources.

P.2.9.1.2 Effects of Climate Change

Climate change is expected to result in many physical changes to the study area. From a terrestrial biology perspective, the most significant changes would include a gradual rise in sea level, increasing water and air temperatures, more frequent drought and extreme rainfall events, and changes in the hydrologic patterns of the rivers and the Bay-Delta channels that influence the terrestrial and aquatic habitats used by terrestrial plant and wildlife. Climate change includes sea level and air temperature increases, as well as changes in the frequency of drought and extreme rainfall events has not been predicted, but these events are expected to be part of future California conditions with climate change. Hydrologic conditions in the rivers and Bay-Delta channels are expected to be altered by changes in precipitation patterns, with a portion of precipitation shifting from snow to rainfall in the winter months. This would increase river flows in winter and early spring, and decrease flows in the remainder of the year as snowmelt runoff decreases. The changes in river flows would generate subsequent changes in west Bay-Delta and Suisun Marsh salinity levels.

The physical changes in conditions in the study area related to the climate change described above, especially the sea level rise, could change the distribution and value of study area habitats. The sea level rise is expected to gradually inundate existing habitats on the periphery of the Bay-Delta, in the lower Yolo Bypass, and the northern and southern edges of Suisun Marsh. Tidal brackish and freshwater marsh could be gradually inundated and converted to more subtidal habitat. In areas where there is no upland barrier (e.g., levees, roads, residential development, agricultural fields), some portion of the tidal marsh may re-establish upslope with the higher water levels if there is sufficient sediment available to provide an appropriate substrate. However, decreases in sediment availability that have occurred in the Bay-Delta and Suisun Marsh over time and that may continue may not keep pace if the higher estimated rates of sea level rise occur (Barnard et al. 2013). The result could be a gradual loss of these tidal marshes. Where barriers exist upslope of existing marsh, the tidal marsh habitat could be gradually inundated and subtidal areas would remain. Subtidal habitat is less valuable to the special-status and common terrestrial plants and wildlife of the study area. Low-lying upland grassland and riparian areas that border the study area waterways could also be gradually converted to tidal marsh, but would be expected to re-establish upslope where open ground exists and there are no physical barriers. Where these deeper water incursions bisect existing wildlife corridors, the ability of certain species to move and interact with adjacent populations would decrease. Population numbers of riparian, grassland, and tidal marsh species would be likely to decrease and population distribution would be altered. The habitats adjacent to study area waterways would also be exposed to more frequent inundation and desiccation as precipitation levels show greater fluctuation.

Land subsidence, sea level rise, gradual or catastrophic levee failure, or a combination of these conditions, should they occur, would result in flooding and inundation that could significantly damage existing facilities and infrastructure, uproot and kill vegetation to an unknown extent, permanently flood Bay-Delta islands, and drastically alter the salinity of Bay-Delta waterways and wetlands. Depending on the extent and duration of flooding, significant short- and long-term changes could occur in the availability of shallow tidal wetlands, riparian and grassland habitats and managed lands useful to certain special-status and common species (e.g., cultivated lands, managed wetland). Depending on the amount of human intervention to drain islands and rebuild levees, there may be a gradual succession of habitats less valuable to the plant and animal species currently relying on the Delta for growth and seed production, cover, breeding, nesting, resting, movement corridors and foraging.

While similar risks would occur under implementation of the action alternatives, these risks may be reduced by project-related levee improvements, along with implementation of those project elements identified for the purposes of flood protection in Appendix Y. The negative elements of climate change described above would be a contributing factor to any cumulative effects of implementing the projects and programs that are part of the No Action Alternative (Appendix Y). Any negative effects on terrestrial biological resources associated with the action alternatives (see below), when considered with all of the above effects of the No Action Alternative, could create adverse cumulative effects on these terrestrial biological resources.

P.2.9.2 *Cumulative Effects of the Action Alternatives*

This cumulative analysis discusses Alternatives 1, 2, 3, and 4, all of which would result in slight increases in flows throughout the study area. Alternatives 1 and 3 also include restoration and other construction-related activities that could result in impacts on terrestrial biological resources. However, based on the analyses presented in earlier parts of this appendix, these changes would have little or no negative effect on the terrestrial biological resources of concern in the study area and would be expected to improve the long-term viability of special-status species and their habitats. The positive effects of implementing Alternatives 1 and 3 are similar, while Alternatives 2 and 4 include no additional restoration activities but would change flow regimes in the study area. There would be relatively small variations in the acres affected by flow regime changes across the alternatives but larger variations in the acres affected by restoration; thus restoration has the greatest potential to modify natural communities and affect special-status plants and wildlife.

The past, present, and reasonably foreseeable projects, described in Appendix Y, *Cumulative Methodology,* may have effects on terrestrial biological resources. The cumulative projects include actions across California to develop new water storage capacity, new water conveyance infrastructure, new water recycling capacity, and the reoperation of existing water supply infrastructure, including surface water reservoirs and conveyance infrastructure. The cumulative projects also include ecosystem improvement and habitat restoration actions to improve conditions for special status species whose special status in many cases constrains water supply delivery operations.

Collectively, these cumulative projects would have short-term effects but would benefit terrestrial biological resources over the long-term. While flow changes, construction activities, and restoration activities in the short-term period of cumulative projects could temporarily or permanently remove natural communities and modeled habitat for special-status plant and wildlife species, the short-, mid- and long-term result of construction and restoration activities would replace, enhance, and in most cases expand habitat acres and value for these species; therefore the action alternatives' contributions would not be substantial.

In addition, for Alternatives 1, 2, 3, and 4, the avoidance and minimization measures presented are sufficient to avoid cumulative effects from the combined losses due to flow changes, construction, and restoration
